- Ulna is fixed bone in the forearm around which the radius rotates
- DRUJ stability is assessed with the ‘piano key’ test
- Stability assessed in pronation and supination.

The ‘piano key’ test (see earlier) can be further refined if it is also performed in wrist ulnar and radial deviation. If radial deviation increases the tension in the ulnocarpal ligaments sufficiently to reduce the amount of dorsal and palmar translation of the ulna head, then this indicates that following an ulna shortening osteotomy there may be some potential improvement in DRUJ stability.

Tendonitis of the flexor carpi ulnaris (FCU) or ECU tendons may be diagnosed by tenderness or swelling along the tendon sheaths, pain on resisted flexion and ulnar deviation (FCU) or extension and ulnar deviation (ECU), and pain on passive stretch of these tendons (forced extension and radial deviation for FCU and forced flexion and radial deviation for ECU).

**Investigations (Box 12.31.3)**

**Plain radiographs**

A true posteroanterior (PA) radiograph of the wrist in neutral forearm rotation and a perfect lateral of the carpus and the distal radius are the key radiographs required to evaluate DRUJ congruity and reduction.

The true PA radiograph is taken with the shoulder in 90 degrees of abduction, the elbow in 90 degrees of flexion and an overhead x-ray beam. The hand and wrist are placed flat on the x-ray plate to achieve neutral forearm rotation. This view allows an accurate evaluation of the ulna variance. The styloid will appear directly in line with the ulnar cortex of the ulna in this view. If taken incorrectly in supination or pronation there will respectively be artificial lengthening or shortening of the radius apparent on the radiograph.

To determine if a true lateral projection of the wrist has been obtained, the alignment of the carpus should be assessed to ensure the scaphoid tubercle overlies the pisiform. With this projection, the true position of the ulna head relative to the radius will be shown.

To evaluate intra-articular fractures of the distal radius, ulna, and DRUJ, a computed tomography (CT) scan or two oblique views may be helpful.

**Fluoroscopic examination**

Live fluoroscopy of the DRUJ is useful to assess its stability intra-operatively, or if subluxation or dislocation is suspected but plain radiographs cannot be obtained with the forearm appropriately positioned. A perfect lateral of the distal radius is obtained by live imaging, and the position of the ulna head is assessed. Dynamic stress fluoroscopy and clenched-fist views may be obtained to assess dynamic DRUJ and carpal instability. The ability to obtain and maintain reduction of the DRUJ can also be evaluated directly.

**Computed tomography scan**

CT scanning is the imaging modality of choice for suspected DRUJ subluxation or dislocation, distal radial fracture with DRUJ intra-articular extension, or DRUJ arthrosis (Figure 12.31.2).
Ulnar head stability within the sigmoid notch of the distal radius can be determined by CT evaluation of the position of the DRUJ in both pronation and supination, with simultaneous cuts of the opposite DRUJ with equivalent forearm rotation.

**Arthrography**

Arthrography or cine-arthrography may be performed if injury to the TFCC is suspected. Single or triple injection techniques may be employed. Magnetic resonance imaging (MRI) or CT scanning is now commonly performed as an adjunct to arthrography after obtaining plain arthrogram radiographs.

Flow of contrast from the DRUJ to the radiocarpal joint, or into the DRUJ after injection of contrast into the radiocarpal joint is diagnostic of a defect in the TFCC (Figure 12.31.3). Full-thickness central tears of the triangular disc are more commonly attritional and are seen in increasing frequency with increasing age. Peripheral tears that allow tracking of contrast around the triangular disc may result from trauma.

**Box 12.31.3 Investigations**

- Plain radiographs should include neutral rotation AP and lateral
- True lateral confirmed by scaphoid tubercle over lying pisiform
- Consider CT to confirm dislocation or subluxation
- Contrast flowing into DRUJ during arthrogram suggests TFCC perforation
- Arthroscopy gold standard to assessing TFCC.

**Magnetic resonance imaging**

High field strength magnets and dedicated wrist coils are now producing high-resolution MRI scans that offer increasing accuracy in the diagnosis of acute ligamentous injuries of the carpus and TFCC, particularly when a combination of conventional and
magnetic resonance (MR) arthrography is used. These investigations are now commonly performed to obtain additional diagnostic information, which helps to direct and inform the patient and physician, prior to embarking on more invasive procedures such as wrist arthroscopy, TFC debridement or repair, and RU ligament repair or reconstruction.

**Arthroscopy**

Arthroscopic examination of the wrist remains the gold standard for assessing the TFCC. It facilitates diagnosis of perforations (central, peripheral, partial or full-thickness), and chondral injuries of the distal radius, ulnar head, or proximal carpal row. Under surface partial thickness lesions can only be seen with DRLU MR arthrography or arthroscopy.

Wrist arthroscopy is a useful diagnostic and therapeutic adjunct in the acute treatment of distal radius fractures. TFCC tears are present in as many as 68% of distal radial fractures.

**Treatment (Box 12.31.4)**

The treatment of DRLU injuries is dependant of the time since injury, the type of injury, and any associated injuries.

**Acute DRUJ instability**

Acute isolated dislocations with no associated fracture are uncommon. By convention the direction of dislocation is defined by the displacement of the ulnar head in relation to the radius. Dorsal dislocation is more common than volar dislocation. If the injury is acute, reduction is usually easy. The stability of the DRUJ should then be assessed following the reduction. Dorsal dislocations tend to be more stable in supination and volar dislocations are more stable in pronation.

If there is only a moderate degree of DRUJ instability then this can be treated in an above-elbow cast for 3–4 weeks followed by a forearm cast or splint. If the DRUJ is grossly unstable or requires extreme pronation or supination to maintain stability, then the addition of a percutaneous K-wire fixation across the distal radius and ulna should be considered. In these cases, the TFCC is disrupted and surgery to reattach the TFCC will also restore stability.

Distal radius fractures have an associated ulnar styloid fracture in 61% of cases. However, few of these result in DRUJ instability. Fractures of the tip of the styloid rarely lead to instability. If the fracture involves the base of the ulnar styloid (the site of TFCC attachment), and the DRUJ is unstable clinically, then TFCC continuity and joint stability can be restored by internal fixation of the styloid fragment with either a cannulated screw or 2 fine K-wires and a ‘figure-of-eight’ suture to act as a tension band (Figure 12.31.4).

Intra-articular distal radial fractures frequently involve the sigmoid notch and hence the DRUJ. The aim of treatment is to restore anatomical reduction of both the radiocarpal joint and the DRUJ, with stable fixation, to allow early mobilization of the joints.

If DRUJ subluxation or dislocation is associated with an extra articular forearm fracture (Galeazzi injuries and variants) or an elbow injury, then DRUJ stability is frequently restored by the reduction and stabilization of the forearm injury—particularly where the radial fracture is in the distal third. Having completed treatment of the proximal injury, assessment of the DRUJ reduction and stability should be made clinically and radiographically, and treated accordingly.

When closed reduction of the DRUJ is not possible, interposed soft tissue or bone fragments may be blocking reduction. Exploration is performed via a dorsal approach, through the floor of the fifth dorsal compartment, elevating an ulna-based capsular flap and repairing or reattaching the TFCC with transosseous sutures or suture anchors. Care has to be taken to avoid injury to the sensory branch of the ulnar nerve (Figure 12.31.5).
Chronic DRUJ instability

Symptomatic DRUJ instability is often associated with a malunited distal radial fractures. A trial of non-operative treatment should be undertaken initially with splintage and physiotherapy. If symptoms fail to improve and there is a malunion, then a corrective osteotomy will usually restore stability. If there is no bony deformity or secondary degenerative change, then soft tissue reconstructions may be attempted. Where possible the TFCC should be reattached. If the TFCC cannot be repaired, techniques have been described to reconstruct the volar ulnocarpal ligaments using a strip of FCU or both the volar and dorsal ulnocarpal ligaments.

DRUJ arthrosis

Degeneration of the DRUJ may arise due to intra-articular malunion or chronic instability. Symptoms may be controlled by intra-articular steroid injections. When injections fail to achieve adequate symptom relief, several salvage procedures have been described, but if they are performed in the presence of associated DRUJ instability, this must also be addressed using appropriate soft tissue reconstructive procedures:

- Bowers hemiresection arthroplasty involves resection of the articular surface of the ulnar head but retains the ulnar attachments of the TFCC. If performed in isolation, this procedure may increase any existing instability
- The Sauvé–Kapandji procedure involves the creation of a distal RU fusion and a more proximal pseudarthrosis to allow forearm rotation. This procedure has the possible benefit of improved pain relief in arthritis; however, there is a risk of non-union, regeneration of the resected segment with loss of rotation, or significant symptomatic instability of the proximal ulnar stump (which is then difficult to address)
- The Darrach procedure involves resection of the distal ulna at the level of the ulnar neck and is best suited to patients with reduced functional demands
- DRUJ arthroplasty is possible, but requires restoration of stability. Part or all of the ulnar head can be replaced but the long-term results of these procedures are not yet known. Trials are also being undertaken on the new implants that replace both components of the DRUJ.

Box 12.31.4 Treatment

- Acute DRUJ instability may require re-attachment of TFCC ± K-wires across DRUJ
- If the TFCC is avulsed with a fracture at the base of the ulna styloid, it can be reattached with tension band wire
- If DRUJ dislocation is associated with a forearm fracture, anatomical fracture reduction usually reduces DRUJ
- Chronic DRUJ instability may require attempted TFCC reattachment, or a soft tissue reconstruction.

Ulnocarpal impingement (Box 12.31.5)

If a distal radial fracture heals in a shortened position, but with otherwise satisfactory alignment of the distal radial articular surface, then the sigmoid notch of the distal radial articular surface will lie proximal to the articular surface of the ulna head, which may cause DRUJ degeneration. The TFCC is tented over the ulna head, between the proximal ulnar aspect of the lunate and the ulna head, increasing load transmission in the ulnocarpal side of the wrist and progressive degenerative change between the ulna head, TFCC, and the ulnar carpus. Patients present with ulnar-sided wrist pain, especially during axial loading and ulnar deviation of the wrist and forearm rotation (Figure 12.31.6).
The excessively long distal ulna, here a result of radial head resection prior to skeletal maturity, resulted in symptoms of ulnocarpal impingement.

These distinctly different situations all require different surgical solutions:

- Occasionally, if the distal sigmoid notch joint surface is incongruent but the DRUJ articular surfaces are well preserved, a corrective distal radial osteotomy may be possible.
- If the DRUJ joint surfaces are well aligned and preserved, and ulnocarpal impingement is the overriding problem, then an ulna shortening procedure is indicated. A minor degree of shortening (1–2mm) can be achieved by performing an intra-articular resection of the distal articular surface of the ulna head—a ‘wafer’ procedure (performed either open or arthroscopically).
- An ulna shortening osteotomy is indicated when a greater degree of shortening is required. This is reliably performed with an oblique osteotomy stabilized with a compression plate. The aim is to shorten the ulnar and to produce an ulnar neutral or mild ulnar minus variance and a congruent DRUJ.

**Ulnocarpal impingement**

- Ulnocarpal impingement occurs most commonly with positive ulnar variance.
- Cystic change may be seen in ulnar corner of lunate.
- Ulnar shortening by 2.5mm results in a drop in ulnar load to 4.3%.
- Ulnar shortening performed using dynamic compression plate.

- If ulnocarpal impingement and DRUJ arthrosis are present, then one of the salvage procedures described earlier should be performed, whilst ensuring that adequate shortening of the ulna is also achieved.

**Results of treatment**

Early reduction of a dislocated DRUJ will ensure the best outcome. In one study, 25% of patients with dislocation of the DRUJ associated with a radial shaft fracture (Galeazzi), went on to lose more than 25 degrees of forearm rotation. In another study of 19 patients with DRUJ dislocation following Galeazzi fractures, it was shown that in patients in whom anatomical reduction of the DRUJ was achieved, there was minimal loss of function.

The results of soft tissue reconstruction for chronic instability have been variable. However, in one series of 14 patients who had a soft tissue reconstruction procedure, stability was completely restored in 12.

One study using a Bowers procedure following malunion of distal radial fractures, all patients reported an improvement in their symptoms.

Studies have reported that when using the Sauvé–Kapandji technique for post-traumatic instability, 11 of 17 patients were entirely pain-free with an additional five only complaining of minimal pain. Instability of the ulnar stump was a problem in two patients within the series.

The main complaint following a Darrach’s procedure is instability of the distal ulna stump. Several studies have shown that the results are generally worse in patients with higher demands.

Several studies have shown high levels of success with the use of ulnar shortening for ulnocarpal impingement.
In a study of ulna head replacement in 13 patients, initial results (mean of 2 years) showed a reduction in pain scores of 50%. In one series, total DRUJ replacement was performed in 31 patients. Pain was greatly improved. Grip strength increased along with improved pronation and supination at a mean of 5.9 years follow-up.

**Conclusion**

The key to appropriate treatment of the DRUJ is early recognition of the injury. By defining the injury pattern acutely by history, clinical examination, and appropriate imaging, treatment of the upper extremity injury can proceed in an integrated fashion (Figure 12.31.7). Thus the goal of achieving full restoration of function to the injured extremity in as short a time period as possible may be realized.

Distal radius fracture

Introduction

Fractures of the distal radius were first recognized by Pouteau in 1783 and more widely recognized after Colles’ description in 1814. Abraham Colles famously stated that ‘one consolation only remains, that the limb will at some remote period again enjoy perfect freedom in all its motions and be completely exempt from pain: the deformity, however, will remain undiminished through life’.

This is one of the most common fractures in Western societies. With increasing longevity and activity in the middle-aged to elderly population the previous policies of ‘benign neglect’ may no longer be acceptable. Patients expect a strong and mobile hand. We should aim to achieve restore function quickly without exposing patients to additional risk.

Treatment of distal radial fractures is evolving rapidly. Published literature lags behind clinical practice by a year or two, textbooks even more so. Distal radial fracture management is remark-ably diverse as surgeons apply traditional, contemporary, or innovative philosophies depending on factors such as published research, anecdotal belief, technical skill, availability of theatre time, and cost.

Classification

Fractures of the distal radius occur when a large loading force is applied between the proximal carpal row (particularly scaphoid and lunate) and the radial shaft. Various factors will determine the fracture pattern including the angulation of the wrist at the time of loading, the direction and magnitude of the force, the rate of loading, and the state of the underlying bone.

Eponyms are still commonly used but should probably be abandoned since they do not assist in management or prognosis. Many classification systems have been proposed. They should be simple to use, aid in decisions about management, allow an accurate prediction of prognosis, and also be used to define populations of patients in clinical research. In practice these ideals have not been achieved.

Deciding on stability is a useful aid to decision-making. Unstable fractures are those which will malunite if treated in plaster alone. This must be appreciated and treated to avoid long term deformity. Stability is judged from pre-reduction radiographs (Box 12.32.1).

Box 12.32.1 Factors associated with instability

- Age >65 years
- Osteoporosis
- Radial shortening >5mm
- Dorsal angulation >10 degrees
- Metaphyseal fragmentation
- Radial inclination >15 degrees
- Ulnar neck fracture.

Precise measurement of instability remains elusive. However, if any of these criteria are met then malunion could be expected with non-operative management. Many papers have shown that these factors correlate with final radiological outcome. However, they have not generally measured long-term clinical results using validated outcome measures. A key unanswered question is how malunion relates to long-term function.

The AO/OTA classification system is popular in current literature (Figure 12.32.1). This is a detailed classification with three main fracture groups and 27 fracture subtypes.
Recognizing type B fractures is important as the radiocarpal joint may sublux. These are fracture-dislocations of the wrist and patients can only regain useful function if the joint remains congruent.

Outcome assessment

It is important to understand the validity of results when interpreting the large and varied literature on management of distal radius fractures.

Patients are usually grouped according to a radiological classification system: unfortunately no validated classification scheme exists.

There is no standardized way of reporting complications. It is helpful if there is a description of severity. Long-term follow-up may be important to detect complications such as delayed flexor tendon rupture.

Outcome tools measure radiographs, impairment, disability, and handicap. There is some research linking radiological outcome with function.

Impairment is measured using physical parameters such as range of motion and grip strength. Patient-related parameters can also be used. These measure pain, function in the form of disability (competence in defined activities, such as turning a key), or handicap (ability to fulfill certain roles in life, such as returning to work). These can be combined with examination findings to create a hybrid measurement. Hybrid measures include the Green and O’Brien score and the Gartland and Werley scores. Publications using these should be viewed cautiously. Most current clinical research uses patient-related outcome measurements (PROMs). Validated scoring systems for distal radial fractures include the Disabilities of the Arm, Shoulder and Hand (DASH) score, the Michigan hand questionnaire and the patient-related wrist evaluation (PRWE) score. Generic functional health questionnaires such as the SF-36 may also be appropriate.

Epidemiology

This is one of the most common injuries encountered by orthopaedic surgeons accounting for 15–20% of all fractures. The age-specific incidence is consistent across various Western populations including Norway, Sweden, Scotland, and the United States of America. It affects four times more females than males. The incidence is rising as the population ages. Lower average bone density, increased rate of falling, poor vision, and increased activity levels in the elderly have all been implicated in the aetiology of this fracture.

Clinical evaluation

Information about previous fracture or malunion will influence interpretation of radiographs. Assessment of general health and activity levels is important as this will influence the decision on treatment.

There is tenderness in the distal radius, usually with a degree of swelling. If the fracture is dorsally displaced there may be the classic ‘dinner fork’ deformity which is produced by the dorsally displaced carpus. Radial deviation of the hand is common. Sensation in the hand and finger movements should be assessed to exclude acute carpal tunnel syndrome or acute compartment syndrome in the forearm although the latter is uncommon. The skin should be inspected to exclude an open fracture. The compound injury is usually dorsal and ulnar.
Investigation

The mainstay of investigation and diagnosis is posteroanterior and lateral radiographs. These are used to establish the diagnosis and classify the fracture. Deformity is assessed on both views by measurement of dorsal angulation, radial inclination, the radial shift, and the amount of radial shortening.

The dorsal angle is defined as the angle between the long axis of the radius and the joint surface on a lateral radiograph (Figure 12.32.2A). Radial inclination is the angle measured on a posteroanterior (PA) radiograph between the distal radial articular surface and the long axis of the radius (Figure 12.32.2B). Ulnar variance is the commonest measure of radial shortening. This is the vertical distance between the distal end of the ulnar corner of the radius and the ulnar head (Figure 12.32.2C). Shortening of the radius is important because of its impact on ulnar-sided wrist mechanics and symptoms. Metaphyseal comminution can be assessed on plain radiographs, is most commonly dorsal (Figure 12.32.2D), and has a significant effect on fracture stability.

In severe articular or partial articular fractures computed tomography (CT) scanning allows better visualization of the joint. When learning the concepts of intra-articular fracture patterns, surgeons may find such scans helpful. Surface reconstructions now give accurate impressions of fracture morphology. CT scans are excellent for measuring intra-articular steps and gaps, and may also show occult carpal fractures (Figure 12.32.3). They are also useful when planning corrective osteotomies for malunion.

General principles of management

Many factors influence the choice of treatment for a distal radial fracture. These include radiological features and patient factors, particularly age, activity level, and functional needs. General health is important, but having medical comorbidity does not preclude...
Initial treatment

Initial treatment depends on the amount of displacement. If the fracture is minimally displaced then it is sufficient to apply a forearm cast with the wrist in the neutral or slightly flexed position.

In displaced fractures the need for reduction must be assessed. If the fracture is unstable, simple reduction and casting will be insufficient to prevent malunion. This is particularly true in osteoporotic bone. However, this is offset by the evidence that malunion is more likely to be tolerated in patients over the age of 65. There is abundant evidence that manipulation and forearm casting alone is futile for unstable fractures in the elderly. There is little evidence, however, that malunion is a problem in such patients.

Reduction is usually performed under regional anaesthesia or a local anaesthetic haematoma block. Regional anaesthesia allows better pain relief and improved reduction but is more complex to administer.

Stable fractures

By definition, stable fractures will maintain their position in a cast and should need no further surgical intervention to avoid malunion. For undisplaced fractures a simple splint is sufficient, although a cast may protect vulnerable wrists from further injury.

Displaced fractures can be mobilized 3–4 weeks after reduction. Depending on whether the fracture is displaced in a dorsal or palmar direction it is customary to place the wrist in either palmar flexion or dorsiflexion although this may make little difference to the final outcome.

Unstable fractures

Management of unstable fractures of the distal radius is a contentious topic. Different methods of treatment are advocated. None has yet emerged as significantly superior. Management decisions should be based on the individual patient and the fracture type. Surgeons dealing with these injuries should ideally have a range of techniques at their disposal.

Many fractures deemed suitable for manipulation also fulfil the criteria for instability. This is particularly true in osteoporotic bone. Prediction of instability with any degree of certainty is difficult. While instability is defined radiologically there is only weak evidence that malunion affects function. Studies from London, Ontario found that in younger patients (under the age of 65), three unstable fractures needed surgery to prevent one patient from an unsatisfactory outcome, but that in older patients (over 65) eight unstable fractures needed surgery to prevent a single poor outcome. This work is supported by long-term retrospective studies showing that the majority of patients with malunited fractures still have excellent function. It is possible that early anatomical restoration and stable fixation will lead to a more rapid recovery but this is as yet unproven.

Displaced intra-articular fractures

Intra-articular fractures of the distal radius are common. Significant displacement at the metaphyseal fracture line is also common. The distal radial articular surfaces, however, usually remain well-approximated: significant divergence between the articular fragments is rare. Accurate alignment of the joint surface may reduce the risk of post-traumatic osteoarthritis. In a widely-reported article, Knirk and Jupiter found that with articular malalignment of 2mm or more, radiographic osteoarthritis occurred in 100% of cases, 66% of which were symptomatic. However, patient numbers were small, associated metaphyseal malunion was not analysed separately, and non-validated classification and outcome measurements were used.

To minimize risk of malunion, surgical options include K-wiring, external fixation, palmar locking plates, and dorsal locking plates. Most interest at present is between closed reduction and K-wires or open reduction with palmar locking plate fixation. There is limited evidence comparing the results of these two.

Proposed benefits of K-wiring are speed, ease of surgery, low cost, and acceptable long-term results. Disadvantages include pin site infection, cutaneous nerve damage, prolonged immobilization, late loss of fixation, and tendon irritation.

Proposed benefits of plate fixation include more reliable anatomical restoration, stability for early mobilization, reduced rate of pain syndromes, and more rapid recovery. Disadvantages include high cost, operative time, the need for a more skilled surgeon, risk of deep infection, risk of late flexor or extensor tendon ruptures, and need to remove the plate if symptomatic.

In the displaced non-osteoporotic fracture with little metaphyseal comminution, manipulation with closed K-wiring of the fracture fragment is often adequate.

For displaced multifragmentary fractures many surgeons prefer a palmar locking plate. Some centres have used dorsal plates or combined palmar and dorsal plating for such cases. However, popularity for dorsal plates has waned because of the risk of extensor tendon irritation and frequent need for plate removal.

Some surgeons describe arthroscopic assistance to ensure that the articular fragments are perfectly reduced. There is slight evidence to support improved outcome.

If the radiocarpal articular surfaces are unreconstructable, one option is immediate salvage to a radioscapholunate arthrodesis. However, if the joint surfaces can be restored to approximate congruence and held with a plate or bridging fixator some patients obtain surprisingly good results, albeit with significant wrist stiffness.
Patients commonly develop ulnar-sided wrist problems after distal radial fracture. Avulsion of the ulnar styloid is an indicator of disruption to the triangular fibrocartilage complex (TFCC), but stability of the distal radioulnar joint (DRUJ) depends on much more than this alone. If the radius is reduced anatomically the DRUJ is often stable. Patients with ulnar styloid fractures should be treated carefully. If the radius requires operative fixation, DRUJ stability can be assessed at the time of surgery. If, after radial reduction, there is marked instability on anteroposterior (AP) glide testing the ulnar styloid can be reattached by a variety of techniques including tension band wiring (Figure 12.32.4). Basal fractures are particularly associated with DRUJ instability.

After locking plate fixation of the distal radius, DRUJ instability was treated with a tension band wire to the basal ulnar styloid fracture.

Ulnar head and neck fractures should be fixed at the time of radial fixation if unstable. There are few published series of these injuries. Locking or blade plate fixation (Figure 12.32.5) is much more reliable than percutaneous K-wires which also prevent early mobilization.

Widely-displaced fractures treated with a locking plate to the radius and a 2-mm condylar blade plate to the ulna.

High-energy injuries of the distal radius in younger patients are associated with injuries to the proximal carpal row. Scaphoid fractures are relatively rare in this situation; if the radial fracture requires operative fixation it is sensible to stabilize any scaphoid fracture at the same time using a compression screw. Injuries to intercarpal ligaments are surprisingly common when the joint is assessed arthroscopically. There is little evidence to support aggressive repair in such cases although the evidence is reasonable for isolated ligament injuries in the absence of a radial fracture. Ligament repair often requires a period of protective immobilization which may delay mobilization of the radiocarpal joint, but this has not been studied. Conversely, occult intercarpal ligament injuries may heal spontaneously with traditional fracture immobilization, but remain unstable if the wrist is mobilized early after fixation of the radius.

Treatment options

Remanipulation and cast
Remanipulation of a distal radial fracture and application of a further cast has been the traditional method of treating unstable distal radial fractures. Lasting improvement following this method is rare, especially in the older age group. If maintained anatomical reduction is required other methods of treatment should be used.

**Percutaneous wiring**

Percutaneous pinning of distal radial fractures is usually performed with K-wires. Various methods of closed K-wiring have been advocated. In Kapandji’s technique of intrafocal pinning the pins are introduced through the fracture to aid reduction as well as fixation (Figure 12.32.6). Plaster is usually used until fracture healing occurs.

![Click to view larger](Fig. 12.32.6)

A dorsal intrafocal Kapandji wire and a neutralization radial styloid wire used to stabilize an unstable osteoporotic fracture.

Good results are reported using these techniques, although usually in younger patients. In the presence of osteoporosis or significant fragmentation, as is more commonly encountered in the older patient, it is more difficult to maintain a reduction: short and dorsal radial malunions are common. Specific risks include pin track infection, overcorrection of radial angulation, extensor tendon damage, and injury to cutaneous nerve branches.

**Buttress plating**

Buttress plating is generally used for palmar displaced fractures of the distal radius. The usual approach is through the bed of the flexor carpi radialis tendon sheath. Locking plates can be used to prevent the risk of dorsal malunion due to over-correction. Reports on the outcome of palmar buttress plating are sparse. Results are generally reported as good to excellent.

In palmar partial articular fractures (anterior marginal shearing fractures), the buttress effect of the plate may be adequate without screws in the distal fragment but redisplacement is common. A strong plate is required with good distal support (Figure 12.32.7).

![Click to view larger](Fig. 12.32.7)

A palmar-displaced partial articular fracture of the lunate facet held with buttress plate and additional locking screw for further stability.

In dorsal partial articular fractures there are various fixation options. One of these is to apply a dorsal buttress plate (Figure 12.32.8). Another is to reduce the fracture using percutaneous techniques, but then to hold the reduction with a palmar locking plate (Figure 12.32.9).
Palmar locking plates

The philosophy of locking plate fixation is well-established. These plates allow reliable fixation of extremely unstable and multifragmentary fractures (Figure 12.32.10).
There are many techniques to achieve and then confirm anatomical reduction. The surgical approach can be modified to aid reduction. Reduction can be confirmed by eye, by fluoroscopy or with an arthroscope. With anatomically-designed plates some surgeons prefer to apply the plate to the radial shaft and then use this as a template to restore anatomical alignment. Others prefer to apply the plate to the distal fragments (after reduction of any interfragmentary displacement) and then reduce these to the shaft. A third method is to reduce and hold all fragments with temporary wires and then apply the plate, allowing for small adjustments in fixation for residual displacement. Different methods of reduction may be needed depending on the type of plate available and the nature of the fracture.

Locking plates come in a variety of shapes and materials. Generally larger lag screws are used for fixation to the radial diaphysis, while smaller locking screws or smooth locking pegs are used for distal fixation. Distal fixation should be into subchondral bone and may be parallel or divergent. Many plates allow fragment-specific fixation of both the lunate fossa and radial styloid. Some plates have fixed-angle locking while others allow polyaxial locking. Most plates are designed for the average distal radius but it is useful to have a variety of plate sizes and templates available. Finally, plates have a variety of devices for targeting the locking elements.

Open reduction and fixation of such fractures can be difficult. In the hands of an inexperienced surgeon the results may be significantly worse than with traditional treatment. Whichever plate is used, it is very important that both proximal and distal fixation is adequate for the type of fracture and any postoperative mobilization regime. It is important to ensure the metalwork does not irritate the overlying flexor tendons at the end of the procedure: flexor tendon rupture is a more serious complication than radial malunion. There should be no penetration of distal screws or pegs into the extensor compartment (to avoid extensor tendon rupture). In this respect pegs may be safer than self-tapping screws. It is essential that no metalwork is inadvertently placed in the radiocarpal or distal radioulnar joints.

**Dorsal locking plates**

Palmar locking plates allow for fixation of dorsally unstable fractures with dorsal bone deficits. There is therefore less enthusiasm for dorsal plating. Dorsal plating can cause irritation and even rupture of extensor tendons. There may still be a role for combined palmar and dorsal plates in selected complex fractures. Dorsal partial articular fractures and those with central joint depression may also be held with dorsal plates (Figure 12.32.11).
External fixation

Traditional external fixation bridges the wrist joint using two threaded pins in the second metacarpal and two in the radial diaphysis proximal to the fracture. Successful reduction depends on ligamentotaxis.

Before the advent of locking plates, bridging fixators were popular for complex and unstable distal radial fractures. Non-bridging fixators between the radial diaphysis and articular fragment were an option for metaphyseal fractures. However, the use of fixators has dwindled as locking plates offer equally stable fixation but with the additional benefit of open anatomical fragment-specific reduction.

External fixation still has a role in open fractures and extremely distal multifragmentary fractures in which the joint surfaces are not easily reconstructable but for patients in whom other options (such as radiocarpal fusion) are unattractive (Figure 12.32.12).

Bone grafting

Bone graft is traditionally used to augment fixation of unstable fractures. It can support the overall interfragmentary alignment when there is metaphyseal comminution. It can also be used to prevent subsidence after elevation of depressed articular fragments (Figure 12.32.11). The use of bone graft has waned with the advent of palmar locking plates as these rarely require augmentation.

Complications

Malunion

Malunion is probably the most common complication of distal radial fractures. Malunion, whether extra-articular or intra-articular, is associated with poor function. Intra-articular malunion is associated with radiocarpal arthritis on radiographs, although secondary radiocarpal salvage surgery (such as limited arthrodesis) remains uncommon for this indication.

Extra-articular malunion is common and involves loss of radial height, loss of radial inclination and dorsal angulation. In the short term this is commonly associated with ulnar-sided wrist pain and loss of rotation, particularly supination. In many patients the pain slowly improves. Long-term problems include ulnocarpal abutment syndrome (because of the shortened radius) and DRUJ instability (because of associated injury to the ulnar stabilizers as well as loss of soft tissue tension as a result of radial shortening).

If the radius is simply short but otherwise well-aligned, an ulnar-shortening osteotomy is a simple treatment. If there are significant translational and angular elements to the malunion, then a corrective radial osteotomy should generally be performed initially. For minor dorsal opening wedge osteotomies of 30 degrees or less a palmar approach can be used holding the osteotomy with a palmar locking plate. A variety of bone grafting methods have been described in association with this including bone autograft, bone substitutes and no bone graft at all. For larger corrections of 40 degrees or more, particularly in osteoporotic bone, a dorsal approach with structural autograft and plate or wire fixation may be more reliable and allows correction of more complex multiplanar malunions (Figure 12.32.13).
Excision of the ulnar head (a Darrach procedure) is not advisable in this situation and can have unpredictable consequences. Similarly the Sauvé–Kapandji procedure has an unpredictable satisfaction rate and is difficult to salvage later. An arthrodesis is performed between the ulnar head and sigmoid fossa of the distal radius along with creation of a soft tissue interposition pseudarthrosis just proximal to the arthrodesis site that preserves forearm rotation. An ulnar head replacement can be useful in cases of post-traumatic DRUJ impingement or to salvage unsuccessful earlier procedures. However, the long-term survival of these implants in active patients is not yet established. Occasionally patients develop DRUJ instability despite normal articular alignment. Such patients may require repair of elements of the TFCC or formal ligament reconstruction.

Occasionally patients present with severely limited wrist motion because of partial joint subluxation from underestimated partial articular injuries. The proximal carpal row is therefore unable to move in its normal axis, obstructing both radiocarpal and mid-carpal motion. Such cases require an intra-articular osteotomy to restore normal mechanics.

Complications of casting

A tight cast can lead to swelling of the hand and fingers which if not relieved promptly leads to intrinsic contractures and finger stiffness. Overzealous wrist flexion prevents finger function and may create carpal tunnel symptoms. A common error is to extend the cast over the metacarpophalangeal joints which will also create stiffness. It is an avoidable tragedy if a patient recovers from a wrist fracture only to suffer iatrogenic finger stiffness as a result of poor plaster management.

Complex regional pain syndrome

The pathophysiology of complex regional pain syndrome (CRPS) remains obscure. The fault probably lies in cortical processing pathways rather than peripherally. It complicates as many as 25% of distal radial fractures treated in plaster.

Features include unexplained diffuse pain often extending beyond the zone of injury, altered skin colour and temperature, diffuse oedema, stiffness. Occasionally the pain is accompanied by fixed dystonic posturing. In later stages there are trophic changes in the skin, and osteopenia in underlying bones.

Most cases settle with activity, encouraged by physiotherapy and desensitization programmes. It should be treated intensively, and not allowed to fester. Protective splints should be avoided. Neuromodulation with low-dose amitriptyline or gabapentin is a useful adjunct in more severe cases. In patients with signs of sympathetic overdrive (marked colour changes and excessive sweating) guanethidine blocks can help. These patients have abnormalities in sensory cortical processing: sensory stimulation and retraining have also been used with devices such as the mirror box.

Infection

Infection can occur after operative fixation of any fracture. Pin site infection is common with K-wire and external fixation devices. It is easily diagnosed and usually settles with pin site care and oral antibiotics. Deep infection after internal fixation of the distal radius is rare. In general the treatment is to suppress the infecting organism with antibiotics until the fracture has united and then remove any metalwork. Early removal of metalwork risks creating an infected non-union which is then extremely difficult to manage.

Nerve compression

Nerve injury may occur after distal radial fracture as a result of the fracture or its treatment. Acute carpal tunnel symptoms may settle within hours of the injury, particularly if the fracture is provisionally reduced. Patients with persistent symptoms should have prompt carpal tunnel release. If the fracture is unstable it may be prudent to stabilize the fracture at the same time. There is some evidence that patients with acute carpal tunnel syndrome are more likely to develop a florid CRPS.

Ulnar nerve dysfunction is uncommon after distal radial fracture. Most cases are associated with displaced ulnar neck fractures.
and settle spontaneously. The terminal branch of the radial nerve may be damaged by percutaneous or open surgery along the dorsoradial surface of the wrist.

Tendon rupture

Extensor pollicis longus (EPL) tendon rupture is the most common tendon problem after closed injury. It is often associated with a minimally displaced or undisplaced fracture and may be due to a combination of trauma and poor blood supply. K-wire damage to extensor tendons can also occur, and surgeons should be particularly careful when passing wires across the third and fourth extensor compartments, putting the EPL and extensor digitorum communis (EDC) tendons at risk.

Iatrogenic tendon rupture, however, has become much more common with the use of plate fixation (Figure 12.32.14). Dorsal plates have particularly high quoted rates of extensor tendon irritation and rupture. However, there are many reports of both flexor and extensor tendon ruptures associated with the use of palmar locking plates. The majority of these ruptures relate to surgical technique.

![Click to view larger](image)

Fig. 12.32.14
A screw from a palmar locking plate penetrating the fourth dorsal extensor compartment causing rupture of the tendons of extensor indicis proprius and extensor digitorum to index and middle fingers.

EPL rupture is usually treated by extensor indicis proprius transfer: this is simple and reliable. Irritation of the EDC tendons and subsequent rupture is treated with urgent removal of the offending metalwork and then side-to-side transfers. Flexor tendon rupture (usually FPL or FDP tendons) is more difficult to treat. Urgent prophylactic removal of the metalwork is sensible, with bridging graft across any tendon defect.

Further reading

Summary points

- Failure to restore anatomical alignment of the radius and ulna will result in significant functional limitations
- Plating techniques should be considered the gold standard in displaced fractures of the adult forearm.

Incidence, prevalence, and mechanisms

The function of the arm is to position the hand in space. Functional recovery after forearm fracture is dependent on the full return of forearm rotation, wrist and elbow function, and hand grip strength. The muscle envelope surrounding the forearm bones normally controls hand positioning but creates complex deforming forces in a fractured forearm. Complete recovery is reliant on the anatomical alignment and relationship of the radius and ulna. The intimate relationship between the radius and ulna and the articulation at each extremity makes management of these injuries challenging.

In the adult skeleton, forearm fractures are associated with high energy, and are consequentially seen more commonly in men. Open injuries are commoner in the forearm than any other bone excepting the tibia. Due to the high-energy nature of adult forearm injuries they not uncommonly present as multifragmentary fractures, often in the polytrauma patient.

In the elderly population diaphyseal forearm fractures are uncommon. A fall to the outstretched hand in the elderly usually presents with the more common distal radial or supracondylar fractures.

Anatomy

The forearm consists of the shorter radius laterally and the longer ulna medially (Figure 12.33.1). The relationship of the two bones is maintained by the distal radioulnar joint (DRUJ), interosseous membrane and proximally by the radial head and annular ligament. The interosseous membrane is the strongest of these elements and provides 75% of the stability.

Box 12.33.1 Anatomy

- Precise restoration of anatomy required for full function
- Interosseous membrane provides 75% stability
- Bowed radius rotates around straight ulna
- Proximal 1/3 fractures—proximal fragment supinated, distal fragment pronated
- Middle 1/3 fractures—proximal fragment neutral, distal fragment pronated
- Distal 1/3 fractures—distal fragment dorsiflexed and radially deviated.

Fig. 12.33.1
Radiograph of the supinated radius and ulna demonstrating the normal radial bow and the forearm articulations at the
The lateral bow of the radius allows the radius to cross the straight ulna mid-shaft in full pronation.

The radial tuberosity is found posteriorly and superiorly on the proximal radius allowing the biceps which inserts here to act as a forearm supinator as well as a flexor. Brachioradialis inserts into the styloid and acts as a pure flexor of the forearm. Distally the radius is grooved medially forming the sigmoid notch articulation with the DRUJ.

The olecranon process, of the proximal ulna, articulates with the trochlear groove of the humerus. The triceps tendon inserts into the olecranon posteriorly and brachialis into the coronoid anteriorly. Distally the head of the ulna articulates with a groove in the distal radius to form the DRUJ, the fulcrum for distal forearm rotation.

On the flexor surface three layers of muscles form the anterior compartment along with median, radial, and ulnar nerves. The first (superficial) layer is formed by brachioradialis with the muscles of the common flexor origin (pronator teres (PT), flexor carpi radialis (FCR), palmaris longus (PL) and flexor carpi ulnaris (FCU)). Flexor digitorum superficialis (FDS) lies deep to these and forms the second layer. The final third layer is formed radially by flexor pollicis longus (FPL), distally by pronator quadratus (PQ) and flexor digitorum profundus (FDP) lies on the ulna aspect.

The muscles of the common flexor origin arise from the medial humerus, proximal radius, and ulna. The flexor carpi radialis and ulnaris (FCU) cross the forearm without attachments to these bones. The deep flexors, unlike the superficial muscles, all originate from the forearm bones and interosseous membrane. The deep flexors arise more distally, FDP originates from the proximal two-thirds of the ulna, and the FPL originates from the middle third of the radius. Aside from the pronators, all forearm flexors insert into the bones of the hand.

The muscles on the radial side of the forearm include the extensor carpi radialis brevis and longus, and the brachioradialis. They all originate from the lateral humerus, and only the brachioradialis inserts on the forearm at the radial styloid. The common extensor origin is located on the lateral aspect of the forearm. It gives rise to extensor digitorum, extensor digiti minimi, and extensor carpi ulnaris. The deep extensors all originate on the dorsal surface of the forearm and interosseous membrane. From proximal to distal they are the abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, and extensor indicis.

The radial nerve divides into its two terminal branches, the superficial radial nerve and posterior interosseous nerve as it passes over the lateral epicondyle. The superficial branch passes over supinator and pronator teres before passing deep to brachioradialis and travelling down the forearm with the radial artery. The median nerve enters the forearm through the two heads of pronator teres. As it crosses the ulna artery it gives rise to the anterior interosseous nerve (supplying FPL, FDP and PQ). It passes between FDS and FDP before passing into the carpal tunnel medial to FCR. The ulnar nerve passes into the forearm through the cubital tunnel. It passes between the two heads of FCU and passes with the ulnar artery down the forearm. It enters the hand through Guyon’s canal.

**Anatomy of movement**

The radius and ulna articulate proximally at the radial head and distally at the distal radial-ulna joint (DRUJ) while the interosseous membrane connects both bones along their length passing obliquely downwards from radius to ulna. The interosseous membrane functions to transmit load from the carpus through the radius to the ulna.

Pronation-supination functions around a complex series of movements. The axis of rotation is from the radial head through the distal ulna into the little finger. During pronation the radius rotates around the ulna at the DRUJ whilst the ulna is abducted (action of anconeus). The centre of rotation of the wrist stays static in space due to the ulna abduction. Conversely during supination, adduction of the ulna occurs (action of supinator) while the radius rotates about its axis. The articulation relies on a bowed radius rotating round a straight ulna to allow for 85 degrees of rotation in each direction.

As both bones work as an articulation with each other throughout their length any fracture within the shaft of either bone must be considered an intra-articular fracture, and this principle forms the cornerstone of management of these injuries.

**Pathological anatomy**

The deforming forces in forearm fractures have differing affects according to the level of the fracture. In proximal third fractures the proximal fragment is flexed and supinated by biceps and supinator whilst the distal fragment is pronated by pronator teres and quadratus. With middle third fractures the interosseous membrane holds the proximal fragment in neutral while the distal fragment is pronated. In distal third fractures brachioradialis dorsiflexes and radially deviates the distal fragment (Figure 12.33.2).
In indirect injuries the direction of angulation is determined by the rotation of the forearm. When pronated a flexion injury with dorsal angulation will occur while when supinated an extension injury with volar angulation will occur.

**Associated injuries**

The incidence of associated injuries is proportional to the severity and mechanism of the initial trauma. Open forearm fractures are associated with severe initial trauma consequently the incidence of neurovascular injury is high. Neurological injury is reported to reach 9% in open both-bone forearm fractures. Careful neurovascular examination and documentation of findings is essential prior to any form of intervention, particularly after high energy trauma. It is prudent to take advice from a vascular surgeon prior to intervention in vascular injury as although reduction of the fracture will usually restore circulation there is an appreciable rate of associated intimal tears. The collateral circulation of the forearm and hand is usually excellent, and even in the presence of vascular injury the functional outcome is predominantly determined by associated musculoskeletal or neurologic injuries.

Compartment syndromes may occur in either closed or open forearm fractures but are usually the result of high-energy trauma. Compartment pressures may be elevated in any forearm injury, and are particularly common in the presence of a muscle crush injury. Compartment pressure monitoring should be considered an adjunct to careful clinical examination and is not the basis on which to make a diagnosis or treatment decisions. Complete open forearm fasciotomies of both flexor and extensor compartments should be undertaken immediately when a clinical diagnosis of compartment syndrome is reached or cannot be excluded.

Associated bony injuries have been reported to the scaphoid and floating elbows in adults. Complete examination of the upper limb and x-rays to include the joint above and below are essential to rule out these and other associated injuries.

**Classification**

Forearm fractures are usually described based on the location of the fracture (proximal, middle, and distal thirds) and involvement of the joints at either end. The location of the fracture can be used to determine the deforming forces and the most appropriate surgical approach.

Because the radius and ulna are joined by a proximal and distal joint, it is fundamental in the diagnosis and management forearm fractures that if there is a displaced fracture of one forearm bone, there must be a displaced fracture of the other or a dislocation of the proximal or DRUJ.

The Orthopaedic Trauma Association (OTA) and the AO–ASIF both developed more specific classification systems, which have now been merged. Although most commonly used in research it is simple to use. The classification is based around anatomical location (radius, ulna or both bones) and the increasing degrees of complexity in the fracture pattern (Figure 12.33.3).
The OTA/AO classification of forearm fractures is based on the fracture patterns designated in increasing complexity (types A, B, and C respectively). Subclassification of isolated ulna, isolated radius, and/or both-bone fractures are subclassified into 1, 2, and 3 respectively. 

The Bado classification is used to classify Monteggia fracture-dislocations based on the type of radial head dislocation. 

Physical examination

If the fracture involves complete cortical and periosteal disruption, displacement consisting of translation, shortening, angulation, and malrotation is not uncommon. Consequently, the clinical signs of a both-bone forearm fracture include obvious deformity, abnormal limb motion, prominent swelling, and severe pain.

The elbow and wrist should be palpated for tenderness, the skin inspected to rule out an open injury, and the forearm compartments evaluated. The competency of the ulnar and radial arteries should be established. A thorough neurologic examination of the radial, median, and ulnar nerves should be performed. All the relevant findings must be documented in the medical records.

Investigation

Plain anteroposterior and lateral radiographs centred on the forearm are required for diagnosis. The limb’s malposition often prohibits true anteroposterior and lateral radiographs in this case two orthogonal radiographs will suffice. Plain films must include the wrist and elbow joint, but due to the divergence of the x-ray beams separate views should be obtained if there is any clinical
suggestion of dislocation or bony injury at these joints. Careful assessment of the elbow is crucial to rule out radial head dislocation, and three views may be required in order to do so.

Fig. 12.33.5
A Monteggia fracture dislocation. The diagnosis is made by drawing a line down the long axis of the radius. It should bisect the radial head and capitellum in every view.

Management

External support consisting of a splint or rigid arm board should be secured to the traumatized limb to limit further soft tissue injury. If an open fracture exists, the wound must be swabbed, photographed, and a sterile dressing applied which should not be further disturbed until the patient is in the operating room. Although anatomically similar, forearm fractures represent a spectrum of injury mechanisms. Treatment of these injuries varies greatly in different populations and injury types.

The adult skeleton has no capacity to remodel and as whole forearm functions like a joint treatment should be aimed at anatomical reduction and fixation to minimize residual deformity and functional impairment. Open reduction and internal fixation is the treatment option of choice in all but totally undisplaced fractures of a single bone. If possible absolute stability and direct bone healing should be obtained by use of a lag screw and neutralization plate or by compression plating. In those circumstances where the state of the soft tissues or the fracture pattern make this undesirable, bridging plate fixation is an option. Temporary external fixation can be considered as a second line treatment, though this will often lead to some loss of function.

Treatment modalities (Box 12.33.2)

Manipulation and casting

Manipulation and casting has no place in the management of adult forearm injuries. As adults have a thin periosteum it is impossible to effectively manipulate and hold a both bone forearm fracture closed. Cast bracing can only be considered for select fractures that are non-displaced and minimally swollen in patients who can reliably tolerate the treatment. This group of patients will require frequent follow-up and may have to accept mild loss of motion and the risk of surgical intervention in the event of loss of position or non-union.

Plates

Plating is a type of fixation, not a mode of fixation or a type of healing. Plates can be used in the forearm in a variety of ways and it is important to decide on the aims of fixation prior to treatment.

Achieving absolutely stable fracture fixation is the conventional way of managing a displaced forearm fracture in the adult. In an oblique fracture pattern this is best achieved with a lag screw and neutralization plate, while compression plating is required for transverse fractures. Preoperative planning is mandatory, and the surgeon should have decided the method and mode of use of the plate for each forearm bone before the operation starts. In normal adult forearm bone, conventional screws are normally adequate. Standard compression type plates should be used. The lighter one-third tubular type plates have no place in the stable fixation of adult diaphyseal forearm fractures, although they can be used in small children. Compression plating in this manner has been shown to give a high union rate with a low rate of complications in children and adults (Figure 12.33.6).

Box 12.33.2 Management of both-bone forearm fractures

- Very limited role for non-operative treatment
- Plate fixation (3.5mm) through separate approaches is the standard
- Assess stability proximal and DRUJs. NB Monteggia and Galeazzi fractures
Early active range of motion should be encouraged when fractures fixed with absolute stability.

Both-bone forearm fracture treated by open anatomic reduction and internal fixation of both bones with 3.5 mm dynamic compression plates. Absolute stability and primary bone healing has been achieved and the patient went on to uneventful union.

Bridging plating in forearm fractures should be reserved for cases where there is extensive fracture comminution and/or soft tissue damage. This makes any attempt to achieve absolutely stable fixation likely to cause devascularization of bone fragments, which would lead to non-union. Although anatomical reduction of the fracture is not obtained, overall anatomical alignment of the radius and ulna is still necessary to prevent loss of pronation/supination. In using a bridging plate the surgeon is accepting some loss of function in an attempt to maintain blood supply to the fracture fragments and get them to heal.

Where the bone is of poor quality or the plate is used for bridging, then ideally a locking plate should be used. The advantage of the additional purchase provided by locking screws and no requirement to contour the plate accurately to the bone, may well justify their increased cost.

Intamedullary nailing

Elastic nailing in the adult is inappropriate as it does not provide stable anatomical fixation. Contoured interlocking intramedullary nailing systems are now available. Good early clinical results have been reported in small studies.

External fixation

External fixation should be considered a temporary treatment for open injuries with significant soft tissue damage. It is not common practice to use external fixation for these injuries. However, in some circumstances with extensive soft tissue trauma and bone loss, temporary external fixation may provide stability whilst awaiting definitive internal fixation.

Approaches to the radius

Henry approach

The anterior approach to the distal radius as described by Henry (Henry 1927), provides access to the distal two-thirds of the radius and may be extended proximally if required. The approach makes use of the plane between brachioradialis and FCR.

Position the patient supine with the arm supinated on an arm table. A curvilinear skin incision is made over the palpable border of FCR and extended proximally to within 5cm of the elbow crease. Identify the interval between brachioradialis and the flexor carpi radialis. The radial artery and the superior cutaneous branch of the radial nerve lie in this interval and must be identified before proceeding. Take the artery medially and the nerve laterally. Develop the plane with blunt dissection—a well-placed finger is often safest—to reflect the muscles. Pronation of the forearm will expose the radial boarder and FPL and PQ can be elevated on a subperiosteal flap, though in practice the fracture has often done this already (Figure 12.33.7).
The volar (Henry 1927) approach is an extensile approach to the forearm. The approach makes use of the plane between FCR and brachioradialis. Note the superficial radial nerve is taken radially and the radial artery deflected to the ulna aspect.

Proximal lateral radial approach (Boyd)

Boyd describes a proximal approach to the radius which makes use of the plane between ECU and FDP. This is the authors’ preferred proximal approach to the forearm for Monteggia and radial head fractures as it may be extended proximally into a Kocher’s approach to the distal humerus and elbow if required.

The patient is positioned spine with the forearm pronated on the arm table. Make a skin incision from the lateral part of the distal 2cm of the triceps insertion, over the palpable radial head and along the subcutaneous border of the ulnar 6cm distally. Identify the radial border of the triceps tendon and the interval of ECU and FDP distally. Divide the ulnar insertion of anconeus and reflect the insertion remnant and FDP towards the flexor compartment as a subperiosteal flap (Figure 12.33.8). Lifting the belly of anconeus exposes the ulnar origin of supinator. Detach supinator carefully as a flap at its ulnar origin and reflect the muscle radially to protect the posterior interosseous nerve. This exposes the radial head and the proximal shaft of the radius.

Fig. 12.33.8
The proximal lateral approach (Boyd) approach is a useful approach to the proximal forearm. The approach makes use of the plane between ECU and FDP. Note elevation of the supinator protects the posterior interosseous nerve. This approach may be extended proximally, but not distally.

Do not extend this incision distally beyond the proximal ¼ of the radius as both the dorsal interosseous artery and radial nerve are at risk. It may however be extended proximally to Kocher’s lateral elbow approach.

Posterolateral approach (Thompson)

This approach provides access to the proximal two-thirds of the radial shaft, and makes use of the plane between ECRB and EDC. The patient lies supine with their abducted arm lying on an arm table and the forearm pronated. The incision runs over the proximal two-thirds of a line from 1.5cm anterior to the lateral humeral epicondyle to the centre of the dorsum of the wrist.

Identify and split the interval between ECRB and EDC (Figure 12.33.9). This exposes the underlying supinator muscle. Supinator can be elevated off the radial shaft by subperiosteal dissection reflecting the muscle medially. It is important to start from distally and work proximally protecting the posterior interosseous nerve within the belly of the muscle. This may be helped by supinating the forearm. If required the nerve can be identified emerging from supinator inferiorly or within the muscle belly via a small muscle split.
Fig. 12.33.9

The posteriolateral (Thompson's) approach is a useful approach to the whole posterior radius in the forearm. The approach makes use of the plane between ECRB and ECB. Note elevation of the supinator protects the posterior interosseous nerve. This approach may be extended distally, but not proximally.

Approaches to the ulna

The subcutaneous approach to the ulna is the only commonly used approach to the ulna shaft. Approach the ulna through an incision just volar to the subcutaneous border. Develop the incision through the deep fascia. Identify the plane between FCU and ECU and part the muscles using blunt dissection. The ulnar nerve lies deep to FCU should be protected throughout the dissection.

Post-treatment care

The postoperative regimen will vary from surgeon to surgeon and fracture to fracture. Early active mobilization to avoid stiffness is becoming more common after operative fixation, and this is the authors’ practice. Fractures fixed with absolute stability should be aggressively mobilized although dangerous or heavy activities should be restricted until the fracture has united.

Complications

There is an appreciable risk of neurovascular damage in open procedures to the forearm, and these injuries represent the majority of interoperative complications. Reduced range of movement can be minimized with anatomical stable reduction that allows early rehabilitation. Other postoperative complications include synostosis, refracture, infection, and loss of reduction.

Synostosis is a recognized complication of both bone forearm fractures. It is associated with high-energy injuries, malreduction, delayed surgery, single incision fixation of both bones, fractures at the same level in both bones, and excision of the radial head. After the ossification has matured (usually 1–2 years) the bone bridge can be excised and interposition performed.

It has been common practice in the past to remove forearm plates, and this is still common practice in children. However, the literature demonstrates a high refracture rate of up to 11% and a significant risk of wound complications and neurological damage particularly when removing plates from the radius. We do not advise or routinely remove plates unless crossing a growth plate or causing symptoms. Elective removal of plates should not be undertaken before 1 year and some authors have argued that the high refracture rate warrants a 2 year delay for plate removal.

Special cases

Monteggia fractures

It is important in any seemingly isolated ulna fracture to obtain good lateral and AP views of the elbow. Treatment is based around the nature of the ulna fracture, not the type of radial head dislocation. The same principles are used as for other forearm fractures. The radial head cannot be reduced closed in approximately 10% of cases due to soft tissue interposition, and open reduction is indicated. Annular ligament reconstruction is controversial. Bado type IV injuries with radial head fracture dislocations require open reduction and internal fixation of large radial head fragments. If radiocapitellum stability is not compromised, small fragments of the radial head are best excised. Injuries with severe comminution of the radial head and significant ligamentous disruption, require radial head replacement to maintain stability.

Galeazzi fracture

A Galeazzi fracture is fracture of the distal third of the radius with an associated dislocation of the DRUJ. Also called the fracture of necessity by Campbell, the injury is often unrecognized and diagnosis relies on true lateral radiographs at the time of injury. Failure to anatomically reduce and hold this fracture pattern will result in almost universal poor outcomes. For this reason the authors advocate open reduction and internal fixation of the radius. This will usually reduce the DRUJ and if it is stable through a full range of pronation/supination then early functional rehabilitation can be considered. If the DRUJ remains unstable other treatment options are required (see Chapter 12.31) (Figure 12.33.10).
Essex-Lopresti fracture

The Essex-Lopresti lesion is a fracture of the radial head in combination with a disruption of the interosseous membrane and disruption of the DRUJ. This is an unstable injury as the stabilizing function of the interosseous membrane is lost. Treatment should consist of reconstruction or replacement of the radial head to restore the radial length and stability.

Nightstick (single bone fractures)

The classic nightstick (truncheon) injury is described as a transverse fracture of the distal ulna. Typically caused by a blow to the ulna border of the forearm in an adult, who raises their arm over their head to ward off a blow, it may occasionally have a less violent aetiology and represent a fragility fracture. Radial fractures and displaced fractures of the ulna have been associated with a high incidence of non-union if managed conservatively. For this reason plate fixation is the treatment of choice.

Elbow fractures and dislocations

DOI: 10.1093/med/9780199550647.003.012034

Summary points

- These are very complex fractures to treat; the elbow is intolerant of immobilization in the adult
- Posterior approach best for complex fractures
- AO classification widely used
- Most intra-articular fractures best internally fixed
- Most distal humeral fractures require two plates.

Introduction (Box 12.34.1)

Fractures of the elbow region are among some of the most difficult fractures to treat; they occur in three groups of patients: children, young adults typically following high-force injuries, and the elderly, where even low-energy trauma may cause severe fragmentation. This chapter deals only with adult fractures where the epidemic of osteoporotic elbow fractures is particularly challenging.

The adult elbow is intolerant of any immobilization. Hence there has been an increasing tendency over recent years to operatively manage elbow fractures.

Distal humerus

Anatomy

The trochlea and capitellum make up the articular portion of the distal humerus and are held to the shaft of the humerus by the medial and lateral supracondylar ridges.

Medially, the trochlea sits like a cotton reel between the ends of the two supracondylar columns (Figure 12.34.1). The trochlear axis lies anteriorly, in internal rotation and in valgus relative to the humeral shaft. This creates the ‘carrying angle’ not to be in compression contact with the bone preserving blood supply, but care must be taken to ensure that soft tissue compromise is not caused by overly prominent metalware.

Box 12.34.1 Principles

- The elbow is intolerant of immobilization
- Osteoporotic fractures can be difficult to manage
- Physiotherapy input essential.

Fig. 12.34.1
Schematic representation of the trochlea, capitellum, and distal humeral columns (note the trochlea located between the columns while the capitellum forms part of the lateral column).

On the lateral side the entire distal part of the column is available for screw fixation as the capitellar articular surface only occupies the anterior and distal aspects. The lateral column, flattened in its proximal part, is composed of cortical bone and readily accepts a plate. At a point approximately level with the middle of the posterior olecranon fossa, the lateral column sweeps anteriorly. In this region the anconeus muscle originates and on the anterior surface lies the radial fossa accommodating the radial head in full flexion. Particular care must be used when placing screws in this area otherwise the radial fossa or the articular surface of the capitellum will be penetrated leading to damage of the radial head.

**Surgical approaches (Box 12.34.2)**

The authors prefer the posterior approach to the elbow particularly for complex fractures. This gives optimal access to the distal humerus but requires an olecranon osteotomy.

The more limited medial or anterolateral approaches are rarely used and only for isolated fractures of the condyles without fragmentation.

The anterior approach of Henry should be limited exclusively to exploration of the anterior neurovascular structures.

**The posterior approach**

- Prone, arm on bar forearm hanging
- Extensile incision, medial to olecranon and locate nerve (minimizes flap over ulnar nerve)
- Olecranon osteotomy best (Figure 12.34.2). Chevron cut with power saw completed with osteotome. Repair with tension band
- Consider transposing ulnar nerve.

Classification

Many classification systems have been devised for distal humeral fractures. These have evolved in parallel with the change from non-operative methods to operative methods.

The AO group have defined an alphanumeric fracture classification system for the distal humerus (Figure 12.34.3). Jupiter and others have attempted to improve the AO system to reflect both fracture complexity and methods of reconstruction (Figure 12.34.4). The fractures are divided into three main groups.

- I. Intra-articular
  - A. Single column
  - B. Bicolumnar
  - C. Capitellar
  - D. Trochlear
- II. Extra-articular
- III. Extracapsular.
**Box 12.34.2 Distal humerus—approaches**

- Posterior approach with olecranon osteotomy most useful
- Lateral approach for isolated non-comminuted lateral condyle fractures
- Henry approach to explore vascular structures only.

**Fig. 12.34.3**
The AO classification system for distal humeral fractures.

**Fig. 12.34.4**
The classification system for distal humeral fractures used by Jupiter and Mehne (1992).

The extra-articular fractures are either high fractures or low fractures. The extracapsular fractures are those of the epicondyles. They do not use the term condyle as they feel that it is neither helpful nor descriptive in this region. This system has only 19 classes and compares favourably with 61 classes in the full AO system. For practical utility the authors recommend either the AO system used to the ‘type’ level (13A to C) or the Jupiter system.

**Mechanisms of injury and presentation**

Fractures of the distal humerus normally result from a direct blow to the elbow, or a fall on the outstretched hand. Unicolumnar fractures possibly result from abduction or adduction forces, although this has never been proved.

The elbow with a distal humeral fracture is usually swollen and exquisitely painful; although in the polytraumatized patient this may be missed. Care must be taken not to miss posterior wounds. Closed degloving injuries can occur posteriorly which may necessitate a delay in surgery. The skin condition must be carefully assessed but in general the sooner an operation can be carried out, the better the healing. The distal neurovascular status of the limb requires careful examination.

**Investigations (Box 12.34.3)**

Standard anteroposterior and lateral radiographs of the distal humerus may be sufficient to appreciate the pattern of injury (Figure 12.34.5A, B). Traction radiographs obtained under anaesthesia at the start of the operation often allow a fuller understanding of the
fracture pattern and facilitate surgical planning (Figure 12.34.5C, D).

Fig. 12.34.5
A) and B) Radiographs of intercondylar AO 13C type distal humeral fracture. C) and D) Original anteroposterior radiographs and in-theatre traction radiographs of AO 13C fracture.

Computed tomography (CT) scanning with three-dimensional reconstruction is increasingly helpful especially in elderly patients where elbow replacement is being considered.

Careful preoperative planning is essential for implant positioning and adequate reduction.

Box 12.34.3 Distal humerus—investigations

- Biplanar x-rays
- Traction film may be useful
- CT scan where total elbow replacement (TER) considered.

Treatment (Box 12.34.4)

Intra-articular fractures

The authors recommend operative fixation for the majority of intra-articular elbow fractures, without any absolute contraindication. Closed methods usually require prolonged immobilization causing permanent stiffness in the adult elbow. The authors have not been impressed with the results of so-called ‘bag-of-bones’ treatment even in the frail elderly patient.

The goal of treatment must be an anatomically correct, congruent and mobile joint correctly aligned with the shaft. Fixation must be robust enough to resist the forces generated by early active motion of the joint particularly those directed posteriorly caused by tension in the forearm muscles with the elbow flexed. To this end humeral K-wires have no role other than temporary stabilization. Avoid ‘one-third-tubular’ plates which frequently break in this situation.

True single-column fractures are unusual but may be fixed using a transverse screw along the width of the trochlea with a supporting plate to maintain the strength and alignment of the distal humerus. The great majority of distal humeral fractures are safest fixed using two plates.

Box 12.34.4 Distal humerus—treatment

- Majority of intra-articular fractures should be fixed
- Capitellar fractures must be fixed
- Extra-articular intracapsular fractures either splint or fix or TER
- Extra-articular fractures usually need fixation.

Screws alone have often proved insufficient to resist the forces generated by early active movement leading to painful non-union. Supporting plates have proved much safer.

The bicolumnar fracture in any of its guises (T, Y, H, or Λ) poses the greatest difficulty in fixation. Improved techniques mean many of these fractures can be successfully stabilized using classical AO plating techniques (Figure 12.34.6A). The apparent advantages
of fixed angle locking plates are yet to be proved in long term studies. The positioning of these plates in rotation is difficult if intra-articular penetration by locked screws is to be avoided.

Fig. 12.34.6
A) Radiographs showing the internal fixation of the distal humeral fracture shown in Figure 12.34.5A,B using ‘conventional plates’. B)–D) Radiographs showing the internal fixation of the distal humeral fracture shown in Figure 12.34.5A,B using ‘locking plates’.

These injuries should be operated on in the first 24–36h if swelling and any closed degloving injuries allow. All open injuries must be urgently stabilized. In exceptional circumstances temporary external fixation can have a role.

As the triangle formed by the epicondylar ridges and the trochlea is gradually reassembled it often proves necessary to make slight final adjustments. Because the distal humeral columns have a complex three-dimensional geometry, the 3.5-mm AO reconstruction plate (Synthes) which can be contoured in three dimensions is the ‘workhorse’ for the distal humerus especially on the medial side.

The posterolateral plate may be extended as far distally as the margin of the capitellar articular cartilage at the extreme inferolateral margin of the humerus.

On the medial side the plate may rarely be contoured through a right angle to cradle the medial epicondyle allowing a screw to pass upwards along the condyle. However, it is preferred to avoid risking damage to the medial ligament and to use a long transverse screw through the plate which can stop just above the tip of the condyle so avoiding later discomfort from prominent metalwork.

No screws must cross the anterior coronoid or posterior olecranon fossae (Figure 12.34.6B, C).

Bone graft from the iliac crest may, rarely, be needed to impart structural integrity to the fracture construct. Non-union is associated with inadequate implant stability.

Isolated capitellar fractures are rare. The pattern is usually of a coronal shear detaching the capitellum from the front of the lateral column of the distal humerus. Recent work has redefined coronal plane fractures of the distal humerus, into:

1) Type 1 (by far the most common variation): a shear fracture of the capitellum with/without part of the lateral trochlea ridge
2) Type 2: those with the capitellum and whole trochlea as one piece
3) Type 3: those with the capitellar and trochlea fragments as separate pieces; these patterns may or may not have posterior column comminution.

Operation is mandatory for these fractures. Small fragment screws from the back may be employed if there is sufficient cancellous bone attached to the fragment or buried head screws such as the Herbert screw or the Headless Compression Screw from Synthes (HCS) may be used from the front. If the articular cartilage is very damaged or the fragments comminuted, then excision of the capitellum alone may be the better option but beware of compromising the stability of the elbow by inadvertently also removing a substantial part of the trochlea. To achieve open reduction and internal fixation the authors use a lateral, posterolateral or full posterior approach (with olecranon osteotomy) depending on the level of access required. Beware on the initial radiographs a double outline to the displaced fragment as this is a clue to the fracture including a substantial part of the trochlea (Figure 12.34.7). Excision of such large pieces causes instability with subsequent arthritis.
Extra-articular intracapsular fractures

These fractures are all transcolumnar of varying sorts, either high and easy to fix or low and difficult. The low transcolumnar injuries usually occur in the osteoporotic bone of elderly female patients.

The higher extension fractures may be managed in some patients, as one would in a child, by closed reduction and splintage but at the expense of poor functional outcome. However, for the low fractures surgery is needed if painful non-union is to be avoided. In a few elderly patients, where the low transcolumnar fracture has scuffed off a thin shell of bone, the authors advise total elbow replacement as in displaced intracapsular fractures of the neck of the femur or anatomical neck of the humerus (Figure 12.34.8). Good medium-term results with the Coonrad–Morrey elbow have been reported either as a primary or as a secondary method for fractures in the elderly; most of the patients where secondary surgery was required had been treated with immobilization alone or with inadequate fixation often only K-wires.

Extra-articular extracapsular fractures

Extra-articular fractures include those of either the medial or lateral epicondyle. They are far less common in adults than children and normally require screw rather than K-wire fixation. As the fragments are often small, a 3.5-mm diameter cortical lag screw should be anchored into the opposite cortex. Particular importance should be attached to medial epicondylar fragments that may have all or a substantial part of the important anterior band of the medial collateral ligament attached to them. They may also carry with them the adjacent ulnar nerve, sometimes into the elbow joint.

Postoperative management (Box 12.34.5)

Following operative fixation of distal humeral fractures early motion is of the essence. A successful outcome requires both pain-free motion of the elbow joint and union of the fracture. The use of a sling is allowed for pain relief on leaving the operating room. Plaster splints carry the risk of Volkman’s ischaemia and are best totally avoided as postoperative swelling is always considerable. However, the arm should be removed from the sling within 24h for active exercises to commence. Exercises include active or gentle active-assisted. The use of indwelling brachial catheters can be useful where pain control is difficult.
Complications and their management (Box 12.34.6)

**Infection**

Infection is an ever-present risk in either open fractures or those managed by open methods. The reported infection rates for distal humeral fractures range from 1–6%.

**Vascular complications**

Vascular complications are very rarely associated with adult distal humeral fractures. The clinician should be alert to the possibility of damage to anterior neurovascular structures, and may need to adjust the surgical approach should this be the case.

**Neurological complications**

Although the median nerve may be compromised anteriorly and rarely requires an anterior exploration, the most common neurological complication of distal humeral fractures involves the ulnar nerve. The incidence is around 5–7% of cases. It can be involved preoperatively, perioperatively, or later as ‘tardy ulnar palsy’. In high-energy injuries the nerve may be lacerated by bone fragments, but more frequently it is damaged during the operation when it may be exposed to excessive traction or trapped between fragments. Because of disrupted anatomy, the nerve may be very displaced. Early identification proximal to the fracture and careful protection throughout the operation is mandatory. Late ulnar nerve palsy has sometimes been seen in relation to internal fixation devices impinging on the cubital tunnel behind the medial epicondyle.

**Malunion and non-union**

Malunion is a result of either failed surgery in the first instance or failed fixation which has united in a malreduced position.

Non-union may follow high-velocity injuries and is predictable if unstable fixation techniques have been used. Low transcolumnar fractures are more prone to non-union, perhaps as a result of their more precarious blood supply. Patients with non-union commonly complain of pain, instability about the elbow, and general weakness of the limb. Stable compression plating using two plates at right angles as described earlier, with or without bone graft, is normally effective in the management of such problems. O’Driscoll has shown success using parallel medial and lateral anatomical plates. In some circumstances, particularly low fractures in the elderly patient with non-union, salvage by a TER is the correct treatment. As the collateral stabilizing ligaments have then been lost, a semi-constrained hinge arthroplasty is needed.

Implant failure and non-union may also occur at the olecranon osteotomy. The incidence is in the range of 0–10% of cases. It is not often a clinical problem, though removal of tension band wiring is often needed for comfort. When symptomatic olecranon non-union occurs, refixation using a compression plate and a small bone graft is advised.

**Stiffness and heterotopic ossification**

Loss of range of elbow motion is very common following distal humeral fractures. Loss of extension is more prevalent and takes longer to resolve than restricted flexion. There is rarely any restriction of supination or pronation. The normal cause of the stiffness is contracture of the anterior joint capsule.

**Box 12.34.5 Distal humerus—postoperative management**

- Movement is critical
- Physiotherapy important
- Flowtron may help
- Plaster splints best avoided.

If stiffness below the normal functional range (30–120 degrees of flexion) persists beyond 6 months, intervention may be required. Most severely stiff cases referred for later treatment have been inadvisedly immobilized for several days or weeks immediately after operation. Early active motion is the best prevention.

**Box 12.34.6 Distal humerus—complications**

- Infection 1–6%
- Vascular complications unusual but must be vigilant
- Ulnar nerve may be compromised at injury or later (tardy)
- Non-union/malunion commonest with high velocity injuries
- Heterotopic calcification commoner with delayed fixation or immobilization
- Arthritis may follow intra-articular fractures.
Heterotopic ossification around the elbow appears to be mainly related to elbow dislocation, burns, or associated head injury. Massive new bone formation, also called myositis ossificans, only occurs in around 4% of cases. The incidence is much higher in cases where internal fixation has been delayed more than 7 days. Removing it by arthrolysis is very beneficial.

**Osteoarthritis**

Few papers discuss the incidence of osteoarthritis following fracture of the distal humerus, with or without internal fixation. Malreduction or malalignment of the articular surface predisposes the joint to osteoarthritis which occurs within 10 years in such cases. Jupiter’s series followed-up at a mean of 5.8 years showed some narrowing of the joint space in 68% of cases, and extensive radiographic osteoarthritis in just over 20% of these. The changes correlated with fracture severity but not with the functional outcome.

In the authors’ experience, patients with precisely anatomical reduction, even after severely comminuted intra-articular fractures, had little or no functional complaints even at 18 years and no radiological signs of deterioration in the joint. When instability remains after treatment, the joint very rapidly deteriorates and severe painful osteoarthritis ensues within very few years.

**Outcomes from treatment**

Results have improved and been maintained after stable anatomical internal fixation of distal humeral fractures in all age groups. Patients with severe comminution, major soft tissue damage, whether open or closed, such as follows high-velocity road traffic collisions, extensive falls, gunshot injuries, and side swipe injuries, tend to do worst.

Excellent long-term results, albeit with significant numbers lost to follow-up, have been reported with plate stabilization of distal humeral fractures using a number of validated upper limb outcome measures.

---

### Olecranon and coronoid fractures

#### Introduction

The olecranon is the proximal articulating part of the ulna, proximal to the coronoid process but excluding the coronoid process itself. The subcutaneous position of the olecranon makes it vulnerable to trauma and various different fracture patterns are found with treatment options depending on the pattern. The majority of olecranon fractures are intra-articular except those of the very tip, although, some fractures in the centre of the trochlea notch may not involve articular cartilage.

Elbow instability after reduction of a dislocation is associated with some coronoid fractures.

#### Aetiology

Olecranon fractures are sustained as a result of direct trauma to the subcutaneous proximal ulna either in low-velocity falls or in high-velocity accidents which result in more complex injuries.

#### Classification of olecranon fractures

Colton’s classification is a simple system that divides the fractures according to the anatomy and mechanism of the fracture (Figure 12.34.9). The fracture patterns are as follows:

- **Group 1**: avulsion injuries of the olecranon tip
- **Group 2**: oblique fractures
- **Group 3**: fracture–dislocations (Monteggia)
- **Group 4**: unclassified.

---

Fig. 12.34.9

Colton’s classification system for fractures of the olecranon. (After Colton (1973).)
The AO classification attempts to classify all fractures of the proximal radius and ulna under one heading, namely segment 21. The classification system for the forearm bones differs from that for the other bones and this inconsistency makes it difficult to follow and of little clinical application.

Classification of coronoid fractures

Fractures of the coronoid process are classified as:

- Type I, fractures avulsing just the tip of the coronoid
- Type II, those that involve less than 50% of the coronoid, either as a single fragment or multiple fragments
- Type III, those involving more than 50% of the coronoid. These types are subdivided into type A (without elbow dislocation) and type B (with elbow dislocation), though transient dislocation may make the differentiation very difficult. The isolated fracture of the anteromedial part of the coronoid with associated avulsion of the lateral ligament complex of the elbow has been recently recognized as the consequence of a varus injury to the elbow joint and frequently needs operative repair to stabilize the elbow and prevent the rapid onset of arthritis.

Symptoms and signs

Pain with proximal ulna fractures is localized to the posterior and medial aspects of the elbow. As the proximal ulna lies in a subcutaneous position, localized swelling from fracture bleeding is readily recognized and the fracture line may be palpated. A haemarthrosis may be observed by filling of the sulci on each side of the elbow. Open fractures usually present with wounds on the subcutaneous border. Isolated coronoid fractures are difficult to assess as the coronoid lies deep at the front of the elbow.

Investigations

Plain radiography remains the mainstay of radiological investigation of the elbow. Standard anteroposterior and lateral films can be augmented by the ‘radial head, capitellar view’ which can help visualize the coronoid. Where the elbow cannot be placed in extension, repeat radiography, with either sedation or ‘on-table’ traction views, can be valuable prior to any surgery. CT scans can be helpful in planning the operative strategy particularly with three-dimensional reconstruction images.

Treatment options

The goals of treatment of proximal ulna fractures are the restoration of triceps extension function with reconstruction of articular surface anatomy and alignment with joint stability.

For undisplaced fractures (Figure 12.34.10), where the triceps extension mechanism is intact, the elbow is immobilized for a minimum period of time, with clinical and radiographic assessment at 1 week in a sling followed by gentle active controlled movement under a physiotherapist’s supervision. They rarely displace later and prolonged immobilization should be avoided.

Extra-articular fractures

Extra-articular fractures of the tip of the olecranon are part of a spectrum of triceps avulsion injuries, most commonly seen in elderly patients presenting with loss of extension. If an appreciable gap (15mm or more) is noted then an ultrasound scan will demonstrate the state of the extensor apparatus. These injuries should be treated by triceps reattachment with strong non-absorbable sutures, with or without excision of the avulsion flake depending on its size. If missed, and presenting late the problem is compounded and a difficult repair with V–Y tendoplasty may be needed.
Transverse intra-articular fractures

These are the most common fractures of the proximal ulna and usually involve the mid-part of the greater sigmoid notch. Depending on the degree of confluence of the articular facets within the notch, transverse fractures affect varying amounts of articular cartilage. Simple, two-part fractures of this pattern are best internally fixed using the tension band principle (Figure 12.34.11).

![Click to view larger](Fig. 12.34.11)

A) A lateral radiograph of a displaced transverse fracture of the olecranon. B) and C) Tension band wiring of the fracture. (NB The longitudinal wires have not been passed through the anterior cortex in this case.)

The K-wires must be bent into a staple shape then driven through slots cut vertically in the triceps tendon and embedded deeply in the olecranon in order to avoid rapid loosening once triceps regains its power.

Some low-demand and surgically unfit elderly patients with intact triceps mechanism but some degree of fracture displacement do well without operation, simply allowing early motion but avoiding weight bearing through the arms for a few weeks.

Oblique intra-articular fractures

Displaced oblique fracture are not amenable to treatment by tension band wiring alone as the compression required by this technique is axial along the ulna and will displace an oblique fracture. The fracture should be compressed with a lag screw and this should be ‘neutralized’ with a plate applied dorsally (Figure 12.34.12).

![Click to view larger](Fig. 12.34.12)

An olecranon fracture stabilized with lag screws and a 3.5-mm AO reconstruction plate (anteroposterior and lateral views).

Comminuted intra-articular fractures

These fractures represent the greatest challenge in the management of proximal ulna fractures especially if associated with fractures of the radial head and/or distal ulna. There are frequently multiple planes of fragmentation. Reconstruction should try to achieve the objectives described previously. These are sinister injuries which risk total forearm ankylosis. Reconstruction may require a combination of techniques including ‘bridge’ plating, ‘minimal’ internal fixation, and the use of articulating external fixators. Although expensive and unforgiving anatomically-specific precontoured locking-plates (Figure 12.34.13) can be useful for very complex fractures of the proximal ulna.
In cases of limited stability due to either tenuous bony fixation or concomitant soft-tissue damage the use of skeletal fixators with wires or half pins is recommended (Figure 12.34.14).

Coronoid fractures (Box 12.34.7)

Coronoid fractures occur either in combination with comminuted fractures of the proximal ulna or as part of an injury complex associated with elbow dislocation (15% of dislocations). They require internal fixation if they are type 3 injuries (whole coronoid) where the elbow is unstable as a result. Other coronoid fractures, if isolated injuries, can be mobilized within 3 weeks of injury.

Postoperative management

Rehabilitation is essentially as for distal humeral fractures. It is crucial to avoid immobilization—particularly in the very severe so called 'high Monteggia' injury with associated dislocation of the radial head.

Outcomes

A study of 52 patients reported 85% 'good' results with tension band wiring, for appropriate fractures, in terms of strength, range of motion, and function. This study reported a 25% incidence of problems with the K-wires backing out into the soft tissues; this problem was reduced if the wires were placed just through the anterior cortex of the ulna.

The results for comminuted proximal ulnar fractures and oblique two-part fractures stabilized using plates are good with minimal functional loss and good performance as measured by validated outcome measures.

Whatever method is used, due to the subcutaneous nature of the olecranon it is often necessary to remove the fixation sometime later.

Complications and their management

The main complication of olecranon fractures is the failure to achieve pre-injury ranges of motion, particularly extension. Poor ranges of motion are more common in complex multifragmentary fractures. Early range of motion within a controlled environment helps to prevent loss of range of motion.
Malunion, non-union, and arthritis are complications of all fractures of joints, and the elbow is no exception. Surgical damage to the ulnar nerve at the time of operation should be guarded against, but this complication is unusual from the fracture itself. Heterotopic bone is of concern after severe elbow injury, particularly where associated with burns or head injury. Gentle passive elbow mobilization in the acute setting does not appear to lead to heterotopic bone, but the mainstay remains active use of the arm from the first postoperative day onwards.

Summary

Undisplaced fractures can be managed without operation. Extra-articular triceps avulsion injuries are best treated by triceps reattachment and protected motion. Displaced intra-articular fractures require internal fixation and early motion other than in a few unreconstructable fractures where fragment excision and triceps reattachment is recommended.

Radial head and neck fractures

Introduction

Radial head fractures are common, comprising 1.7–5.4% of all fractures. They involve about 20% of all elbow trauma. About 15–20% of proximal radial fractures are of the radial neck; but these are mainly in children. The management of simple radial head fractures is uncontroversial and successful, but controversial and less reliable for the more severe injury patterns. The majority of injuries fall into the simple group; however, care must be given to identify the small number of patients who fall into the complex injury group; particularly those with longitudinal injury patterns extending distally to the distal radioulnar joint (DRUJ)—the eponymous Essex-Lopresti injury.

Aetiology

Radial head fractures are usually caused by a fall on the outstretched hand. The radial head is regarded as a secondary constraint to valgus instability. Displaced fracture fragments usually indicate damage to the very important anterior band of the medial collateral ligament with risk of lasting valgus instability. Disruption of the interosseous membrane between the radius and ulna which can extend into the wrist (DRUJ) is an important but rare injury associated with radial head fractures.

Classification

These fractures can be divided into three types

- Type 1 (62%) are ‘fissure fractures or marginal sector fractures without displacement’
- Type 2 (20%) are ‘marginal sector fractures with displacement’
- Type 3 (18%) are ‘comminuted fractures involving the whole head’. No reference is made to the percentage of the articular surface that constitutes a ‘marginal fracture’
- Type 4 fracture where there is a dislocation of the elbow (Figure 12.34.15) has subsequently been added to the basic classification.

Fig. 12.34.15
The modified Mason classification of radial head fractures. (After McKee and Jupiter (2003).)
Symptoms and signs

Fracture of the radial head, with or without associated damage to the anterior band of the medial collateral ligament, presents as pain and swelling on the lateral aspect of the elbow joint with a reduced range of motion, both to flexion–extension and forearm rotation. Examination will reveal tenderness over the radial head and occasional crepitus. The examination should include the medial aspect of the joint for bruising and tenderness suggesting medial collateral ligament damage and the wrist for DRUJ disruption. A haemarthrosis will be noted by loss of the normal medial and lateral sulci of the elbow.

Investigations

Radiological investigation of the radial head should include an anteroposterior and lateral view of the articulation. The lateral radiograph will demonstrate elevated anterior and posterior fat-pad signs due to the haemarthrosis. The oblique ‘radial head, capitellar’ view can be helpful. CT scanning is helpful only if reconstruction of complex fractures is being contemplated.

Aspiration of the elbow joint is both diagnostic and therapeutic. The direct lateral portal is used for aspiration and local anaesthetic can be introduced after aspiration of the 7–10mL of lipohaemarthrosis which accumulates.

Treatment options (Box 12.34.8)

Mason type 1 fractures: no or minimal displacement

Impacted non-angulated radial neck fractures are included in this group. Although early workers raised concern about the possibility of displacement of these fractures, the general consensus is that they should be mobilized early after joint aspiration. This improves the early results, particularly pain relief, but may have little long-term advantage for regained range of motion. As with all elbow trauma, early motion provides better long-term range of motion compared with immobilization. Mobilization can be aided by application of ice to the anterior aspect of the joint to allow early full extension.

Box 12.34.8 Radial head fractures—treatment options

- Type 1: undisplaced aspirate and mobilize
- Type 2: fractures can be treated non-operatively sometimes
- Type 3: fractures—indications for surgery: block to motion or joint instability
- Type 4: radial head excision ± reconstruction.

Mason type 2 fractures: displaced partial-articular fractures

If the radiocapitellar joint is stable and has no block to motion (as assessed after joint instillation with local anaesthetic), these fractures can be managed by initial splintage and then motion. Non-operative management can also be applied to radial neck fractures with less than 25 degrees of head/neck angulation. However some patients with a residual step of 2–3mm will complain for a very long time of clicking on rotation.

If there is a block to motion or joint instability, open reduction and internal fixation should be considered as radial head excision may lead to reduced grip strength and some proximal radial migration (of questionable significance in the absence of a true Essex-Lopresti injury).

Operative treatment is normally carried out through a standard lateral incision. Open reduction and internal fixation has been successfully achieved with standard raised head screws and a variety of sunken head devices including the traditional and cannulated Herbert (Figure 12.34.16) screws.
Where there is significant soft-tissue disruption either at the elbow or of the interosseous membrane, open reduction and internal fixation should be the treatment of choice of Mason type 2 fractures. If open reduction and internal fixation cannot be achieved for these fractures then radial head excision is carried out. If the fragment is small (less than one-third of the head) partial excision is an option. If the fragment is large then partial excision is less satisfactory than total excision. Where instability exists after radial head excision, treat by radial head replacement using a metal head (Figure 12.34.17).

Mason type 3 fractures: comminuted fractures

In these fractures open reduction and internal fixation is often not achievable. Consideration should be given to radial head replacement if there is valgus elbow instability or longitudinal forearm instability. In certain situations the elbow joint may be supported by a hinged external fixator or the DRUJ may be temporarily pinned.

Mason type 4 fractures: associated elbow dislocation

These fractures of the radial head are treated as their pattern would dictate were there no dislocation, noting the high incidence of ligamentous damage to the primary valgus constraints. Always screen the elbow after repair or replacement of the radial head as valgus instability may still be present. Direct repair of the anterior slip of the medial ligament should be considered and is not at that stage too difficult to achieve.

Outcomes

Non-operative treatment can produce good results in type 1 and 2 fracture, but is not reliable for all type 3 fractures. A retrospective review of 29 patients with Mason type 2 fractures showed significantly better results with open reduction and internal fixation than without. Overall results for type 4 fractures are poorer. Non-operative treatment with delayed excision if symptomatic has shown good result in a Swedish population for Mason 2 and 3 fractures.

Initial encouraging results, in small numbers of patients, using a metal replacement have been born out in the last decade. There are concerns regarding loosening of radial head replacements both monoblock and bipolar designs suggesting caution with their usage.

Complications and their management

Non-union and malunion occur with radial head fractures, and are more common with non-operative management. Instability of the elbow and the DRUJ are well-recognized complications. Heterotopic bone can occur at the elbow joint with radial head fracture particularly type 4 fractures and injuries associated with burns or head injury. Nerve injuries are uncommon, but the posterior interosseous nerve is at risk when exploring the radial head and neck. Grip strength is frequently decreased as is overall range of motion, particularly extension in the more severe grade of fracture.

Summary

Radial head fractures are common elbow injuries. They present with a haemarthrosis of the joint which should be aspirated. Undisplaced fractures are treated by early mobilization. Displaced fractures should be internally fixed where possible. Excision of the radial head is used where reconstruction is not possible. Radial head replacement should be carried out where there is marked valgus or any longitudinal instability. Radial head replacement, with a metal implant, can be helpful in complex fractures affecting
the proximal radius and ulna to set the length prior to stabilizing the ulna. It is important to detect the Essex-Lopresti lesion. The so called ‘terrible triad’ injury of radial head fracture, coronoid fracture and collateral ligament injury (dislocation) require a comprehensive and aggressive surgical approach to regain elbow stability. They remain sinister injuries with a guarded prognosis.

Elbow dislocations and instability

Introduction

Acute elbow dislocation has an annual incidence of 6 per 100 000 population. The highest incidence is between the ages of 5–25 years; with the mode occurring in the late teens for both men and women.

Aetiology

The most common cause of elbow dislocation is a fall on the outstretched hand. In this position the olecranon tip impinges on the proximal edge of the olecranon fossa posteriorly and the ulna is levered out of joint by hyperextension.

An alternative mechanism for at least some elbow joint dislocations has been championed by workers at the Mayo Clinic. They suggest that rotatory forces associated with mild-elbow flexion and axial compression are the source of initially lateral ligament and capsule disruption.

Classification

Elbow dislocations are divided into simple (ligamentous injury only) and complex (those with significant associated fracture). Simple elbow dislocations are classified according to the direction of dislocation (Figure 12.34.18). Both lateral and medial collateral ligaments are torn in all elbow dislocations but lateral instability does not always result. Posterior dislocations are the most common (>80%). The other four possibilities—anteri or, medial, lateral, and divergent—are all rare, especially the last of these.

Symptoms and signs

The patient presents with elbow pain and loss of motion. In the majority of elbows seen soon after dislocation, the abnormal anatomical appearance and malpositioning of the olecranon tip relative to the epicondyles is obvious. However, as the swelling increases this may become less apparent. It is important to document any prereduction deficit in distal neurological or vascular function.

Investigations

In many patients the diagnosis is evident without radiographs and reduction can be performed prior to taking radiographs. Where the diagnosis is unclear, standard anteroposterior and lateral radiographs are helpful. These radiographs should be repeated after reduction with the addition of the ‘radial head, capitellar’ views if further information about possible associated fractures is required.

Treatment options

Reduction can usually be carried out under analgesia and sedation in the accident and emergency department (Figure 12.34.19). However, on some occasions or if diagnosis is delayed, general anaesthesia is required. Reduction is achieved by gentle traction on the forearm with counter-traction on the upper arm; medial or lateral displacement is corrected and the elbow is flexed to achieve the reduction. Relocation occurs with an audible or palpable ‘clunk’ and relief of the patient’s symptoms. Following relocation an assessment of the range of stable motion is essential as well as checking post-reduction radiographs. Exact concentric reduction must be confirmed. In unusual circumstances—especially where diagnosis has been delayed or a redislocation missed open reduction is required.
Following reduction a short period (maximum 5 days) of immobilization in flexion is allowable (unless the joint is very unstable), but the aim should be early motion within the stable range of motion assessed at the time of reduction.

Outcomes

The outcome following a simple dislocation is good. Those dislocations in which there is an associated fracture have a worse outcome.

Complications and their management

Complications of elbow dislocation include nerve and vascular impairment, chronic instability, stiffness, heterotopic bone formation, and myositis ossificans. Vascular complications need to be treated early with vascular exploration and fasciotomies. Nerve deficits can normally be treated expectantly unless open surgery has been performed in the vicinity of the nerve trunk. The management of other complications is discussed elsewhere.

Summary

Elbow dislocations are common injuries of adolescents and young adults. The majority occur posteriorly and may be associated with fractures of the coronoid or radial head. Dislocations associated with fractures have a worse outcome and may need surgery. Treatment is normally by closed reduction and early mobilization, aiming to prevent both chronic stiffness and chronic instability. Recurrent dislocation very rarely occurs in adults and the possibility should not prevent strongly advising patients to mobilize the elbow gently as soon as pain is tolerable.

Humeral shaft fractures

Summary points

♦ Deformity is well tolerated
♦ Anterior approach for proximal shaft, but avoid damaging the axillary nerve
♦ Nerve lesions which do not recover within three weeks should be investigated with nerve conduction studies
♦ Most isolated fractures treated non-operatively
♦ Floating elbow, multiple injuries, open or pathological fractures consider fixation
♦ Open plating and nailing both give good results.

Introduction

Humeral shaft fractures are commonly closed injuries which will generally unite with non-operative treatment with good clinical function. A small proportion have an associated injury to the radial nerve, but this lesion is usually in continuity, and the role of early exploration of a nerve lesion present from the time of a closed fracture is controversial. The treatment options and their rationale are discussed.

Incidence and aetiology

In a Swedish study, humeral shaft fractures were seen to occur in 14.5 per 100,000, the incidence increasing with age. While in this study the majority were due to simple falls, high-energy trauma, penetrating trauma, and the indirect trauma of throwing and arm-wrestling, all caused non-pathological shaft fractures. Pathological fractures usually affect the proximal humerus but fractures through tumour deposits (particularly in multiple myeloma) and in patients with severe osteoporosis can be seen in the shaft.

Relevant regional and surgical anatomy

The humeral shaft connects the polyaxial shoulder joint with the elbow, which acts essentially as a hinge. The large range of motion in all planes at the shoulder joint means that malunion of shaft fractures are, for the most part, well tolerated. The humerus is well covered with muscle, minimizing the aesthetic impact of mild degrees of malunion.

The lateral aspect of the shoulder is covered by the deltoid muscle, innervated by the axillary nerve (a division of the posterior cord of the brachial plexus), which runs around the humeral surgical neck along with the circumflex humeral artery after passing through the quadrilateral space.

The anterior (or flexor) compartment of the arm contains the coracobrachialis, brachialis and biceps muscles. These are innervated by the musculocutaneous nerve, which runs in the plane between biceps and brachialis and has as its terminal division the lateral cutaneous nerve of the forearm. Brachialis receives an additional innervation from the radial nerve, the nerve that primarily supplies the posterior (or extensor) compartment muscle, triceps. The radial nerve arises from the posterior cord of the brachial plexus, runs along the posterior surface of the humerus in the spiral groove between the lateral and medial heads of triceps before passing through the lateral intermuscular septum to pass anterior the elbow joint, supplying the radial wrist extensors (extensor carpi radialis brevis from its posterior interosseous division) and brachioradialis.

The median (Figure 12.35.1) (from the lateral cord of the brachial plexus) and ulnar nerves (from the medial cord) traverse the arm without normally innervating any structures, the median nerve crossing anterior to the brachial artery from lateral to lie medial in the antecubital fossa, and the ulnar nerve passing from the anterior to the posterior compartment through the medial intermuscular septum, crossing the elbow behind the medial epicondyle within the cubital tunnel.
Approaches

The differential innervation of the compartments and sites of the neurovascular bundles dictates the common approaches to the humerus. The proximal shaft is usually approached through an anterolateral approach, which is extensile proximally into the deltopectoral approach to the shoulder and distally into the anterior approach to the elbow and forearm (Henry’s approach). This uses the plane between the territories of the axillary and radial nerves posteriorly and the musculocutaneous nerve anteriorly; brachialis is split to expose the anterior surface of the humerus, relying on its dual innervation, giving access to the whole length of the bone. The patient is positioned supine with the arm on a radiolucent hand table. The resultant scar is obvious.

Distal shaft fractures, particularly with extensions into the distal metaphysis, are generally exposed through a posterior triceps-splitting or reflecting approach, which also allows exploration of the radial nerve in the spiral groove in the event of a radial nerve palsy. An early decision whether triceps continuity with the ulna, with its insertion into the olecranon, can be preserved (triceps reflection or splitting) or the extensor mechanism should be reflected in its entirety (olecranon osteotomy) needs to be made; this decision will largely be determined by the presence of a complex articular injury, requiring direct visualization of the distal humeral articular surface (and so requiring an olecranon osteotomy). Patient positioning is more difficult for posterior approaches, with the patient either lying prone or lateral with the arm in a gutter. Access for intraoperative imaging is also more challenging.

The medullary canal of the humerus runs from the head to just above the olecranon fossa distally. Access for intramedullary fixation techniques can be achieved antegrade through the humeral head (via a deltoid-splitting approach, but requiring violation the supraspinatus element of the rotator cuff). Care must be taken to avoid injury to the axillary nerve if the deltoid is split more than 4cm below the acromion. Retrograde insertion through top of the olecranon fossa is an alternative (via a posterior triceps-splitting approach) but risks creating a supracondylar fracture and makes locking in the proximal humerus more difficult.

History and clinical assessment

The energy of the injury is important to determine, to gauge the likelihood of associated injuries and of a pathological fracture, both of which may influence the chosen method of treatment. An assessment of the anticipated level of compliance with rehabilitation advice is similarly influential.

Examination of the patient should exclude associated injuries, treatment of which may well take clinical priority, and the patient’s fitness for anaesthesia. Local examination focuses on the integrity of the soft tissue envelope and confirming the distal neurovascular function, in particular of the radial nerve (tested best by confirming finger extension at the metacarpophalangeal joint (MCP) joint, thumb retropulsion (an extensor pollicis longus function), and wrist dorsiflexion).

Investigations

Plain film imaging in two planes, without rotating the arm, will suffice in the majority of cases. Pathological fractures will usually be in patients with known metastatic disease, but staging investigations will be needed if the primary tumour is unknown. (see Chapter 12.18). Diaphyseal fractures with articular extensions may require cross-sectional imaging if the articular element cannot be accurately defined on the plain films.

Neurophysiological investigation of nerve lesions is appropriate at between 3-6 weeks if there is no evidence of clinical recovery. Leaving studies for a few weeks will allow denervation changes to be seen.
Treatment options

Non-operative (Box 12.35.1)

Given that mild malunions are accommodated with good function and that union with non-operative treatment is the norm, the overwhelming majority of humeral diaphyseal fractures can and are treated non-operatively. This should be an active process, with care directed to the type of brace used and to ensure that the risk of stiffness of the adjacent elbow and shoulder is minimized.

Initial treatment with a plaster splint like a Bohler slab (to cover the shoulder like a cowl and splint the length of the humerus) to control pain is indicated, with collar and cuff support applied and instruction given to keep the elbow dependent so that gravity will assist reduction. If the humeral alignment is slow to achieve, reinforcement of the advice to keep the elbow dependent and application of a forearm cast to provide a little more gravity-assisted traction is appropriate. (Non-operative management is also dealt with in Chapter 12.11.)

Once the fracture swelling and discomfort has subsided, the protective slab can be replaced with a cooptation brace for the arm. This should be kept tight so that the hydrostatic tension within the muscle compartments will support the fracture, allowing micromotion to encourage union, but not too much motion so that union is prevented. Elbow motion should be encouraged.

Union should be expected by 8 weeks, and is achieved in over 90% of cases. Functional brace use may be associated with impaired shoulder function, but gives better elbow function than use of a U-slab throughout the treatment period.
Box 12.35.1 Non-operative treatment

- Mild degrees of malunion are functionally and aesthetically acceptable
- Gravity-assisted reduction to realign fragments
- Initial slab cast for comfort
- Early functional cast-bracing to restore joint motion
- Union anticipated in over 90% by 8 weeks.

Operative

Indications for operative treatment (Box 12.35.2)

Open fractures require debridement and stabilization; in all but the most extreme soft tissue injuries, or where vascular repair is necessary, internal fixation is preferable. Patients with ipsilateral humeral shaft and forearm fractures also require stabilization of both skeletal injuries. Patients with pathological fractures are generally best treated operatively to give early pain control and return of function.

Other indications for acute fixation are relative, but include multiply injured patients (for ease of nursing care), patients where compliance with rehabilitation is likely to be poor, patients in whom a radial nerve palsy has developed during treatment (see later), and certain fracture configurations (relatively transverse fractures, especially in the proximal third, and certain distal shaft fractures when varus mal-union is less well tolerated).

Plate fixation

Open plate fixation of fractures when operative treatment is deemed necessary remains the most common treatment modality. The approach will usually be anterolateral, although fractures of the distal third or those with associated radial nerve lesions or extension into the elbow are better treated through a posterior approach. A large fragment plate (4.5mm) should be used due to the large forces applied to the implant during healing and rehabilitation, with at least four used holes in both the proximal and distal fragments. Some authors recommend the use of supplementary prophylactic bone-graft at the initial fixation to maximize the rate and likelihood of union.

Minimally invasive plating techniques, often using locking plate systems, have been reported with high union rates. As the neurovascular structures are not exposed during the approaches, care must be taken if undertaking this type of fixation.

Box 12.35.2 Indications for surgery

- Open fractures
- Ipsilateral upper and forearm fractures
- Pathological fractures
- Multiple injury
- Radial nerve palsy
Special fracture patterns.

Box 12.35.3 Operative treatment

- Plate fixation:
  - Commonest method
  - Anterolateral approach unless distal fracture, then posterior
  - Minimally invasive surgery may improve union rates (risk of nerve damage)
- Nailing:
  - Rotator cuff symptoms common
  - Often best for pathological fractures
- External fixation:
  - Used for floating elbow/complex open fractures.

Intramedullary nailing

Initial enthusiasm for intramedullary techniques was dampened by reports of cuff impairment with antegrade insertion techniques, supracondylar humeral fracture with retrograde insertion techniques, comminution during nail insertion, fracture non-union (possibly related to poor rotational control), and problems with the instrumentation. Many of these problems have been reduced by improvements in the design and insertion techniques and instrumentation systems, and high union rates of close to 100% have been reported in series of both open and closed fractures. Similar union rates and function but more shoulder pain are reported in series that compared treatment by plate fixation or intramedullary nailing.

Intramedullary nailing has advantages in the treatment of pathological fractures (or impending fracture), where all but the most distal portion of the humerus can be stabilized, and potentially in obese patients, in whom access for open treatment may be difficult.

External fixation

While less commonly used than in other bones, external fixation is used for open injuries, to bridge a ‘floating elbow’ (associated ipsilateral humeral and forearm fractures) and in damage control situations with multiple injured patients.

Complications

Radial nerve palsy (Box 12.35.4)

While injuries to neurovascular structures have been described complicating humeral shaft fractures, most series report an incidence of radial nerve palsy of 11.8%. Radial nerve palsy is significantly more common with transverse and spiral fractures. Spontaneous recovery is seen in 71% of cases and overall recovery in 88% and is little affected by management.

During the period of expectant treatment and recovery, care must be taken to ensure wrist and digit contractures do not occur that will impair the ultimate function. Provision of a splint to hold the wrist dorsiflexed in a functional position and instruction in exercises to maintain passive motion of the wrist and digit joints is essential. Splints that provide a passive extension force to the MCP joints while allowing active flexion can be used, but these splints risk creating a loss of flexion at the MCP joints if full flexion is not maintained (actively or passively) throughout the recovery period. If neurophysiological investigations suggest that the nerve has been divided, exploration and nerve grafting should be undertaken promptly to maximize the likelihood of the best possible outcome. If a long time has elapsed since the injury without evidence of recovery, tendon transfer will give a better functional outcome, although full passive motion of the wrist and digit joints is essential (see Chapter 12.25).

Box 12.35.4 Complications—radial nerve palsy

- Seen acutely in 12%
- 71% recover spontaneously with expectant treatment
- Maintain passive elbow, wrist, and digit motion while recovery occurs
- Wrist extension splint safer than one with finger outriggers
- Neurophysiological evidence of nerve division mandates exploration at 6-8 weeks
- Tendon transfer better than late repair
- Expectant treatment may be reasonable for some lesions that arise during treatment.
While most experts accept that initial expectant treatment of a radial nerve present from the time of injury is appropriate, the optimal treatment when nerve palsy arises during the treatment of a humeral shaft fracture is more controversial. Exploration of the radial nerve is advisable following palsy onset after intramedullary nailing or minimally-invasive plate fixation due to the potential for intraoperative nerve laceration. Nerve injury should be noted if a posterior approach has been used for open plating, but if an anterolateral approach has been used, exploration should be undertaken. Radial nerve palsy during non-operative treatment is the most controversial subject as in the majority of cases, exploration of the radial nerve in these circumstances showed an in-continuity lesion (as is the case with radial nerve palsy present from the moment of injury). As with radial nerve palsy from the injury, an initial period of expectant treatment and active monitoring with neurophysiological investigation at 4–6 weeks is reasonable, although early exploration can be justified.

Non-union (Box 12.35.5)

Rates of non-union with non-operative treatment range from 2–39%. Factors associated with failure to achieve union by non-operative means include the site of the fracture, with fractures of the proximal third being less likely to unite, and the pattern of the fracture, with transverse and short oblique fractures reported as being possibly less likely to unite.

Non-steroidal anti-inflammatory (NSAID) use has also been noted to be associated with non-union of humeral shaft fractures with a relative risk of non-union of 3.7 (95% confidence interval 2.4–5.6). However, in this retrospective study, NSAID use was only significantly associated with non-union at 61–90 days following injury (with opioid use in the same time window also showing a significant association with non-union), raising the possibility that the drugs were taken because of the pain of the impending non-union, and that the drug use may not be causal of the non-union.

Box 12.35.5 Complications—non-union

- Commoner in proximal fractures
- Transverse/short oblique fractures at risk of non-union
- NSAIDs may encourage
- Treat by onlay plating/grafting or reamed nailing.

Non-union may be treated by open plating with onlay bone grafting or by reamed intramedullary nailing.

Summary and conclusion

Humeral shaft fractures can occur at any age, although the incidence increases with age. The majority can and should be treated non-operatively as the outcome is generally good and the degree of malunion that commonly occurs is well tolerated with good function. Exceptions to the non-operative rule include open fractures, pathological fractures and humeral shaft fractures in multiply injured patients.

Non-union should occur in less than 10% of cases with non-operative treatment and can be treated with stabilization and bone grafting. While radial nerve palsy complicates over 10% of humeral shaft fractures, the overwhelming majority of lesions are in-continuity and can be treated expectantly with splintage and mobilization of the wrist and hand to maintain function, and clinical and neurophysiological monitoring to look for signs of early recovery. Prompt surgical treatment should be offered to patients in whom there is concern about radial nerve division.

When surgical stabilization is indicated, open plating and minimally invasive treatment with intramedullary nailing both give good results in terms of union and function, although there is a greater incidence of shoulder pain and dysfunction with antegrade intramedullary nailing. Minimally-invasive plate fixation has been reported, but the theoretical risk of iatrogenic nerve injury means caution should be observed. The role of external fixation in acute treatment is limited.

Fractures and dislocations of the shoulder girdle

Summary points

- The function of the girdle is to position the hand in space
- The spectrum of injuries range from common and uneventful to rare and life threatening
- The functional outcome depends on individual demand, severity of the injury and the presence of complications.

Introduction

The shoulder girdle is a complex structure of three bones and five articulations that aims to position and support the function of the hand in space. As all joints, in order to serve the end-organ effectively the girdle requires range of motion, stability, and strength. Complex movement is shared amongst the five articulations resulting in a particular pattern of motion known as shoulder rhythm. In theory any pathology that affects these elements of girdle function may result in disability; however, as functional demands vary amongst patients and segmental disability may be compensated by the function of neighbouring joints, measurable deficits do not always correspond to functional disability. It is likely that in the average individual loss of 20% of girdle motion will not result in disability.

Acute glenohumeral dislocation

Anatomical considerations

The glenohumeral articulation is universal joint. In order to allow this range the joint depends less on osseous contact and stability relies more on the intra-articular and periarticular soft tissues. The structural and functional components of the glenohumeral joint (GHJ) stability have been extensively studied. The structures contributing to the joint stability are shown in Table 12.36.1.

<table>

<td>Coracoacromial ligament</td>
</tr>
</tbody>
</table>

The labrum provides a 50% increase in the congruency of the glenohumeral articulation whilst the middle and inferior glenohumeral ligaments are the primary ligamentous stabilizers of the joint.

Pathological anatomy

A variety of traumatic lesions corresponding to the vector of the dislocation have been identified. The classic Bankart lesion associated with anterior dislocations represents the detachment of the capsulolabral complex from the anteroinferior portion of the glenoid. Correspondingly the Hill Sachs is an impaction fracture of the posterior part of the humeral head. Common fracture of the anteriorly dislocated shoulder is an impaction fracture of the glenoid with the great tuberosity fracture the next most common. Shearing fractures of the glenoid rim are discussed in the section on scapular fractures.

In posterior dislocations the impaction fracture is in the anterior part of the head (reverse Hill Sachs) and may be associated with avulsion of the lesser tuberosity or the subscapularis tendon.

Aging of musculoskeletal system results in inelastic tissues. Whilst fractures are more common in young adults, rotator cuff injuries have been identified in up to 85% of patients over 40 years of age. The presence of massive rotator cuff tears affects the outcome of shoulder dislocations.

Epidemiology

Anterior dislocation of the GHJ is the most common joint dislocation with a prevalence of 1.7%. It most commonly occurs as a sport related injury in young males and after a fall in elderly females. Posterior dislocation accounts for 2% of the GHJ dislocations. With the higher prevalence of high-energy injuries such as motorcycle crashes dislocations of the GHJ occur in conjunction with proximal humerus fractures (PHF). The obvious fracture and the difficulty of obtaining adequate imaging may result in a missed dislocation.
Clinical assessment, treatment principles, and outcomes

The history and clinical appearances are pathognomonic of the anterior dislocation of the GHJ. Caution is required in circumstances where the history is unclear or other clinical pathologies such as epilepsy prevail. In contrast with the young adult the history of injury in the elderly can be vague, the complaints minor and the appearances subtle. Hence the diagnosis may be delayed or even missed.

Essential part of the clinical examination prior to any reduction manoeuvres is the neurological status of the arm. In anterior dislocation the axillary nerve is often involved although a recent study suggested a significant incidence of nerve involvement up to 48% when electromyographic (EMG) studies were used as a diagnostic tool. Multiple neural structures can be affected; however, the long-term prognosis is good with recovery evident 12–45 weeks following the injury.

Plain radiographs in two planes are the minimum standard of care regarding the imaging of the injury. Poor imaging may lead to error in diagnosis and management. The anteroposterior view must be in the plane of the GHJ. Axial views are difficult due to pain, however adequate analgesia and skilled radiography will produce adequate views in almost all circumstances. The direction and associated osseous injuries must be considered. The documentation of the dislocation is of importance in the long term in order to differentiate individuals with unidirectional traumatic dislocation from patients with multidirectional instability.

A multitude of reduction techniques have been describe for reduction of the anterior GHJ, the Hippocratic one being the oldest described. The principle of reduction, however, remains the same: adequate analgesia and monitored sedation followed by disimpaction, controlled traction, and reduction of the joint. Techniques that do not involve physicians in the process, such as the prone position and over the chair traction with weight application, are preferable. Contraindication to reduction in the emergency department is the dislocation with an undisplaced fracture of the humeral neck. Dislocations of the GHJ associated with humeral neck fractures are rarely successful in the Emergency Department and best avoided as the repeated trauma during the attempts may lead to a variety of complications and affect outcome.

Debate exists regarding the of postreduction after care. Multiple studies suggest no difference in the incidence of recurrent instability with or without immobilization in a sling and swathe or Velpeau bandage. An elegant study demonstrated that the avulsed capsuloligamentous flap (Bankart lesion) is best apposed to the glenoid neck with the arm in external rotation. However, the application of the finding in clinical practice has yet to be tested. Whilst the early surgical intervention has been lingering for some time, a recent well-structured study from Edinburgh suggested that early arthroscopic Bankart repair significantly decreases the risk of redislocation within the first 2 years in young individuals (15–27 years).

Box 12.36.1 GHJ Dislocation: summary points

- Relies on osseous, static and dynamic stabilizers for stability
- Associated with:
  - Bankart lesion
  - Hill Sachs lesion
  - Tuberosity fractures
  - Rotator cuff tears
  - Glenoid rim fractures
- Prevalent in:
  - Young sportsman
  - Elderly females (often missed, occult associated injuries to the rotator cuff and plexus and early redislocation)
- AP and axial views
- Reduce with adequate analgesia and monitored sedation

Fig. 12.36.1 Fracture of the proximal humerus with posterior dislocation of the humeral head.
Consider arthroscopic Bankart repair in young (15–27 years).

It is hardly surprising that the redislocation is likely to occur in the ‘sportingly active’ group as the injury is sports related and they are unwilling to modify their activity. Multiple studies confirmed the fact and demonstrated a significant risk of up to 55% in the 2 years increasing to 66.8% at 5 years for the 15–27 age group.

Whilst recurrent dislocation is the most common injury-related complication in the young, the presence of rotator cuff damage and/or glenoid rim fracture predispose to redislocation of the GHJ in the elderly within the first 6 weeks. Pathognomonic of post-reduction incongruence of the GHJ is painful rotation: in almost all non-fractured dislocations, rotation with the humerus in neutral position is comfortable and well tolerated. In the incongruent GHJ rotation is invariably limited and associated with pain and occasional crepitus.

Fracture dislocations can pose significant dilemmas and can be challenging to treat operatively. Reduction and fixation in young adults is preferable whilst in the elderly and low-demand patients with poor bone stock shoulder hemiarthroplasty may be the better option. Fractures of the greater tuberosity usually reduce once the GHJ is congruent. Displacement of the tuberosity fragment may occur, possibly suggesting associated rotator cuff tear. Early recognition will result in easier reconstruction and better outcome in terms of range of GHJ motion.

Fractures of the proximal humerus

Anatomical considerations

At the proximal end of the humerus the anatomical neck at 45 degrees to the shaft leads to the head that carries the head in average of 20 degrees of retroversion. The rotator cuff attaches to the great tuberosity that is on average 8mm lower than the edge of the articular surface. The bicipital groove allows the uninterrupted and smooth function of the long heads of the biceps. Medial to the groove the subscapularis attaches to the lesser tuberosity. Studies have demonstrated that the vascular supply to the head is via four routes (Figure 12.36.2 and Box 12.36.2). Fractures through the anatomical neck of the humerus may have a significant risk of avascular necrosis (AVN) whilst fractures through the surgical neck will spare the blood supply to the head.

Fractures of the proximal humerus

Anatomical considerations

At the proximal end of the humerus the anatomical neck at 45 degrees to the shaft leads to the head that carries the head in average of 20 degrees of retroversion. The rotator cuff attaches to the great tuberosity that is on average 8mm lower than the edge of the articular surface. The bicipital groove allows the uninterrupted and smooth function of the long heads of the biceps. Medial to the groove the subscapularis attaches to the lesser tuberosity. Studies have demonstrated that the vascular supply to the head is via four routes (Figure 12.36.2 and Box 12.36.2). Fractures through the anatomical neck of the humerus may have a significant risk of avascular necrosis (AVN) whilst fractures through the surgical neck will spare the blood supply to the head.

Epidemiology, mechanisms of injury, and classification

Proximal humeral fractures are common, compromising 5% of all fractures. It is a spectrum of injury ranging from physeal Salter–Harris II fracture in adolescents with excellent prognosis to high-energy fractures in young adults usually as the result of motor vehicle crashes. However, the majority of fractures occur in the seventh decade of life with a reported incidence of 63/100 000
population at an average age of 64.8 years. Fractures of the proximal humerus are now considered as ‘fragility fractures’.

The mechanism of injury is indirect force with fall on the arm or direct blow to the shoulder. The position of the arm, energy transfer upon impact and the bone stock will result in abduction, or abduction fracture patterns with or without dislocation of the GHJ.

Codman in 1934 described a distinct pattern of fracture of the proximal humerus and his observation remains valid to date: the proximal humerus fails in a predictable pattern due to the vector of force and the attachments of the musculotendinous units. The result is a fracture of the greater tuberosity, fracture of the lesser tuberosity and a fracture through the humeral neck. Neer’s classification (Figure 12.36.3) is based on Codman’s observations and despite criticism and individual interpretation it is still widely used providing a useful template for planning treatment. It classifies fractures according to the number of displaced fragments. Displacement was defined as 1cm and/or 45-degree angulation. This has led to fierce debate especially regarding the fractures involving the greater tuberosity (GT). Current thinking accepts displacement of no more of 5mm when referring to GT fractures. Evolution of knowledge resulted in recognition that valgus four-part fractures carry a different prognosis due to preservation of the head vascularity. Using Neer’s criteria, 80% of PHF are undisplaced and require symptomatic treatment followed by an intensive and structured rehabilitation programme.

The AO/OTA comprehensive classification is a useful system and distinguishes between extra articular, partial intracapsular, and intracapsular fractures.

Assessment and treatment principles

Clinical assessment should document the neurovascular status and the condition of the soft tissues.

Adequate imaging is essential to identify the extent of the fracture, the fracture pattern, and the state of the GHJ and neighbouring joints. Whilst most information can be obtained by adequate good quality plain radiographs, in patients were intervention may be appropriate, computed tomography (CT) of the proximal humerus with reformatted images has become the standard of care.

Patient particulars are of essence to complete the assessment prior to any decision regarding the treatment of the fracture (Box 12.36.3).

Box 12.36.3 Patient factors affecting decision-making for PHF

- Injury-related complications:
  - Stiffness
  - Malunion
  - Non-union
  - AVN
- Treatment-related complications:
  - Stiffness
  - Infection
  - Construct stability
  - AVN.
The most common complication of PHF is stiffness. As the GHJ heavily relies on the surrounding soft tissue structures for its function, early range of motion is of absolute essence in whatever method of treatment is followed.

GT fractures displaced more than 5mm are associated with rotator cuff tear and as such are potentially unstable fractures. Furthermore displacement may result in malunion and lead to impingement. However, the majority of the GT fractures displace superioposteriorly and as such result in an inefficient pulley mechanism resembling massive rotator cuff tear. Hence it is recommended that fractures of the GT displaced more than 10mm are best treated by reduction and fixation. Fractures displaced 5mm should be investigated for an associated tear at the interval. Repair is recommended if a tear is identified.

Displacement of the articular fragment (Figure 12.36.4) resulting in translation of the centre of GHJ rotation may affect the efficiency of the lever system. Correction of the head glenoid relationship restores the centre of rotation and minimizes the risk of pulley inefficiently.

High-energy fractures with or without dislocation in young adults is best treated with reconstruction of the proximal humerus and attachment of the tuberosities. It is postulated that replacement surgery of the humeral head with healed tuberosities is a more predictable procedure than primary replacement of a fracture dislocation that is associated with poor rotator cuff function and severe stiffness.

Fractures of the surgical neck and the metaphysis are usually undisplaced and the fracture configuration allows early mobilization. Widely displaced fractures are unstable; the distal fragment buttonholes through the muscles and may go on to a non-union (Figure 12.36.5). Fractures of the proximal humerus that require manipulative reduction are inherently unstable.

Displaced fractures of the proximal humeral third extending in the metaphyseal region are often unstable injuries associated with high incidence of delayed union/non-union. This appears to be especially true when patients report excessive clicking at the fracture site. Low energy fractures are associated with large soft tissue interposition whilst high-energy injuries result in medial and lateral fragmentation and subsequent gross displacement due deforming forces from the muscle, weight of the arm, and body habitus. These are best treated operatively at the onset (Figure 12.36.6).
Sophistication of knowledge has led to less dogmatic approaches when it comes to fracture treatment. Most injuries can be treated non-operatively with acceptable results. Significant injuries will do badly whatever the intervention. It is the role of orthopaedists to identify the patients that appropriate operative treatment will affect the final outcome. Table 12.36.2 may act as an aid to decision-making.

Operative treatment

Historically, operative repair of PHF was associated with myriads of complications:

Complex fractures, poor imaging, poor understanding of the objectives of treatment, poor bone stock, unfamiliar territory, little experience, inadequate implants were some of the contributing factors that gave operative fixation of the PHF bad reputation. The good news is it could only get better: whilst operative treatment of these injuries remains a challenge some of the factors mentioned are better understood. Due to small numbers of operative cases and variance of patient and injury characteristics it is difficult for the case series reported in the literature to be didactic and help the orthopaedic surgeon decide on the treatment modality.

Evolution of medical technology in imaging and multidisciplinary care of the frail patients has improved the patients’ selection for operative treatment. The development of new plating systems to address the issues of osteopenic bone and fragmentation most often encountered in treatment of the PHF can only be seen as an advantage. However, the new technology is not a panacea and has not altered the indications for surgical treatment. In this context poor patient selection will result in relatively large treatment related complications.

The operative options are reduction and fixation and arthroplasty. The aim of reduction and fixation is to restore anatomy whilst
preserving the blood supply to the bone and create a stable construct to allow early range of motion. Patients will need to follow a structured rehabilitation programme and the fracture will need to heal. There are technical issues relating to fragmentation and bone stock. Results are dependant on patient selection and surgeons’ experience.

Hemiarthroplasty for PHF was recommended by Neer as the outcome following treatment of four part fractures was poor. Stableforth confirmed that the procedure was reliable, providing a pain-free shoulder at the expense of movement. Whilst there has been some understanding and improvement on technical aspects, length of the prosthesis appears still to be an issue with approximately 50% being too long or too short resulting in eccentric centre of rotation of the GHJ. More importantly it is now accepted that the poor functional status of a replaced fractured proximal humerus is directly related to migration, malunion and/or resorption of the tuberosities. Despite the evolution of design in shoulder prosthesis and the repair of the tuberosities this complication continues to date. Survivorship of the prosthesis does not appear to be a problem with a 94% survival rate at 10 years.

Complications

Complications of PHF are related to the injury and the treatment. In addition to immediate fracture related complications such as neurovascular compromise soft tissue disruption commonly experienced complications are listed in Box 12.36.4.

Box 12.36.4 Complications of PHF

- Injury
  - Stiffness
  - Malunion
  - Non-union
  - AVN
  - Osteoarthritis
- Treatment
  - Stiffness
  - Infection
  - Neurovascular damage
  - Hardware failure
  - AVN/Osteoarthritis.

Post-traumatic stiffness is the most common complication of PHF as the shoulder girdle function is heavily dependent on the surrounding soft tissues in order to maintain a wide range of motion with efficiency. Injury severity and prolonged immobilization in internal rotation may result in recalcitrant stiffness and poor functional outcome. Fixed internal rotation or the lack of external rotation is probably the most disabling deformity. It cannot be overemphasized that the fracture pattern or final construct following intervention must allow early movement and in particular external rotation of the GHJ.

Most PHF will eventually heal with a degree of malunion. In the immature skeleton up to 45 degrees of angulation will remodel successfully. The true incidence of symptomatic malunion is unknown as it is poorly defined as to what constitutes malunion in PHF. In a retrospective review, of patients that underwent surgery for malunion, three types were identified (Table 12.36.3). They reported 69% successful reconstruction and 31% complication rate associated with poor outcome. In 79% of the patients there were associated soft tissue abnormalities with 80% being capsular contractures.

Table 12.36.3 Beredjiklian classification of proximal humerus malunion (1998)

<table>
<thead>
<tr>
<th>Malunion of proximal humerus fractures</th>
</tr>
</thead>
<tbody>
<tr>
<td>Type 1 Tuberosity malunion &gt;10mm</td>
</tr>
<tr>
<td>Type 2 GHJ incongruence</td>
</tr>
<tr>
<td>Type 3 Articular surface misalignment &gt;45 degrees</td>
</tr>
</tbody>
</table>

The functional disability often is the result of additional global stiffness rather than structural alone. It appears that tuberosity malunion is the most responsive to treatment either with osteotomy or with acromioplasty, whilst replacement with prosthesis appears less successful and is associated with more technical problems as compared with primary hemiarthroplasty for acute fractures.

Non-union of the PHF is underreported. This may reflect the population characteristics and the practice of short follow-up without radiology. It is, not unreasonably, assumed that the clinical picture does not correlate with the imaging. Neer has described a distinct pattern of non-union and pseudarthrosis often seen in fractures of the surgical neck. Widely displaced two-part fractures of
the proximal humerus are reported to have a 4.7% incidence of non-union. Mobile non-unions are symptomatic as patients often complain of painful clicking and lack of strength in the arm; they are unable to lift themselves off the chair or use their walking aid (Figure 12.36.7). This is a therapeutic challenge as reduction and fixation is challenged by poor bone stock. Hemiarthroplasty for non-union is technically demanding and often results in exchange of a flail arm with stiffness.

AVN is associated with fractures through the anatomical neck and historically with reduction and fixation of four-part fractures. It was initially thought that all four part fractures carried a significant risk of AVN; however the position changed once realized that in valgus displaced fractures the vascular supply of the head fragment is preserved and the outcome is favourable. Appreciation of the vascular pattern of the humeral head and improved operative skills has led to a significant decrease of AVN following surgery. Recent report on the operative treatment of high-energy fractures suggested that the incidence of AVN is 35% with 20.6% partial (Figure 12.36.8) and 14.7% total. As expected patients with AVN did worse as assessed with outcome scoring tools.

Rehabilitation following proximal humeral fractures (Box 12.36.5)

Although stiffness in many circumstances is unavoidable, it is essential to commence physical therapy as soon as the fracture pattern or construct will allow. Results following early and late physiotherapy treatment show a significant difference in the outcomes at 1 year. The Neer regimen of four 3-weekly periods of passive range to resistance exercises with individual modifications to allow for patient characteristics seems to be universally accepted. Measurable improvement continues for approximately 6 months following injury, thereafter, functional improvement is most likely due to compensatory mechanisms and activity modification.

Fractures of the clavicle

Introduction

As with all injuries, fractures of the clavicle it is a spectrum of injury with the majority of fractures resulting in an uncomplicated recovery and return to the pre-injury functional status.

Box 12.36.5 Factors affecting outcome in PHF

- Injury pattern:
  - Displacement fragmentation and stability
  - Anatomical neck, head splitters
  - Dislocation
- Patient factors:
  - Age and bone quality
  - Pre-existing disease
• Functional demands
• Compliance and motivation

♦ Operative treatment:
• No devascularization
• Stable construct
• Early mobilization.

**Functional anatomy, epidemiology, and classification**

The clavicle is an ‘S’ shaped bone with no medullary canal. The ossification starts in the 5th week of gestation, whilst the medial physis ossifies at the age of 25 years. It is the strut connection of the arm to the trunk via the sternoclavicular, acromioclavicular joints and the coracoclavicular ligaments and multiple muscle attachments. It is suspended like a crane via the trapezius, sternocleidomastoid and subclavius muscles and moves 30 degrees in the coronal plane, 35 degrees on the sagittal plane, and rotates 50 degrees to facilitate the version of the glenoid during GHJ movement clearing the arm of the trunk.

Fractures of the clavicle represent 10–12% of all fractures. The prevalence in the adult population is 30–64/100,000/year. It affects all ages with a peak in the young males during sporting activities. Motor-vehicle collision is the second most common mechanism of injury in males whilst the male to female ratio evens with advanced age. Direct impact is in most circumstances the mechanism of injury. Open fractures occur in 1.4% of the fractures treated in a level I trauma centre in the United States of America and are associated with head and torso injuries.

Altman in 1967 classified the fractures in medial, middle, and lateral thirds. Robinson identified subgroups within Altman’s classification after collecting large number of data (Table 12.36.4).

**Assessment and treatment principles**

The clinical diagnosis is obvious in most fractures. Standard radiographs will include an anteroposterior and a 20-degree tilted view as displacement cannot be assessed on single view alone. In high-energy injuries associated girdle injuries or chest trauma may be present and these injuries may require immediate attention. This is especially true in the presence of open clavicle fractures. Widely distracted fractures of the clavicle should raise the suspicion of scapulothoracic dissociation, especially if accompanied by neurovascular compromise. In association with fractures of the scapula the disruption of the superior shoulder suspensory complex (SSSC) may lead to unacceptable displacement.

Eighty-nine per cent of all clavicle fractures go on to uneventful union with symptomatic treatment alone. Open fractures or fractures associated with vascular compromise are absolute indications for operative treatment in line with the general principles of orthopaedic trauma.

Reduction of the displaced fractures of the middle third was recommended using a figure-of-eight strapping. However, the reported results comparing simple sling and the figure-of-eight strapping did not show a difference in the final outcome. The figure-of-eight treatment has been abandoned in United Kingdom practice as it is associated with complications and does not affect outcome in terms of fracture healing.

**Box 12.36.6 Clavicle fractures**

♦ 89% of clavicle fractures heal uneventfully
♦ Displaced and fragmented fractures of the middle third may be prone to delayed/non-union and benefit form primary
reduction and fixation.

- Operative management of middle third fractures is associated with faster recovery and significant complication rates.
- Further work is required to identify the cause of symptoms in malunions.
- Displaced/unstable fractures of the distal third are associated with high incidence of non-union (30%).
- Non-union of the distal clavicle is often asymptomatic and does not affect function.

The dogma that all clavicle fractures unite uneventfully has been challenged in the past with sporadic reports on case series of non-unions. Increasing number of reports identified subgroups of fracture patterns such as severe shortening and fragmentation to be associated with delayed/non-union. Furthermore, there has been some concern that malunion of the clavicle is associated with pressure phenomena and poor functional outcomes. Recent randomized studies suggest that certain fracture patterns may benefit from early intervention in terms of time to union. However the operative treatment was not without complications that were reported to be 37%.

Fractures of the lateral third of the clavicle are another subgroup that has attracted interest as the incidence of non-union is approaching 30% especially for the displaced Neer II/Robinson 3B type of fractures: it is accepted that these non-unions are mostly asymptomatic. In a 15-year follow-up, 95% of non-unions were asymptomatic. In a separate study only 14% of the non-unions required further surgery (Figure 12.36.9).

Operative repair of distal clavicle fractures is not without technical difficulties and complications mainly due to the inherently unstable pattern of injury, poor bone purchase, and need of the fixation crossing mobile areas around the shoulder. The variety of techniques illustrates the difficulty of the problem (Figure 12.36.10).

Operative treatment of clavicle fractures

- **Absolute indications:**
  - Neurovascular compromise (Figure 12.36.11)
  - Open fractures
- **Relative indications:**
• Fragmentation middle third
• Shortening >2cm
• Threatened soft tissue envelope
• Associated girdle/multiple injuries

Acromioclavicular joint injuries

Anatomical considerations

The acromioclavicular joint (ACJ) is a diarthrodial joint with a meniscus and a strong capsule which in conjunction with the coracoclavicular ligaments suspends the scapula from the clavicle. The kinematics of the joint have been studied and a 20-degree arc of tilting, rotation and protraction has been identified.

Epidemiology, mechanism of injury, and classification

ACJ joint injuries are common in males as the result of sporting injuries with direct force on the shoulder. They represent 12% of the shoulder injuries and in their majority these are simple sprains.

The classification in Box 12.36.8 suggested by Tossy 1963 complemented by Rockwood appears to be universally accepted.

Box 12.36.8 Rockwood classification of ACJ injuries

♦ Type 1: simple sprain of the joint no capsular/ligamentous damage
♦ Type 2: ACJ joint disruption/partial incongruence
♦ Type 3: ACJ dislocation with CC ligament disruption
♦ Type 4: posterior buttonhole through trapezius
♦ Type 5: deltoid detachment gross displacement
♦ Type 6: inferior displacement subcoracoid space

The mechanism of injury and corresponding clinical signs are pathognomonic of the injury. Radiographs exclude the presence of a fracture of the distal clavicle. Weight bearing comparative views are occasionally necessary to differentiate a type 2 from a type 3 injury.

Treatment principles, results, and complications

Universal agreement exists for type 1 and type 2 injuries: these are treated symptomatically (Box 12.36.9). Pain usually resolves within 3 weeks and function returns with simple physiotherapy exercises.

Box 12.36.9 Treatment of ACJ injury

♦ Type I + II: non-operative
♦ Type IV, V, and VI: operative
♦ Type III: current evidence supports non-operative treatment
♦ Symptomatic patients benefit from distal clavicle excision, ligament reconstruction, and augmentation.
Whilst there is some debate regarding type 3 injuries, current evidence would support non-operative treatment. Patients are not easily convinced that the symptoms will soon settle and that the shoulder function will return despite the residual deformity. Follow-up consultation in 2–3 weeks allows more insight to the effects of the injury.

Evolving minimally invasive techniques in the acute setting has resulted in increased interest in early intervention as scarring in the region of the coracoclavicular ligaments may abolish the need for ligament transfer and reconstruction (Figure 12.36.12).

Symptomatic patients will respond to reconstructive surgery of distal clavicle excision, ligament reconstruction and augmentation. The Weaver–Dunn procedure with its many modifications remains the template for stabilization of the distal clavicle. Symptoms often relate to cosmesis, lack of strength, and/or painful clicking of the joint in order of frequency.

Early operative treatment is required for the more rare and severe disruptions that will impinge on shoulder movement such as the locked and widely displaced (Rockwood types IV and V) and subcoracoid (Rockwood VI) injuries.

Numerous publications refer to the results of primary operative versus non-operative treatment and later reconstruction. The current practice varies depending the surgeon’s experience and interpretation of the reported literature. It is reasonable to accept that the majority of these patients would do well either with or without operative treatment. With the exception of cosmesis, as a consistent indication for surgery, it is not obvious at presentation which subgroup of patients would benefit from early intervention.

**Sternoclavicular injuries**

**Anatomy, epidemiology, and diagnosis**

The sternoclavicular (SC) joint is a saddle joint connecting the clavicle to the axial skeleton. It has a range of motion of 35 degrees in the coronal plane and 70 degrees in the anteroposterior plane. For all practical purposes the articulation functions as a ball and socket joint. Stability relies partially in skeletal anatomy and more so in the strong and complex ligamentous structures (costoclavicular, interclavicular, anterosuperior, and posterior capsular reinforcement) and the subclavius muscle. The medial end of the clavicle physeal ossifies by the age of 25, hence injuries to the region in young adults represent physeal fractures.

The mechanism of injury can be direct or indirect. As a result it can occur in a variety of injuries such as sport and motor vehicle accidents. The posterior dislocation may be associated with a dramatic clinical picture of airway obstruction whilst the sporting injuries can be easily overlooked.

The overall incidence of the injury to SC joint is reported as 1% of all dislocations and 3% of the dislocations of the upper limb. As with all injuries there is a spectrum of injury (Box 12.36.10).

**Box 12.36.10 SCJ injury spectrum**

- Sprain
- Subluxation
- Dislocation:
  - Anterior
  - Posterior
- Fracture dislocation.
Whilst the history of injury and clinical symptoms are significant often the deformity is mild (especially with posterior injuries) and the plain radiographs difficult to interpret. Special views and measurements have been recommended but CT is the investigation of choice (Figure 12.36.13).

Fig. 12.36.13
Missed posterior fracture dislocation of the SCJ following rugby injury.

**Treatment, results, and complications**

Immediate reduction of a posteriorly displaced medial clavicle is part of the ATLS protocol for emergency treatment of airway compromise. In the less acute setting the treatment options vary according to the injury, the individual and the timing of the diagnosis (Table 12.36.5).

There are few relatively small case series in the literature reporting the results of operative techniques. Whilst there is no conclusive evidence regarding the treatment methods, it appears that open reduction with autologous tendon reconstruction without transfixation is associated with the best results (Figure 12.36.14) whilst medial clavicle excision and joint transfixion are associated with poorest results and highest incidence of complications respectively.

### Scapular fractures (Box 12.36.12)

**Epidemiology and topographic classification**

The scapula is a mobile platform suspended from the axial skeleton by the clavicular ligaments, the ACJ capsule and a variety of muscles. It provides the fulcrum (glenoid) for the arm movements and rotates to facilitate universal arm movement (scapulothoracic articulation) and is the site of origin for 17 muscles. Fractures of the scapula account for 1% of all fractures, 3–5% of fractures of the shoulder girdle, and occur in 3% of patients with multiple injuries.

#### Box 12.36.12 Scapula fracture

- Often associated with polytrauma and frequently missed
- 5–12% incidence of neurological and vascular complication
- Operative treatment rarely indicated
- Outcomes depend on injury severity and associated complications

Fractures of the scapula are subdivided according to anatomical topography. As considerable force is required for scapular fractures to occur, concomitant injuries are associated with particular fracture types (Table 12.36.6).

**Assessment and treatment principles**

Despite the history of significant trauma scapula fractures are missed at presentation in 43%. Likely reasons are the incidence of associated injuries (85–90%) mainly of the ipsilateral shoulder girdle or to the thorax and poor visualization on plain radiographs. It is expected that with the liberal use of CT to assess thoracic trauma the pick-up rate of scapula fractures will increase.

The incidence of associated neurological and vascular complications is reported to be 5–12%.

**Glenoid and glenoid neck fractures**

Glenoid fractures account for 10–15% of the scapula fractures. Approximately 10% are significantly displaced to pose a treatment dilemma. Hence the absolute incidence of displaced glenoid fractures to be considered for intervention is 1:10 000 fractures. Glenoid fractures are classified according to Ideberg based on the force vector of the humeral head on the glenoid fossa (Table 12.36.7).

Type Ia fracture of the glenoid treated non-operatively.

Fig. 12.36.15
Type Ia fracture of the glenoid treated non-operatively.

Principles of treatment of articular fractures in terms of joint stability and congruence are valid and reproducible; however, the true incidence of degenerative changes due to intra-articular malunion is unknown.

Glenoid neck fractures in association with a clavicle fracture were described as 'the floating shoulder'. The injury was considered highly unstable and thought to be associated with poor outcome. However, recent experience has questioned the dogma of instability of floating shoulders and clarified the indications regarding the need for intervention. Current thinking relates to the medial and caudal displacement of the glenoid fragment. It considered that caudal tilt greater than 40 degrees and medial displacement more than 1cm may affect GHJ motion and represent indication for operative intervention.

**Fracture of the scapula body**

Fractures of the scapula body including the spine are the most common fractures of the scapula. In the absence of articular involvement the fractures are treated symptomatically with particular care to the associated chest injuries. Fractures that involve the supraclavicular notch may be associated with suprascapular nerve damage that in the context of loss of function due to pain may be difficult to diagnose early.

**Acromion fractures**

Fractures of the acromion are extremely rare as it is more likely that a direct force would result in injuries to the neighbouring anatomical structures mainy the acromioclavicular joint. Concerns and dilemmas with malunion and or symptomatic non-union are raised with significant displacement. Os acromiale may pose a diagnostic pitfall.

**Coracoid fractures**

Coracoid fractures compromise 2–5% of scapula fractures and have been related to a variety of mechanisms of injury. Fractures of the base are more common; despite the rarity of the injury six types have been recognized and operative treatment recommended for injuries associated with AC disruption.
Scapulothoracic dissociation

Scapulothoracic dissociation (SCTD) is a potentially life-threatening injury depicting a closed forequarter amputation with neural and vascular damage and essential disarticulation of the scapulothoracic joint. Since the original description in 1984 variations of the injury have been described and the spectrum of injury further classified (Table 12.36.8). Whilst immediate management relies on timely revascularization of the limb it appears that the long term outcome of injury heavily relies on the presence and extent of brachial plexus injury.

Management principles (Box 12.36.13)

Attention should initially address life and/or limb-threatening conditions.

Specific treatment for scapula fractures is based on small retrospective case series and knowledge boosts from their meta-analyses. Most scapula fractures are treated symptomatically. It has been estimated that, using current indications, an orthopaedic surgeon would operatively treat 1.5 fractures of the scapula during his/her career.

Box 12.36.13 Indications for operative treatment of scapula fractures

- Glenoid involvement with step >5mm leading to joint incongruence
- Glenoid fossa fracture resulting in GHJ instability (>20% surface area)
- Caudal angulation glenoid >40 degrees
- Medial displacement of glenoid >1cm
- Displaced acromion/coracoid fractures
- Scapulothoracic dissociation.

A recent meta-analysis of the literature identified 243 patients from 17 publications that had operative treatment for scapula fractures. Most of the fractures involved the glenoid (48%) and 20% involved the glenoid neck. Using a variety of scoring systems results were rated excellent and good in 84% and fair and poor in 16%. Operative treatment complications were infection 4.2% and nerve damage (suprascapular) 2.4%.

Further reading

Summary points

♦ Clinical criteria and the nature of the injury determine who needs imaging
♦ Plain films are still commonly employed though CT finds more fractures
♦ Alignment, bony contour, cartilage (Disc and facets) and soft tissue are assessed in turn (ABC’S)
♦ CT is superior to MRI in assessing the bony configuration of fracture
♦ MRI is superior to CT in assessing the ligament tears and associated disc herniations
♦ Plain films have little role in the assessment of more chronic back pain and radiculopathy
♦ Sacral insufficiency fractures may be misdiagnosed as metastases on MRI.

Introduction

The aims of this chapter are to:

1) Describe how to clear the spine
2) Describe the common injury patterns and radiological findings.

The concept of risk of spinal injury is very important in helping to decide the appropriate imaging strategy. This is often difficult as a good history of mechanism and potential injury pattern is not always available.

The NEXUS study retrospectively applied the following clinical criteria in relation to potential cervical trauma: absence of midline tenderness, no focal neurological deficit, normal level of consciousness, no evidence of intoxication, and no evidence of distracting injury. If all of these criteria were negative then imaging was not considered necessary. The study included 34,000 patients and found that eight of 818 (1%) cervical spine fractures would have been missed; two of the eight were deemed serious. Their conclusion was that if the clinical criteria listed were all negative there was no need to perform any imaging.

The Canadian Cervical spine Rules (CCR) studies, through the application of clinical criteria, identified the following: persons of high risk who all required imaging, patients of low risk on whom it is safe to assess the active range of movement of the cervical spine, and finally patients with the ability to actively rotate their heads 45 degrees in both directions who required no imaging.

Prospective studies have been applied to both the NEXUS and CCR and found CCR to have a sensitivity of 99.4% for clinically important injuries, versus 90.7% for NEXUS.

In 2002 The British Trauma Society published a series of guidelines for the management and assessment of spinal injury that was, in essence, a hybrid of the conclusions of NEXUS and CCR, concluding that if a patient cannot be clinically cleared then imaging should be performed to exclude cervical spine injury.

Once the decision to image has been made, several imaging options need to be considered. Plain radiography is universally available. Traditionally the three view series (anteroposterior (AP), lateral, and peg views) has been employed. An essential requirement of the lateral view is that the cervicothoracic junction is demonstrated, as up to 20% of cervical injuries involve this segment. If traction on the arms fails to depress the shoulders sufficiently, a swimmer’s view may be necessary. If clinical concern persists, computed tomography (CT) is indicated. The five-view series (the three-view series augmented by oblique views) is now largely redundant, as the obliques rarely add useful diagnostic information. CT scanning has largely replaced other x-ray techniques.

The plain film

The plain radiograph remains the essential first step in the assessment of the spinally injured patient. The majority of vertebral injuries can be accurately diagnosed and classified using AP and lateral views. Some fractures can be subtle and will only be detected by an ordered evaluation of the radiographs and by recognizing subtle changes in the normal anatomical relationships.

Five per cent of cervical trauma radiographs are misinterpreted, resulting in delays in diagnosis with death or further neurological deterioration in up to 30% of the missed injuries. In half of these patients a complete three-series set of films had not been obtained.

Analysis in the cervical spine begins with the lateral view proceeding to the AP and peg views.

In turn, alignment, bony contour, cartilage, and soft tissue spaces (ABCs) are examined. Normal alignment on the lateral is confirmed by the integrity of three lines; the anterior vertebral line, the posterior vertebral line, and the spinolaminar line (Figure 12.37.1). Apparent subluxation of C2 on C3 is often identified in children and is physiological. This can persist up to the mid-teens. The most important portion of the spinolaminar line is between C1 and C3. A straight line joining the spinolaminar arcs of C1 and C3 should pass within 2mm of C2. This relationship is disturbed in patients with displaced fractures of C2 (Figure 12.37.2).
The distinctive anatomy of the upper cervical spine renders it prone to a different pattern of injury compared with the lower cervical region.
The upper cervical segments are also more commonly injured in children. A variety of measurements have been used to describe the normal relationships between the occiput and the atlas. Most of these are now superseded by sagittal CT reconstructions.

The atlantoaxial relationship can be examined using the ratio of the height of the atlantal spinolaminar line to the atlantoaxial interspinous distance. This ratio is normally 2. The distance between the spinolaminar line and the articular pillars can also be used to assess unifacial dislocation. Abrupt alteration of this distance suggests spinal rotation and has a strong association with unifacial dislocation following hyper flexion injury. Another common injury to C1–C2, rotary subluxation, will be discussed in relation to the peg view later in this chapter.

The posterior arch of C1 can be found anywhere between the occiput and the spinous process of C2. Angulation between the anterior arch and the dens is also commonly observed in normal individuals. The posterior arch of C1 is often not ossified and absence must not be misconstrued as a fracture. Abnormal widening may be seen (>10mm) between the spinous processes of C1 and C2 in patients with significant cord injury without other plain film findings.

The C2 vertebral body may show several fracture patterns, and careful review may be necessary to detect them. Small avulsions from the anteroinferior body of C2 may be the only clue. It is useful to look carefully at the apparent dense ring (Figure 12.37.3) projected over the C2 vertebral body, as disruption may be a clue to an underlying fracture, although in many cases this line is incomplete without injury. In a review of 165 injuries, 41% were dens fractures, 38% were traumatic spondylolistheses (hangman’s fractures), 13% were extension teardrop fractures, and 6% were hyperextension dislocations. The remainder were fractures of the lamina and spinous processes. Consistent with other series, no type 1 dens fractures were reported, suggesting that a type 1 fracture, if it exists, is a rarity.

Dens fractures (Figure 12.37.4)

There are three types:

- Type I: a fracture of the tip of the odontoid (rare)
- Type II: through the base of the odontoid
- Type III: through the body of the odontoid (commonest, 69%).

Hangman’s fracture

Traumatic spondylolistheses (hangman’s fractures) are divided into three types:

- Type 1 are undisplaced
- Type 2 are displaced
- Type 3 are associated with bilateral facet subluxation.

The lower cervical spine

The pattern of injury of the lower cervical spine differs from that of the upper two levels. Before diagnosing injury, a number of variations have to be recognized. The fourth and the fifth vertebral bodies can normally be slightly smaller than the adjacent third and sixth vertebral bodies without pathology being present. This can be particularly marked in children, possibly as a result of exaggerated hypermobility during ossification. In general, the difference between the anterior and posterior heights of a vertebral

[Click to view larger]

Fig. 12.37.3

Lateral cervical spine radiograph. The cervicothoracic junction is well seen. Note the white ring projected over the body of C2 (large arrows). If it is disrupted a careful search for a fracture is indicated. The smaller arrows indicate the posterior facets.
body should be no greater than 3mm. More than this implies an anterior wedge fracture.

The clay shoveller' fracture involves the spinous process of C6 or C7 (Figure 12.37.5). In hyperflexion sprain, it is a stable injury. The plain radiograph is often normal, and widening of the interspinous distance may be seen. The flexion teardrop is seen as a small anteroinferior fragment. It indicates an unstable injury and is often associated with abnormal neurology, particularly the anterior cord syndrome. The hyperextension teardrop is smaller and is more common in the upper cervical spine. Displacement is unusual and neurological abnormalities are less frequent. The plain film in hyperextension sprain is also normal unless views are obtained in extension.

The most obvious sign of facet dislocation on the lateral plain film is vertebral body subluxation. Half of these injuries are unilateral facet injuries and half are bilateral. In bifacetal dislocation, subluxation can reach 50% (Figure 12.37.6). In unifacet dislocation displacement is usually less than 25% and can often be difficult to detect, particularly if the film is rotated. Once suspected, a careful examination of the facets will reveal the abnormality. Below a dislocation the facets are seen in the true lateral projection with the right facet overlapping the left. Above a unifacet dislocation, the facets on one side will lie more anterior to the other. The lateral mass is seen obliquely and resembles a bow tie. These injuries are frequently associated with fracture of the facet, best seen on CT. At the level of the injury, the superior articular process of the inferior vertebral body does not articulate with the corresponding inferior process of the vertebral body above. This is called the naked facet sign. Oblique views show loss of the normal ‘tiled roof’ appearance of the overhanging facets. Facet fracture–dislocation represents approximately 7% of cervical spine fractures. The incidence of neurological abnormality is high, up to 90% in some series, and is particularly common in bilateral injuries. MRI is necessary to exclude an associated disc prolapse which can cause neurological deterioration following facet reduction.

The diagnosis of a cervical injury may depend on the detection of abnormal alignment between vertebrae. Immediately following injury, the presence of muscle spasm may cause the vertebra to maintain their normal relationships and obscure injury. Persistent pain following an injury is an indication of missed injury, and some centres employ flexion and extension views to exclude abnormal segmental motion. If flexion is adequate, the mandible should form an angle of at least 66 degrees with the horizontal. The film should be examined for angulation between the posterior border of the vertebral bodies and for fanning of the spinous processes. The latter is present when the interspinous distance is more than 2mm greater than the spaces above and below. Angulation of more than 3 degrees between vertebral bodies is considered abnormal. If the angle reaches 11 degrees the injury is considered unstable.

The anteroposterior view

The standard cervical AP view should be scrutinized for alignment along both lateral borders and the spinous processes. Abrupt loss of alignment of the spinous processes is seen in unifacet dislocation and may be the most obvious sign of this injury.
Subtle fractures of the lateral pillars may only be appreciated on the AP view. Sagittal oriented fractures appear normal on the lateral view in up to a third of cases and the majority are unstable. Fractures of the upper ribs imply a high-velocity injury which may be associated with lower cervical vertebral fractures and rupture of the great vessels.

The pedicles are also best seen in the AP projection. Absence of a pedicle may be due to destruction by tumour or congenital absence, although this is more common in the thoracic or lumbar spine. The AP view can be obtained with caudal tilt to show the posterior arch, or cranial tilt to give better delineation of the vertebral bodies. In cases where better definition is required, CT is usually employed to better effect.

**The peg view**

The AP projection of the peg shows its relationship to the lateral masses of C1 and C2. The combined distance between the peg and the lateral masses should be no more than 7mm (Figure 12.37.7). Displaced fractures of the arch of C1 (Jefferson fractures) are recognized by an increase in this measurement and by lateral displacement of the lateral mass of C1 with respect to C2 (Figure 12.37.8).

![Normal Peg view](Click to view larger)

**Fig. 12.37.7**

Normal Peg view. Note the symmetry of the distances between the peg and the lateral masses of C1 and the normal lateral alignment (arrows).

![Displaced lateral mass of C1 with associated fractures of the ipsilateral facet of C2](Click to view larger)

**Fig. 12.37.8**

Displaced lateral mass of C1 with associated fractures of the ipsilateral facet of C2 (white arrow).

The classical Jefferson fracture involves four breaks in the arch of C1, two anterior and two posterior, although fewer are frequently seen (Figure 12.37.9).
Axial CT through C1, the ring is disrupted in three locations (black arrows) with slight lateral displacement of the left lateral mass. A faint line is seen in the intact arch (white arrow) this represents a vascular groove and not a fracture.

The injury can also be unstable if there are fewer breaks but the posterior longitudinal ligament is torn. Many injuries of this type are not obviously displaced on initial plain films.

Asymmetry between the right and left spaces without an absolute increase in the total measurement occurs when there is rotation of C1 on C2. Abnormal rotation can occur following trauma, viral infection, or torticollis, particularly in children. Asymmetry may be seen in normal individuals even with correct positioning of the head. Failure to correct with 15 degrees of rotation to either side has been termed fixed atlantoaxial rotatory subluxation (ARS), and is said to distinguish traumatic rotation from other causes, but only if combined with positive clinical signs. Rotation also causes an apparent increase in the size of one lateral mass (that furthest from the film) and a decrease in the size of the other. In true fixed ARS, axial CT sections may show an associated fracture of the facet. In the absence of a fracture, haemorrhage, or synovial entrapment within the facet may account for the fixed rotation. CT is also used to classify fixed ARS based on the peg–anterior arch distance. A distance greater than 5mm implies an unstable lesion which requires surgery.

Undisplaced peg fractures can be difficult to diagnose in the early stages on standard plain films. Fractures are usually oriented in the axial plane and therefore can be overlooked on standard axial CT sections. Coronal CT reconstructions will show the fracture line; however, thin sections have to be acquired to provide sufficient resolution to avoid reformatting artefact. These problems can be overcome with multislice CT and orthogonal voxel acquisition (Figure 12.37.4).

Plain film vs computed tomography

Plain film radiography has been the mainstay of spinal imaging for decades, but there is no doubt that even with excellent radiographic technique and accurate interpretation, a significant number of bony injuries are not detected. The percentage of missed injuries is age dependent and may be as much as 10–20%. With this high miss rate there is a strong argument for bypassing plain film radiography in favour of multislice CT in all apart from the low-risk groups, particularly as the multiply traumatized patient often requires CT imaging of the brain, chest, and abdomen and other injuries. The main counterargument to screening with CT is radiation burden, particularly to the thyroid gland, which is very radiosensitive.

When single slice CT was first introduced it was used as a problem solving tool for areas like the craniocervical or cervicothoracic junctions that were not well visualized on plain film. Helical slice CT and subsequently multislice CT followed with the latter permitting 1-mm slice thickness and isotropic voxels enabling multiplanar image reformatting, have tended to be used to image the entire cervical spine between the foramen magnum and T4. This aids in the perception of difficult subtle fractures and dislocations particularly fractures through the pedicles, pillars and posterior arches. Sensitivities of 95% and specificities of 93% are quoted.

Improvements in CT technology and computing power have facilitated the development of isotropic voxel imaging using multislice CT. This means that slice thickness is now so thin that multiplanar reformatting can be performed on the original voxel data set (Figure 12.37.10). Not only are sagittal and coronal reformats used routinely, but oblique and three-dimensional modelling now
become possible. The three main imaging plains axial, sagittal, and coronal are all complementary and useful in the detection and analysis of different fractures (Figure 12.37.11). Plain film radiography has no equivalent to the axial plane in which the CT data set is acquired and here lies the greatest advantage of CT over plain film and this is that the bony canal can be clearly demonstrated and the relationship of bony fragments to the canal can be directly delineated (Figure 12.37.12).

Fig. 12.37.10
Sagittal reformat of the whole spine from a polytrauma CT showing a wedge compression fracture of L1 with a small retropulsed fragment.

Coronal and axial CT showing sagittally orientated fractures through the vertebral body of C6 which was not visible on the plain film.

Fig. 12.37.12
Sagittal and axial images showing burst L2 fracture, note the axial image clearly defines the relationship of the bony fragments and the canal.

**Magnetic resonance imaging vs computed tomography**

MRI is used in the assessment of the cord and disc herniation in patients with neurological deficit and the assessment of ligamentous structures.

The four main indications for MRI are suspected spinal cord injury, suspected ligamentous injury, radiculopathy, and progressive neurological deficit, which is an indication for emergency MRI. Sequence optimisation is particularly important in...
maximizing diagnostic yield. However, the basic examination of the cervical spine should include a $T_1$-weighted sagittal sequence, a $T_2$ or more preferably a fat saturated $T_2$ sagittal sequence and axial images with either $T_1$, $T_2$, or GRE $T_2^*$ images, or a combination of these. Further sequences can be obtained depending on the clinical scenario and bespoke investigation can be tailored as appropriate. For example if nerve root avulsion is suspected, specific axial oblique $T_2$ or $T_2^*$-weighted images are obtained through the exiting nerve roots.

The $T_1$ images are particularly useful for displaying anatomy, for example the sagittal $T_1$ sequence beautifully demonstrates the anterior longitudinal ligament. Likewise the STIR (short-tau inversion recovery) or $T_2$ fat sat images are crucial for detecting bone marrow oedema and microfracture. CT and plain films miss 0.5% of significant injuries in the obtunded patient.

Other indications for MRI in trauma include:

- Diffuse idiopathic skeletal hyperostosis (DISH) and ankylosing spondylitis
- SCIWORA (spinal cord injury without radiological abnormality)
- Vertebral artery trauma, traumatic meningocoeles, CSF leaks after nerve root avulsions, post-traumatic syrinx, syringohydromyelia, and myelomalacia.

Posteriorly the interspinous ligaments lie between the spinous processes and lamina, they are not as conspicuous as the ALL and PLL on sagittal images but abnormal signal or haematoma in their location infers disruption and potential instability when taken into context with the other injuries seen. As well as assessing alignment of the longitudinal and interspinous ligaments, the paravertebral soft tissues and cord (Figure 12.37.13) should be examined, as vertebral fractures may be associated with paravertebral haematomas. The MRI signal characteristics of blood are complicated and evolve with time, as the oxygenated haemoglobin released from the red blood cells undergoes degradation via deoxyhaemoglobin and methaemoglobin to haemosiderin, all of which have different and definable signal characteristics.

Fig. 12.37.13
Sagittal $T_2$ image of the cervical spine showing a fracture through the sixth cervical vertebra, with a posteriorly displaced fragment causing spinal compression, note the abnormally high signal in the compressed cervical cord, also note the abnormally high signal in the C6/7 disc which indicates the fracture involves the disc.

Thoracolumbar spine

Injuries to the thoracolumbar spine account for approximately 60% of all spinal injuries. In adults, 90% are between T11 and L4, and the majority of these occur between T12 and L2. In children T4 and T5 also figure prominently. The standard projections are AP and lateral views, which can be supplemented by cone lateral views of the injured area.

On MRI, the axial images are best suited for assessing the paravertebral areas, canal and spinal cord. Haematoma is not uncommonly seen within the spinal canal, usually in the epidural space. Epidural haematomas may be compressive and reactive cord oedema is identified as high signal on the fluid sensitive sequences within the cord itself. Differentiation from cord haemorrhage can be achieved by considering the different signal characteristics of oedema and haemorrhage. Finally, the osseous structures should be considered, as previously stated it is well known that MRI is relatively insensitive to detecting fractures, even if STIR sequences are employed. The classic signal characteristics of a fracture are low signal lines on $T_1$ imaging (Figure 12.37.14) and associated high signal on $T_2$ (Figure 12.37.15) and other fluid sensitive sequences. If fat saturation techniques are employed, the fatty signal of the marrow can be negated to exaggerate the fluid signal associated with fracture and micro fracture, improving the pickup.

Click to view larger

Fig. 12.37.15
Sagittal T2 image showing collapse of T12 with associated high signal, also note the loss of vertebral body height of L4, both fractures were osteoporotic in aetiology.

Anteroposterior projection

On the AP projection, the margins of the vertebral bodies can be difficult to distinguish owing to overlap with the posterior elements. A careful scrutiny of the superior and inferior margins will demonstrate wedging; however, this is much easier to assess on the lateral view. The upper thoracic vertebra can be difficult to assess on the lateral view; therefore particular attention must be paid to these on the AP view. Signs of vertebral injury on the AP view also include paravertebral haematoma, apical capping, and mediastinal widening. These are also features of vascular injury. Aortic rupture causes a variety of plain radiograph changes, but the most reliable are tracheal or oesophageal deviation to the right, apical capping, and depression of the left mainstem bronchus. The right paravertebral line lies in close proximity to the vertebral column throughout its length; the left is slightly more laterally placed as a result of displacement by the aorta and can be up to 1cm from the vertebral column. A focal increase in these distances can occur with a paravertebral collection of blood or pus. Displacement due to an ectatic aorta or large osteophytes is the more common cause and tends to be diffuse rather than focal. Below the diaphragm, the psoas shadows may assist in the diagnosis of a paravertebral mass or haematoma. The left psoas shadow can be identified in more than 70% of normal subjects. The right is more variable in its appearance and is not seen in up to 60% of normal subject. Blurring or enlargement of the psoas shadow may be a sign of retroperitoneal haemorrhage.

Evaluation of the AP view should also include an assessment of the costovertebral joints, the pedicles, and the transverse and spinous processes. The pedicles are normally oval in shape and the spinous processes are teardrop shaped. The cortical margins of both structures should be carefully scrutinized for fracture. There is a gradual increase in the interpediculate distance between T1 and L5. An increase in this distance, following trauma, to more than 4mm greater than adjacent levels indicates involvement of the posterior column and a burst fracture. The presence of a fracture of the transverse process should prompt a search for associated renal injury.
The lateral view

The anterior and posterior margins of the vertebral body should be compared on the lateral view. Minor anterior wedging is acceptable, but the anterior vertebral margin should not differ from the posterior vertebral height by more than 3mm (Figure 12.37.16). More significant wedging causes retropulsion of the posterior vertebral margin into the spinal canal. The most common site of retropulsion is from the posterosuperior margin of the vertebral body. Signs of fragment retropulsion include a convex configuration of the posterior vertebral margin which may be associated with loss of the normal cortex and an increase in the posterior vertebral bony angle to more than 100 degrees. Fragments from both superior and inferior margins are next in frequency. CT will assess the precise nature of the retropulsed fragment and the degree of spinal canal compression; however, the latter does not necessarily correlate with the degree of neurological deficit. A limbus vertebra may mimic a compression fracture. It can be differentiated by its more rounded contour and the corticated fragment of bone isolated by hemiated nuclear material (Figure 12.37.17).

Fig. 12.37.16
Plain lateral radiograph showing loss of anterior height of T12 greater than 3mm indicating fracture.

Fig. 12.37.17
Limbus vertebra. A residual ring apophysis (white arrow). Separated from the underlying vertebral body by prolapsed disc material. An incidental Schmorl node (open arrow) and traction spur (arrowhead) are noted.

When the fulcrum of force is anterior to the vertebral body, a 'lap-belt' or Chance fracture ensues (Figure 12.37.18). Distraction forces may result in tearing of the interspinous ligament, facet subluxation, or horizontal fractures through the vertebral body, pedicles, or laminae. Vertebral body height is characteristically increased.
The most common cause of pathological thoracic vertebral fracture is osteoporosis. The most common cause is postmenopausal osteoporosis, but myeloma as a cause of osteoporosis should be considered and excluded. Multiple osteoporotic fractures are more likely to be contiguous. Plain film changes suggestive of malignancy include involvement of the pedicles (usually spared in multiple myeloma), cortical destruction and a soft tissue mass. MRI is the investigation of choice in distinguishing benign from malignant causes and in determining whether osteoporotic fractures are acute or chronic.

Displaced fractures of the pars interarticularis are readily identified on plain films. Undisplaced fractures may be identified on the lateral view, or, more easily, on the 45-degree oblique projections. This technique has been replaced by CT (Figure 12.37.19) and MRI. The authors consider MRI to be the more justifiable imaging technique, as it is more sensitive and does not involve ionizing radiation. These patients are often young, and a negative plain film in suspected pars defects often does little more to progress the differential diagnosis. Sagittal T1-weighted MRI shows the defect as a focus of the intermediate signal within the pars and is the method of choice for the initial evaluation of the pars. In the majority of cases an interruption to the normal bright marrow signal within the pars is seen on the sagittal T1-weighted images. MRI also has the advantage of demonstrating the adjacent exit foramen in patients with associated root compression secondary to spondylolisthesis (Figure 12.37.20). Degenerative disc changes at the level above the pars defect can also be diagnosed. Traumatic spondylolisthesis can be distinguished from the degenerative type by a relative increase in the AP canal diameter. Sagittal STIR or fat-suppressed images may demonstrate edema in the adjacent marrow secondary to attempts at repair; however, these changes are uncommon. In some cases, high signal is demonstrated within the pars in the absence of an established fracture and this is termed stress response. Differentiation of injury at this occult stage may be important in the training athlete, as modification of the training programme may prevent progression to established fracture. In patients with known pars fracture, CT is superior to MRI in determining healing. Skeletal scintigraphy, preferably with single-photon emission CT (SPECT), shows increased uptake at these sites of repair and is also sensitive to the prefracture stage.
Fig. 12.37.20
Displaced pars defect with root compression. The arrow indicates a swollen distorted nerve root within a distorted exit foramen.

The sacrum, sacroiliac joints, and coccyx

The sacrum can be difficult to assess on plain radiographs, as anatomical detail can be obscured by overlying soft tissue. Particular attention should be paid to the lateral margin of the bone and the integrity of the arcuate lines (Figure 12.37.21). If either of these landmarks are blurred or interrupted, cross-sectional imaging with CT (Figure 12.37.22) or MRI may be necessary.

Fig. 12.37.21
Anteroposterior view of the pelvis showing the sacrum and arcuate lines (arrows).

Fig. 12.37.22
Axial CT showing disruption of the arcuate lines secondary to sacral fracture.

Fractures of the sacrum are frequent in the osteoporotic patient. One or both ala may be involved and a linking fracture may cross at the S2 level giving the classical H or Honda sign configuration. The fractures are easier to see on MRI than plain films. Fractures of the pubic rami are frequently present in these patients.
Coccydynia is a common problem in the general population, usually following trauma, particularly parturition. In these cases imaging is of little help. If sinister pathology is suspected by the clinical history and rectal examination, MRI or CT is the investigation of choice.

**Further reading**

### Summary points

- Unconscious patients should have CT scan of neck
- Emergency MRI if possible in spinal cord injury
- Avoid flexion/extension views if possible
- In spinal shock avoid over transfusion and consider epinephrine; high dose steroids probably not indicated
- Reduce dislocation acutely (MRI before in intact patients if possible)
- Do not put distraction injury into traction
- Urgent surgery for traumatic disc herniation, expanding epidural haematoma, depressed lamina fracture or complex facet fractures with dislocation.

### Prehospital care (Box 12.38.1)

A patient with spinal cord injury and neck deformity would usually benefit from a general realignment effort and subsequent protective immobilization prior to transport.

In children, placement on a conventional backboard can lead to undesirable cervical kyphosis as paediatric heads are disproportionately larger than those of adults. Using a specialized backboard with a cutout for the head or placing a folded blanket under the victim’s torso helps to avoid this.

Exceptions to the principle of supine positioning of trauma patients on a hard board for retrieval purposes are rare. Neurologically intact patients who present with significant painful neck deformity, such as patients with ankylosing spondylitis, are preferably immobilized in situ with sandbags and folded towels in a semi-upright position to accommodate their deformity, provided that their vital signs are stable. It may also be helpful to ask the patient about their pre-injury posture and neck alignment as well as position of comfort, since patients with pre-existent neck deformity may be subject to further cord impingement and subsequent neurological deterioration attempts from ill-advised manipulation.

### Box 12.38.1 Prehospital care

- **On site management:**
  - High degree of suspicion for cervical spine injury
  - Attention to ATLS guidelines for extrication
- **Patient transport on spine board**
  - For children use occipital cutout to avoid excessive flexion
- **Use rigid neck collar ± sandbags and tape for patient transport**
- **Establish/document basic four-extremity neurological status prior to transport.**

### Emergency diagnostic measures (Box 12.38.2)

#### Clinical evaluation

Unconscious patients should receive an emergency head computed tomography (CT) scan as soon as possible to exclude intracranial lesions and caudal extension of this scan to include the cervical spine. This allows visualization of the entire cervical spine and the cervicothoracic junction.

Log-rolling is performed with proper spine precautions maintained by a team approach. The cervical collar is released during palpation of the neck. Strict spine precautions should be maintained in all trauma victims until appropriate radiographic and clinical clearance have been completed; however, positioning on a rigid board for more than 4h increases the risk of developing sacral or occipital decubiti.

Neurological assessment starts with determination of mental status and cranial nerve function and is followed by systematic spinal cord functional evaluation following the principles established by the ASIA system (American Spinal Injury Association 1992) (Figure 12.38.1). The effects of sedatives, muscle-relaxing medications, and limb injuries on rating motor strength should be considered during this evaluation. Formal neurological status evaluation for trauma patients routinely includes evaluation of the anal reflex and assessment of perianal sensation.
sphincter region for perianal sensation, spontaneous sphincter tone, quality of voluntary contraction, and presence or absence of bulbocavernous reflex. For patients with neurological deficits, an attempt is made to establish the level of sensory and motor injury. Further differentiation of complete and incomplete neurological injuries is of importance with regard to timing of treatment and patient prognosis. Repeat neurological evaluations should be obtained and recorded to exclude neurological deterioration which may occur, for instance, in the event of a developing epidural hematoma or malreduced spine. The presence of a bulbocavernous reflex has been described as implying absence or resolution of spinal shock. Similar to neurological deficits secondary to spinal shock, patients with incomplete spinal cord injuries may recover some neurological function. Sacral sparing can present with signs of preserved voluntary anal sphincter contractility, perianal sensation, and voluntary long toe flexor function.

Imaging

The ABC principles as formulated in the Advanced Trauma Life support algorithm had recommended three initial trauma radiographs, consisting of anteroposterior (AP) chest, AP pelvis, and lateral cervical spine views for several decades. The more ready availability of rapid image acquisition CT-scan technology, such as offered with helical CT, allows for comprehensive imaging of head, cervical spine, and torso with pelvis regions and has largely replaced conventional imaging in the emergency department setting. Despite this technological advance, a lateral cervical spine radiograph still remains the single most relevant diagnostic entity for trauma in most centres (Figure 12.38.2).

Significant injuries to these transition zones of the cervical spine (occipitocervical and cervicothoracic spine) are among the most common regions of missed cervical spine injuries due to limitations placed on conventional radiographic imaging. Helical CT has been consistently shown to be more sensitive, less time consuming, and more cost effective compared to the traditional work-up, with increased patient radiation exposure the only major downfall. Practitioners need to remember that certain cervical spine injuries are not readily seen on axial CT images, such as type II odontoid fractures and distractive injuries. Reformatted views in sagittal and coronal planes are integral to establishing CT as the sole imaging modality of trauma patients. Specific fine cut CT-scans in defined regions may be helpful to detect specific injuries such as craniocervical dissociations.

Emergency magnetic resonance imaging (MRI) scanning is indicated in patients with cervical spinal cord injury, unexplained
neurological deficit, discordant skeletal and neurological levels of injury, and worsening neurological status (Figure 12.38.3). Barring contraindications to MRI, such as presence of stimulators, pacemakers or ferromagnetic clips and other foreign bodies, urgent indications for scanning present predominantly in patients with non-osseous encroachment of the spinal cord. Emergency CT myelography should be considered if there are contraindications to MRI, or if MRI is not readily available. Although sagittal MRI sequences such as T2-weighted images can be helpful in depicting discoligamentous injuries, this imaging study can usually be obtained on a non-emergency basis.

![Fig. 12.38.3](image)

**Fig. 12.38.3**

A) This 42-year-old female presented with neck pain and hyper-reflexia but no extremity motor or sensory deficits following a motor vehicle accident. An emergency MRI scan was obtained prior to attempting closed reduction of the bilateral facet dislocation in order to exclude a traumatic disc herniation. This sagittal MRI shows a C4–5 dislocation with cord impingement caused by the displacement of the spinal column and a retropulsed C4–5 disc. In patients with displaced cervical spine dislocations without significant neurologic compromise, an emergency neural imaging study, such as an MRI, can influence further management considerably. In this patient closed reduction would probably lead to retropulsion of the C4–5 intervertebral disc into the spinal canal with possible additional neural compromise. B) Treatment consisted of emergency anterior C4–5 discectomy with interbody fusion and plate fixation. The patient continued to demonstrate signs of myelopathy postoperatively, but maintained normal extremity motor and sensory function.

Dynamic radiographs, such as flexion–extension lateral radiographs of the cervical spine, are effective in assessing stability. However, in order to obtain flexion–extension radiographs, the patient must present without cognitive impairment and have a normal, entirely non-focal neurological examination with normal plain radiographs. Recent studies have suggested that follow-up flexion–extension radiographs are not efficacious when a negative CT has been performed in blunt trauma without neurological findings. Recent evidence has also suggested that initial CT imaging identified all unstable cervical spine injuries in obtunded trauma patients. Subsequent upright radiographs did not identify any additional injuries but significantly delayed spine clearance.

In the setting of a hectic Emergency Department we recommend against routine acute flexion–extension radiographs because of the risk of incurring neurological deterioration by failure to satisfy all the criteria mentioned earlier. Furthermore, a patient with an acutely sprained neck is unlikely to provide a useful neck motion effort in the acute postinjury phase, thus rendering the study less meaningful. We recommend putting the patient into a neck brace and then performing flexion–extension radiographs at 1 to 2 weeks.

Injuries to the vertebral arteries (VAI) should be suspected in any patient with cervical spine trauma presenting with altered mental status. Injuries with significant vertebral displacement and displaced fractures involving the transverse processes should also alert the clinician to evaluate the patient for possible vertebral artery injuries. Any fracture extending into the foramen transversarium or with significant displacement, as in the setting of jumped facets, may be associated with overt or occult vertebral artery injury. Catheter angiography has been the gold standard for the diagnosis of VAI; however, new 16-slice CT angiography seems to have sensitivity and specificity which is as good. Vertebral angiography can also be performed at the same time as aortic angiography (Figure 12.38.4). Magnetic resonance angiography and Doppler evaluation are non-invasive techniques for assessing cranial flow abnormalities with as yet unclear clinical implications. In those patients with identified vertebral artery injury, serial monitoring with transcervical Doppler over a 3-day period is used to assess for emboli. Treatment options include observation, antithrombotic agents, anticoagulation, and endovascular treatments. Although some authors have advocated antithrombotic therapy for most asymptomatic VAI, there is a lack of class I evidence to support any strong guidelines for treatment.

**Box 12.38.2 Emergency Department management principles**

- Early recognition and treatment of cervical spine injury
- Serial neurological examination and documentation
- Radiological assessment:
  - Initial lateral x-ray (optional)
  - Spiral CT scan head and cervical spine through T1/2 disc space (preferred)
  - Beware non-contiguous injury (40%)
Prevent further harm:
- Immobilize with collar, sandbags or traction, move patient off backboard.

Emergency therapeutic intervention

Resuscitation

After a brief initial period of hypertension, spinal shock results in flaccid paralysis, decrease of systemic vascular resistance, and subsequent hypotension. In patients with thoracic spinal cord injury above the T6 level, loss of sympathetic input to the heart can lead to bradycardia and hypotension. Neurogenic shock may mask other important causes of trauma-related hypotension. Patients with neurogenic shock will not usually respond to continued intravenous fluid substitution. Excessive fluid resuscitation efforts may lead to pulmonary oedema and congestive heart failure. Administration of intravenous epinephrine (adrenaline) by bolus or with an intravenous drip for instance with dopamine is recommended to reverse the deleterious haemodynamic effects of neurogenic shock.

Emergency pharmacological treatment

Some units give glucocorticoids to patients with spinal injuries. The rationale is based on animal experiments which show stabilization of neural membranes, prevention of uncontrolled intracellular calcium influx, decrease of lysozyme enzyme effects, and decrease of swelling and inflammation, thus limiting the effects of the secondary injury to the spinal cord.

Two multicentre studies have shown that high doses of methylprednisolone, using a loading dose of 30mg/kg over 1h, followed by 5.4mg/kg/h over 23h, is beneficial for adult patients presenting within 8h of spinal cord injury. However, there has been mounting concerns about the methodology of data analysis of these studies and the occurrence of side effects such as gastric bleeding and infections. This has led to the use of intravenous steroids for the treatment of spinal cord injury to be considered a 'treatment option'. There is near universal agreement, however, that methylprednisolone has no influence on recovery of neurological deficits for patients with spinal nerve root injuries or ballistic trauma.

New promising drug-based therapeutic approaches include regenerative strategies to neutralize myelin-mediated neurite outgrowth inhibition, neuroprotective strategies to reduce apoptotic triggers, the targeting of cationic/glutamatergic toxicity, anti-inflammatory strategies, and the use of approaches to stabilize disrupted cell membranes. All of these substances, however, are experimental in nature and far from routine clinical administration.

Of a number of other measures, hypothermia has received a great deal of more recent attention due to its purported benefits in the treatment of some high-profile individuals, despite previous studies failing to show benefits. Formal repeat review through larger spine societies led to rejection of the stated benefits of hypothermia as treatment for acute spinal cord injury. Although there is some hope for advancements in our understanding of modulating acute spinal cord injury, current intervention results have been modest or unclear at best. Therefore pharmacological measures currently remain focused on blood pressure normalization, correction of anaemia, and hypoxia to maximize cord perfusion.

Primary treatment (Box 12.38.3)
Hyperextension of the cervical spine in adults should be avoided due to its risk of increasing spinal canal stenosis. In adults, infolding of the ligamentum flavum may increase canal occlusion by 19%.

In spinal cord injuries, timing of the removal of any ongoing mass effect acting upon the spinal cord may contribute to potential neurological recovery. Animal studies have shown a brief time window of 6–8h during which removal of spinal cord compression can lead to reversal of spinal cord injury. In clinical reality such time frames are highly unrealistic to achieve and commonly are incompatible with other vital patient resuscitation efforts. In the cervical spine, however, indirect spinal cord decompression with cervical traction can facilitate effective decompression of a compromised spinal cord.

Application of cervical traction with reduction of displacement can decompress the spinal cord by reducing bony canal encroachment and flattening the ligamentum flavum. Reversal of physiological cervical canal occlusion caused by compression using cranial traction improves canal clearance by 12% in intact human cadaveric specimens. Similarly, the effect of ligamentotaxis can be used to reduce spinal canal compromise caused by burst fractures of the cervical spine and facet dislocations.

Skeletal cervical traction is unsuitable for patients with distractive injury patterns or specific conditions such as fractures in ankylosing spondylitis. Relative contraindications to cervical traction also present in patients with skull fractures, in distractive cervical spine injuries such as occipitocervical dissociations, and in combative patients who cannot be pharmacologically sedated. Reduction of a dislocated cervical spine in unconscious or anesthetized patients without spinal cord injury may endanger the spinal cord, and should preferably be performed with spinal cord monitoring or after a disc herniation is excluded with neural imaging studies.

**Box 12.38.3 Management of cervical dislocation**

- **Acute closed reduction:**
  - **Indications:**
    - facet subluxations/dislocations
    - burst fractures with canal compression
  - **Contraindications:**
    - skull fracture or distractive trauma
    - ankylosing spinal disorder (relative)

- **Timing**
  - After initial resuscitation completed
  - Reduction prior to MRI scan in the awake, cooperative patient

- **Note:**
  - Urgent reduction in emergency department with fluoroscopy safe and effective
  - Preferred treatment for patients with cervical spine spinal cord injury
  - Disc disruption (22–50%) commonly associated with such injuries.

Skeletal cranial traction should be applied by means of suitable devices such as Gardner–Wells tongs or a halo ring (Figure 12.38.5). These devices should be MRI compatible in order not to impair neural imaging in spinal cord injury patients. In trauma patients use of cranial sling setups such as a head halter device is not desirable due to the risk of airway encroachment, aspiration, and limitations of weight that can be safely applied (Box 12.38.4).
Conventional Gardner–Wells tongs are usually not appropriate in paediatric patients, for whom a halo ring is usually more suitable. Success of a closed reduction effort is related to timing following injury, monitored muscle relaxation and analgesia and by providing a controlled setup with shoulder pulldown and fluoroscopy unit. Reduction by manipulation is generally discouraged. Serial neurological re-evaluations are strongly encouraged to minimize the risk of a secondary traction-induced neural deterioration being missed.

Halo-ring placement is more complicated than tong placement and requires at least one assistant or a dedicated halo positioning board (ACE-Fisher). Open-back halo rings have become increasingly popular due to greater ease of application and some improvement in patient comfort. Closed reduction of cervical dislocations is performed with the patient supine on a hard cushioned stretcher with both upper extremities pulled caudally by straps or surgical tape attached to the shoulders. We recommend intravenous analgesics, muscle relaxants, and nasal oxygen in responsive patients. Monitoring of vital signs such as automated blood pressure, pulse rate, and oxygen saturation is very helpful in titrating sedatives adequately. It is important that the patient remain awake in order to provide neurological feedback during the closed reduction.

Over-distraction should be avoided during cervical traction. We recommend starting with low initial weights of 2–5 kg (5–10 pounds), and checking a lateral radiograph for focal widening beyond 1.5mm between each cervical segment. Particular attention must be directed toward the occipital–cervical junction to assess for an undiagnosed cranio cervical dissociation. If there is no over-distraction, traction weight is increased in 2- to 5-kg increments accompanied by clinical and radiological assessment (Figure 12.38.6). Older patients and patients with injuries of the upper cervical spine usually require lower weights to achieve the desired reduction results. Skeletal cervical traction weights usually should not exceed half to two-thirds body weight or approximately 45kg. Changes in the pull-angle that place the neck in a more flexed position can help in disengaging locked facets. Flexion is generally needed to reduce flexion type injuries in order to unlock the facets and allow them to translate back to their native position; in-line traction cannot accomplish this. Possible causes of unsuccessful closed-reduction efforts are inadequate muscle relaxation, presence of a fracture dislocation with comminuted lateral masses, or dislocations of the cervicothoracic junction.

**Box 12.38.4 Technique of closed reduction with skull traction**

- Experienced personnel
- Fluoroscopy suite
- Analgesia/sedation/pulse oximetry
- Garner–Wells tongs
  - Betadine wash
  - 1% lignocaine
  - 1cm posterior to external auditory meatus
  - Finger breadth above ear
  - Use new stainless steel tongs if high weights anticipated
- Commence with 5kg (10 pounds) axial traction:
  - Increase in 5-kg (10-pound) increments every 5–10min with head in flexion trajectory
  - Neurological and radiological assessment at each step
  - Weights up to 65kg (140 pounds) may be required
- Cease if:
  - Neurological deficit—transfer to MRI/operating room
  - Mechanical block
  - >1cm distraction at injury level
- Reduction obtained
  - Decrease skeletal traction weight to <10kg (20 pounds)
  - Lower traction trajectory to horizontal angle
  - Place towel in interscapular region to maintain neck in extension
  - Patient placement in Rotorest-type bed (preferred).
compromise. This positioning is unsustainable over a longer period due to increase in intracranial pressure and progressive cardiopulmonary reduction with a reverse Trendelenburg position can be achieved with the head protected by circumferential sand sacks; however, similar upper cervical spine distraction injuries a reverse Trendelenburg position will likely cause further distraction. Postural of sandbags around the patient's head and securing it with tape placed across the head. For craniocervical dissociative injuries or particularly concerning due to their propensity for further displacement and subsequent neurological deterioration (see Figure 12.38.4). Temporary reduction under gentle compression can be attempted by application of a halo ring and halo vest or placement of sandbags around the patient’s head and securing it with tape placed across the head. For craniocervical dissociative injuries or similar upper cervical spine distraction injuries a reverse Trendelenburg position will likely cause further distraction. Postural reduction with a reverse Trendelenburg position can be achieved with the head protected by circumferential sand sacks; however, this positioning is unsustainable over a longer period due to increase in intracranial pressure and progressive cardiopulmonary compromise.

This 34-year-old male presented within 4h of a barefoot waterskiing accident with a neurologically complete C6 tetraplegia. There was no sacral sparing present; the patient also had an absent bulbocavernous reflex. Lateral plain cervical radiographs demonstrated a bilateral C6–7 facet dislocation. Along with intravenous methylprednisolone administration the patient underwent immediate closed reduction with cranial tong traction, without undergoing an MRI first. B) Following sequentially increasing cranial skeletal traction, the facets were found to be perched on lateral radiographs at 60 pounds traction. The patient noticed immediate recovery of trunk and leg sensation. C) The facet dislocation reduced with 80 pounds traction. No manipulation was used for the reduction sequence. Notice the overdistraction at the C6–7 interspace. D) Following reduction, the traction weight was reduced to 20 pounds in order to avoid potential damage from persistent overdistraction. The entire duration from initial presentation to complete reduction lasted for 45min. The patient was kept in a rotating bed. E) A postreduction MRI scan was obtained to exclude a persistent space-occupying lesion affecting the spinal cord. This T2-weighted MRI scan demonstrates anterior and posterior discoligamentous injuries to the C6–7 segment and confirms absence of any residual cord compression. Increased signal within the cord substance is reflective of cord haemorrhage. F) and G) The patient received anterior cervical discectomy and fusion at C6–7 48h after injury. Apart from unilateral C7 root pain the patient made a full neurologic recovery within 5 days of his injury. These lateral cervical flexion-extension radiographs demonstrate solid fusion in anatomic alignment. H) At 5 months postinjury the patient received an MRI scan to assess his unilateral C7 radiculopathy. A focal area of spinal cord injury probably representing gliosis was noted at the C6–7 interspace. There was no evidence of any residual cord or nerve root compromise.

Continued controversy surrounds the timing and technique of reduction of cervical spine dislocations. Reduction carries with it a theoretical risk of the intervertebral disc displacing into the spinal canal with potential for subsequent secondary neurological deterioration. Neural imaging, preferably in form of a MRI scan, has been suggested to rule out presence of a potentially cord compromising mass prior to embarking on closed reduction efforts (see Figure 12.38.3). However, the time taken for such imaging studies introduces a potentially critical delay in realigning and thereby indirectly decompressing the spinal cord. There is also a certain degree of risk in transferring a patient with an unstable dislocated spine from a trauma stretcher onto an imaging table.

The overwhelming majority of studies addressing this controversy of timing with a defined patient cohort have found immediate closed reduction to be a safe and effective intervention with successful reduction achieved in over 80% of patients and few, if any, cases of secondary neurological deterioration. While the incidence of visualized disc herniation on postreduction MRI has been described to range from 10–25% of patients, the vast majority of these lesions did not compromise the cord. Not surprisingly, the incidence of these disc herniations appears to be somewhat higher in patients with unilateral compared with bilateral facet dislocations. Based on these experiences the following protocol has become widely accepted: patients with neurological injury preferably receive emergent reduction using a formal skeletal traction sequence prior to receiving an MRI scan. In contrast, patients who are neurologically intact can be considered for prereduction MRI as long as this imaging modality is readily available. For cognitively impaired patients a best faith judgement call as to likelihood of presence of concurrent spinal cord injury can be used to guide the decision of emergent traction reduction. In general, however, the risks of leaving a patient with a dislocated spine appear to outweigh the risks associated with expeditiously performed closed skeletal reduction. Should a traumatic disc herniation with cord compression be identified on neuroimaging, anterior surgical decompression and fusion are recommended instead of pursuing closed reduction. Similarily, patients with failed attempts at closed reduction should be considered for emergent surgical reduction and stabilization.

For patients with unstable cervical spine injuries unsuitable for early surgical stabilization traction may be considered as a temporizing alternative. In order to minimize the risk of thromboembolic disease, decubital ulcers, and pulmonary deterioration during prolonged recumbence spinal injury patients who are unsuitable for early surgical stabilization are preferably placed in dedicated hospital beds, which maintain spinal alignment while allowing for some horizontal mobilization such as afforded by rotating trauma beds (ROTOREST).

Of several contraindications to the application of cranial traction, patients with distractive injuries to the cervical spine are particularly concerning due to their propensity for further displacement and subsequent neurological deterioration (see Figure 12.38.1). Temporary reduction under gentle compression can be attempted by application of a halo ring and halo vest or placement of sandbags around the patient’s head and securing it with tape placed across the head. For craniocervical dissociative injuries or similar upper cervical spine distraction injuries a reverse Trendelenburg position will likely cause further distraction. Postural reduction with a reverse Trendelenburg position can be achieved with the head protected by circumferential sand sacks; however, this positioning is unsustainable over a longer period due to increase in intracranial pressure and progressive cardiopulmonary compromise.
Emergency surgical intervention (Box 12.38.5)

Early surgical intervention is now felt to be generally safe and effective. It has consistently shown decreased pulmonary decompensation, and shortened intensive care and overall hospital stays.

Surgical intervention for patients with cervical spine injuries serves the purpose of decompressing the spinal cord, minimizing further trauma to the injured segment, realigning and stabilizing the spinal column, and mobilizing the patient expeditiously in order to maximize spinal cord recovery. Unlike cord injuries in the thoracic region, cervical spinal cord injuries offer a greater hope for recovery not only due to the propensity for root area functional return but also in terms of cord level recovery. Results of animal experiments and evolving clinical data support the concept of emergent surgical decompression and stabilization with current instrumentation techniques for cervical spine injuries with spinal cord compromise that are not reducible by closed means. A recent ongoing multicentre study also supported the hypothesis that patients with early surgical management have improved outcomes over those treated in a delayed fashion. There is also emerging evidence that surgery within 24h may reduce length of intensive care unit stay and reduce postinjury medical complications.

Box 12.38.5 Consideration of urgent surgery

- Increasing neurological deficit
- Displaced fracture in ankylosing spinal disorder
- Unsuccessful closed reduction
- Uncooperative, unconscious patient
- Residual compression seen on MRI in patient with neurological deficit.

The role of routine emergent surgical intervention in spinal cord injury remains controversial. Fortunately, most displaced cervical spine injuries can be reduced with closed means using the protocol described earlier. Surgical intervention may be beneficial if indirect decompression of the spinal cord is unsuccessful. Patients with worsening neurological status in the presence of an unstable spine may also be considered for expeditious surgical decompression and stabilization. Patients with conditions not amenable to indirect closed decompression, such as traumatic disc herniation, expanding epidural haematoma, depressed lamina fracture, or complex facet fracture dislocations, may similarly benefit from surgical decompression and stabilization (Figure 12.38.7). Patients with unusual distractive injuries, such as occipitocervical dissociations, or patients with acute injuries superimposed on pre-existent spine deformities, such as ankylosing spondylitis or diffuse idiopathic hyperostosis are also candidates for early surgical stabilization due to inability to maintain closed reduction in these patients.

Fig. 12.38.7
A) This 36-year-old male presented with a complete C5-level tetraplegia and high-grade open fractures of three of his extremities following a high-speed rollover accident. Lateral cervical trauma radiographs demonstrated interspinous C5–6 widening and loss of facet parallelism. The patient received intravenous methylprednisolone and aggressive volume resuscitation. B) An emergency MRI scan demonstrates a large traumatic disc herniation at the C5–6 interspace and disruption of the posterior ligamentous structures of the same level. C) Concomitant with surgical care of the open extremity fractures, an emergency anterior C5–6 discectomy with bone graft and instrumentation was carried out. The time from injury to surgical decompression was calculated to be 6h. The patient improved to an ASIA D level of function within 5 months of injury and currently is a household ambulator living independently.

From an anaesthetic point of view, atraumatic intubation and maintenance of normotension is desirable. In any emergent surgical undertaking, the potentially deleterious effects of a ‘second hit’ in form of hypotension on neural cell survival following initial resuscitation should be considered in preoperative planning. Spine instrumentation should be used with the goal to facilitate early mobilization and the minimum necessary bracing. In considering the various factors previously mentioned, there has been an international trend favouring anterior procedures with rigid locking instrumentation over posterior or combined surgeries for a majority of cervical spine injuries. Exceptions to this observation present in patients with ankylosing spinal disorders or patients with depressed lamina fractures.

Patients with VAI pose a different set of problems in management due to continued bleeding or intimal damage leading to thromboembolic events. Interventional angiography can allow for embolization or stenting of the lesion site as needed. Usually a period anticoagulant therapy is recommended for patients with emboli emanating from intimal vertebral artery injuries as long as spinal cord or unstable column injury has been excluded (Figure 12.38.4). Should the cervical spine injury require surgical care, it
is desirable to expedite such surgery so that a suitable anticoagulant therapy for the concurrent VAI can be started as soon as deemed safe. Delay of spine surgery in a patient who has already been started on anticoagulant treatment is usually far more complicated.

**Conclusions**

From the perspective of spinal cord pathophysiology most primary cellular damage has occurred by 6h or 8h, with cord necrosis present at 24h post-trauma. Current treatment mainly aims to reduce secondary zone spinal cord injury by minimizing cord swelling and maximizing cord perfusion. To date, the most meaningful emergency intervention for cord-injured patients consists of the earliest possible closed reduction of cervical spine dislocations or burst fractures by controlled skeletal traction. While there are few indications for emergency surgical decompression and fusion, the preponderance of recent publications favour early intervention over delayed surgery in patients who have been adequately resuscitated.

Current literature has redefined the role of high-dose methylprednisolone in the management of spinal cord injuries as optional. Novel neuroprotective therapies, including rho antagonists, minocycline, and sodium/glutamate blockers are the main pharmacological agents undergoing investigation.

Preferably, care of patients with spinal cord injury should be concentrated at specifically designated centres at the earliest possible time to allow for comprehensive treatment and to enhance our understanding of these measures by using standardized intervention measures.

**Further reading**

Upper cervical injuries

Summary points

- Upper cervical spine injuries should be considered in all blunt trauma patients.
- Critical review of plain radiographs or CT should carefully examine the alignment of the articulations between the occiput-C1 and C1-2 to determine if ligamentous injury is present.
- The initial stabilization of unstable upper cervical injuries usually should avoid the use of traction in favour of the halo vest.
- Definitive stabilization is based on fracture type and the status of the cranio-cervical ligaments.

Introduction

The upper cervical spine is a transitional zone between the skull and the mobile cervical spine. It protects the medulla oblongata, spinal cord, and vertebral arteries. Despite this important function, the upper cervical spine has a large range of motion with over 50% of rotational motion and 20% of anterior, posterior, and lateral bending, respectively. The anatomy is complex and has many anomalies that may be associated with important disease processes and surgical procedures.

This chapter will examine injuries of the occipital condyles, craniocervical articulation, the atlas, the atlantoaxial articulation, and finally the axis. Because these five different areas of injury are anatomically and kinematically related, injury to more than one of these locations occurs commonly.

Occipital condyle fractures

Occipital condyle fractures are increasingly being diagnosed with prevalent use of computed tomography (CT) for evaluation of blunt trauma patients following injury. The common mechanisms of injuries are from cranial trauma (impaction of the skull base on the cervical spine) or rapid head deceleration. Occipital condyle fractures should be suspected in all patients with high-energy closed head trauma, altered consciousness, lower cranial nerves paresis, upper cervical spine tenderness, retropharyngeal haematoma or swelling, and in those patients with atlantoaxial instability.

The occipital condyles are concave projections from the caudal surface of the occiput that lie in corresponding concavities of the lateral masses of the atlas. This creates a shallow articulation that is congruous along its entire extent. Normally, separation is less than 2mm between the occipital condyle and the atlantal lateral mass. The paired alar ligaments are primary stabilizers of the occipitoatlantal articulation and extend from the dens tip to tubercles on the inner surface of the occipital condyles. The other important stabilizer is the tectorial membrane which is the continuation of the posterior longitudinal ligament spanning from the posterior aspect of the dens to the basion at the anterior margin of foramen magnum.

Patient presentation

Occipital condyle fractures occur in 1–4% of patients with traumatic brain injury, and have an associated loss of consciousness in up to 65% of cases. In an awake patient, pain and tenderness can be elicited but this may not always be present. Range of motion may be reduced, although it is not recommended that this be checked until stability of the cervical spine is confirmed. Various neurological syndromes may occur, including the XII cranial nerve (hypoglossal) which exits on the anterior lateral aspect of the occipital.

Plain radiographs rarely visualize occipital condyle fractures although retropharyngeal swelling is commonly present. The diagnosis of occipital condyle fractures is usually by CT. The stability of these fractures is related to the status of the alar ligaments and therefore displacement between the occipital condyles and atlantal lateral masses should be carefully analyzed on sagittal and coronal CT reformations (Table 12.38.1). MRI has been shown to evaluate these structures in some instances but requires coronal and fat suppression techniques.

**Classification (Figure 12.39.1)**

There are three fracture types:

1. Type I fractures are comminuted fractures secondary to impactions of the occipital condyle on the lateral masses of C1. These are stable.
2. Type II are skull-base fractures where the fracture line involves a large amount of the occipital condyle.
3. Type III are traumatic avulsions from tensile forces of the alar ligament. These may be unstable.

**Classification of craniocervical instability (Figure 12.39.2)**

Craniocervical instability refers to injuries resulting in displacement or potential displacement between the occipital condyles and atlantal facet articulations, or injuries to the ligaments that stabilize these joints. Craniocervical instability is life threatening and until recently, survivors of dislocations were only reported in small case series. Most injuries are highly unstable. Spine clearance protocols using modern imaging including CT and, in some cases, magnetic resonance imaging (MRI) have led to an increasing recognition of these injuries. Neurological deficits occur in up to 40% of cases. Associated injuries are common.

Craniocervical instability refers to injuries resulting in displacement or potential displacement between the occipital condyles and atlantal facet articulations, or injuries to the ligaments that stabilize these joints. Craniocervical instability is life threatening and until recently, survivors of dislocations were only reported in small case series. Most injuries are highly unstable. Spine clearance protocols using modern imaging including CT and, in some cases, magnetic resonance imaging (MRI) have led to an increasing recognition of these injuries. Neurological deficits occur in up to 40% of cases. Associated injuries are common.

**Classification of craniocervical instability (Figure 12.39.2)**

1. Grade I normal CT but increased MRI signal in craniovertebral ligamentous structures or occipitoatlantal joints
2. Grade II, abnormal displacement of the occipitoatlantal articulation and abnormalities on MRI suggesting injury to AO joint, alar ligament or tectorial membrane.

A simple classification system is based on direction of displacement, Figure 12.39.2. Other systems take into account that there is a spectrum of injury severity as described below.

Diagnosis

Craniocervical injuries are often overlooked and have a delayed diagnosis in up to 40% of cases despite modern imaging. Also there is a strong association with delayed diagnosis and neurological deterioration. Joint asymmetry is abnormal and gapping of more 2mm indicates disruption of the craniocervical ligaments. Another sensitive measurement based on two plain radiographic findings is the Harris rule of 12. First the basilar dens interval (BDI) is less than 12mm. Secondly the distance from the basion to a line drawn along the posterior aspect of the axis (posterior axillary line) is less than 12mm. Distances exceeding 12mm on either of these indicates occipitoatlantal injury (Figures 12.39.3 and 12.39.4).

Treatment

Initial treatment

See Table 12.39.2. Once a craniocervical injury has been identified stabilization of the head and neck is essential. Reverse Trendelenburg may help to reduce distractive forces, however, traction is contraindicated. Application of a halo vest is recommended as a temporary stabilizing method.

Author’s recommendations are in bold face.

Reduction, if required, may be performed manually after halo application under fluoroscopic guidance. The halo vest should not be considered as adequate mobilization as displacement can occur and, in particular, distraction may be created at the craniocervical junction. Verification of alignment should be repeatedly performed while awaiting definitive treatment, especially after upright immobilization.

Definitive treatment

See Table 12.39.2

Outcomes

Most patients will achieve fusion, and unless there is a complete cord injury spinal cord function usually improves. Many patients die of associated injuries.

### Atlas fractures

Atlas fractures are relatively common cervical spine injuries accounting for up to 8% of all injuries. They are associated with other cervical injuries, especially of C2, in 30–75% of cases. Treatment of these other injuries will often complicate or take precedence over the treatment of the atlas injury. Neurological injuries are rare secondary to the large size of the spinal canal at this location and the tendency for fracture displacement to occur radially with resultant increase in the size of the spinal canal.

The anatomical characteristics of the atlas lead to unique fracture patterns (Table 12.39.3). Displacement of the ring structure of the atlas usually requires a minimum of two fractures, especially when injury results from axial loading secondary to abnormal hoop stresses. The only structurally important musculoligamentous structures attached to the atlas are the transverse ligament and longus colli muscles making avulsion injuries rare. The large thick lateral masses favour injury patterns which involve the smaller arches. From an anterior projection, lateral masses are wedge-shaped. Therefore axially directed forces are transferred laterally and tend to laterally displace the lateral masses. This is resisted at first by the anterior and posterior arches, then by the transverse ligament and finally by the alar ligaments.

</table>

The mechanisms of injury are usually due to axial loading forces from blows to the cranium and hyperextension. Lateral displacement of greater than 6.9mm of the C1 relative to C2 lateral masses on plain radiographs is consistent with complete transverse ligament disruption. As the lateral masses displace, the cranium settles downward on the cervical spine with concomitant rostral migration of the dens with possibility of brain stem compression (Figure 12.39.5).

![Click to view larger](image1.png)

Fig. 12.39.5 Thirty-two-year-old motorcyclist sustained C5 and C6 burst fracture with complete C5 quadriplegia. A comminuted atlas fracture was treated with a collar. Two months later he developed brain stem compression from cranial settling and medullary compression from the dens. Traction improved alignment and posterior occipitocervical fusion was performed complicated by vertebral artery injury of a traumatic pseudoaneurysm. A) Fracture of the left lateral mass of C2 and 5mm displacement of C1 over C2 is seen on coronal CT. B) Bilateral anterior arch fracture and fracture posterior to right lateral mass of atlas. This creates potential for separation of the two lateral masses. C) Significantly more displacement of the C1 lateral masses over C2.
Classification

See Figure 12.39.6.

Stable fractures

Type 1 isolated arch fractures are stable, as are many Type 2 and Type 3 fractures when the transverse ligament is intact. This includes bursting-type fractures with less than 6.9mm displacement and lateral mass fractures without significant lateral displacement.

Unstable fractures

Type 2 bursting fractures with greater than 6.9mm displacement are unstable and may have progressive displacement despite treatment. The transverse ligament injury may be either an avulsion fracture or midsubstance tear; the former having a better healing potential. The plough fracture with posterior C1–2 dislocation and the lateral mass fracture with occipitocervical dislocation are highly unstable.

Treatment of isolated atlas fractures

Stable injuries

Stable injuries can be immobilized in a collar for 6–12 weeks. Controversy exists regarding the stable bursting fractures as some authors recommend use of a halo vest. Serial upright radiographs including open mouth views should be critically analyzed for displacement during immobilization.

Unstable injuries

No consensus is available regarding the best treatment of the unstable burst-type fractures. Osteosynthesis is appealing, as reduction is theoretically obtained and no fusion is performed. Occipitocervical fusion is indicated for displaced fractures, excessive comminution, subluxation of the occipitocervical articulation, or when brain stem compression is present. In many of these cases, a C1 laminectomy is also performed (see Figure 12.39.5).

See Table 12.39.3 for details

Atlantoaxial instability

Atlantoaxial instability is rarely considered as a separate entity as it is frequently a component of other more obvious injuries (Table 12.39.4). The atlantoaxial articulation lacks inherent bony stability except for resistance against posterior translation. Ligamentous stability is provided by the transverse and alar ligaments. The C1–2 facet articulations are biconcave and have a wide range of motion and if imaged with the head turned (even minimally) may appear subluxated. The facet capsules are redundant to allow motion and, therefore, have little inherent strength. Injury to the alar and transverse ligaments or their bony attachments can result in displacement in anteroposterior, lateral, or axial (rotation) directions.

### Aetiology

The most common aetiology of atlantoaxial instability is displaced odontoid and atlas fractures. Subluxation of the C1–2 facets is often not considered and may explain the loss of range of motion after healing. More specific injuries, generally considered as atlantoaxial instability, are transverse ligament rupture and rotatory subluxation. Transverse ligament rupture occurs from tensile failure of the ligament or bony attachment to the atlas associated with anterior shear so that anterior subluxation occurs.

### Classification

Radiographically, atlantoaxial instability from transverse ligament rupture is present when the anterior atlantodens interval (ADI) exceeds 3mm in adults and 5mm in children. When the ADI exceeds 7–8mm then the secondary restraints, the alar ligaments, have been injured. Because of injury to the alar ligaments this condition may be associated with occipitocervical instability. Rarely, vertical atlantoaxial instability occurs as evidenced by diastasis greater than 2mm between the facets. The ligamentous injury may be a midsubstance tear or a bony avulsion from the atlas, the latter having a better prognosis for healing.

Rotatory subluxation occurs almost exclusively in children usually from low energy trauma or following infection (Grisel’s syndrome). The child presents with a ‘cock robin’ head position: the head rotated to one side and tilted to the other. Radiographs are difficult to assess due to the head rotation. The injuries are best evaluated with CT and three-dimensional reconstructions. There are four types:
1) Type I is rotatory subluxation around the dens with intact transverse ligament. This is difficult to differentiate from normal physiological motion.

2) Type II is associated with transverse ligament injury with ADI from 3–5mm.

3) Type III is similar to Type II with greater than 5mm ADI.

4) Type IV is the rare posterior dislocation where the atlantal arch is posterior to the dens (Figure 12.39.7).

**Treatment**

The treatment of patients having other associated injuries such as atlas and odontoid fractures will be described elsewhere in this chapter. Isolated injuries resulting in atlantoaxial instability are discussed as follows.

**Transverse ligament rupture**

The healing of isolated transverse ligament injury is dependent on the type of tear (midsubstance or bony avulsion), the severity of subluxation, and the patient age. Young children with smaller amounts of subluxation or patients who can be maintained in a reduced position and who have bony avulsion may be treated in a halo vest for 12 weeks. They are assessed by flexion-extension radiographs at the end of treatment for atlantoaxial stability. Adults and patients without bony avulsions are best treated by posterior C1–2 fusion with screw fixation.

**Rotatory subluxation**

Traumatic Type I rotatory subluxations do not have a significant ligament injury and are treated by reduction and immobilization. Usually the reduction can be achieved by muscle relaxation and analgesia or halter traction. Resistant cases may require tong traction. After reduction immobilization for a short time in a collar is prudent. If redisplacement occurs, an injury to the transverse ligament should be considered.

Types II and III are characterized by presumptive injury to the transverse ligament. Initial treatment is aimed at reduction which can be accomplished by halter, tong traction, or halo. In acute injuries, the best treatment remains unknown given the rarity of these conditions. Options include halo vest immobilization or C1–2 posterior fusion. In younger patients, halo vest immobilization can be attempted. In the author's experience, recurrent deformity is common (Figure 12.39.10). Posterior C1–2 fusion with rigid fixation is indicated for adult patients or those who fail halo vest immobilization. Type IV injuries are associated with ligamentous injury to the alar ligaments and therefore an occipitocervical fusion should be performed.

**Vertical distraction injuries**

Diastasis greater than 2mm between the atlantoaxial articulations indicates injury to the alar ligament and tectorial ligament creating an unstable craniocervical segment. These injuries should be treated with posterior occipitocervical fusion.

**Odontoid fractures**

Odontoid fractures are the most common fracture occurring in the axis and account for up to 25% of cervical injuries. Biomechanically, the odontoid process functions as an axis around which the atlas rotates. The relationship between C1 and C2 is maintained by the odontoid process, the atlas, and the transverse ligament. These combined structures prevent shear in the
anteroposterior and lateral directions. Loss of stability from odontoid fractures places the spinal cord at risk and is a frequent cause of fatality especially in the elderly.

Fig. 12.39.8
A 6-year-girl fell from a tree sustaining humerus fracture. Over the next 3 days she developed torticollis. A) One month later her lateral radiograph shows possible rotatory subluxation of the atlas. B) Three-dimensional CT reconstructions demonstrate Type II rotatory subluxation with an increased atlantodens interval. She was initially treated by reduction and halo vest but had recurrent subluxation 3 months later. Definitive treatment was a posterior C1–2 fusion.

Classification (Figure 12.39.9)

Type I
Type I injuries are an avulsion fracture at the dens tip from the attachment of the alar ligaments. Because the alar ligaments are primarily responsible for craniocervical stability, Type I fractures may be associated with atlanto-occipital instability. This is assessed by critical analysis of the occiput–C1 and C1–2 articulations and the Harris rule of 12.

Type II
Type II injuries occur through the waist of the odontoid and do not have fracture lines that involve the C1–2 articulations. Grauer has further classified Type II fractures to aid in determining treatment. Type IIA are non-displaced. Types IIB are displaced transverse or those with oblique fracture lines that are oriented anterior-superior to posterior-inferior. Type IIC are comminuted or have fracture lines that are oriented posterior-superior to anterior-inferior. Type IIB injuries are amenable to anterior screw fixation whereas Type IIC would be significantly more difficult to fixate as the fracture line runs parallel to the screw.

Type III
Type III are C2 vertebral body fractures at the odontoid base which extend into the atlantoaxial articulations. These involve cancellous bone and therefore have a good potential for osseous healing.

In addition to the fracture location, the status of the atlantoaxial articulations should be considered. Displacement may occur unilaterally or bilaterally in either anterior, lateral, or posterior direction. Rarely vertical distraction may be present. The presence of initial odontoid displacement and therefore accompanied by atlantoaxial subluxation is a major predictor of poor outcome and continued instability.

Fig. 12.39.9
Classification of odontoid fractures. (After Rechtine and Landsman.)

Treatment
The choice of treatment should be based on a synthesis of the best available evidence, patient factors and patient preference (Table 12.39.5). Two recent systematic reviews provide evidence based data that can guide treatment although they are limited by the poor quality nature of the studies included in their analysis.

The author's preferred treatment is in bold.

**Type I**

Type I injuries without atlanto-occipital instability are stable and can be treated with either simple immobilization or halo vest. Although only a few case reports are available satisfactory outcomes have been achieved with either treatment. Given the lower risk of brace management, the author recommends non-halo vest management. Type I fractures associated with occipitoccipital instability are treated by posterior occipitocervical fusion.

**Type II**

Type II fractures have a poorer prognosis secondary to associated instability, and small fracture surfaces involving mainly cortical bone. Up to 50% develop non-union. Risk factors include:

- Initial fracture displacement and angulation
- Displacement and angulation at the time of discharge
- Fracture gap greater than 1mm at discharge
- Patient age greater than 65.

Many treatments of Type II fractures are advocated but no consensus exists for the exact indications for non-operative treatment versus surgery or the best surgical approach. Overall healing rates using non-rigid braces, halo vests, odontoid screws and posterior fusion are 51.3%, 68.4%, 84%, and 93.4% respectively. Based on this information in younger patients, the best treatment is defined by the relative risk of healing as well as the shared decision making with the patients.

In patients who are at low risk of non-union, halo vest immobilization for 12 weeks is recommended. Healing in all Type II patients treated by halo vests is 68% but in this selected group would be expected to occur in up to 80% of patients. Younger patients who are at risk for non-union are surgical candidates. Surgical indications include displacement greater than 5mm, or angulation greater than 20 degrees, inability to control fracture site displacement in a halo vest, or persistent fracture gapping.

Both anterior and posterior techniques can be used to treat Type II dens fractures. Posterior C1–2 fixation with rigid fixation has a high fusion rate with low rate of adverse events (Figure 12.39.10). The disadvantage of this technique is the loss of atlantoaxial rotation. Anterior odontoid screw fixation is an alternative for fractures with favourable patterns (Grauer IIB) that can be reduced (Figure 12.39.11). Odontoid screws are an osteosynthesis technique where no fusion is performed thereby theoretically maintaining atlantoaxial motion. Only about 50% of normal atlantoaxial rotation is preserved after odontoid screw fixation. Complications such as implant failure, loss of reduction, and non-union are significantly higher with odontoid screws compared to posterior fusion.
Type II fractures in the elderly (Figure 12.39.10)

Odontoid fractures occur in a bimodal distribution with peaks in the third and eighth decade, these latter are usually the result of low-energy trauma and initially may appear minimally displaced. However, these fractures are associated with a high mortality similar to that seen following hip fractures. Causes of death include respiratory failure, cardiac arrest, and thromboembolic disease. Other complications include decreased respiratory function, dysphagia, fracture displacement despite rigid immobilization, multiple medical comorbidities, and fixation failure. Much of the morbidity may be related to the treatment. The halo vest is poorly tolerated in this age group with high rates of complications and death reported. Surgery in the elderly patient with an odontoid fracture is challenging due to poor bone stock, difficulty in achieving reduction, loss of fixation, pre-existing deformity making screw placement difficult, and medical comorbidities. The choice of an anterior or posterior technique remains controversial. Higher rates of implant failure secondary to screw cut out from the C2 body and higher mortality have been reported after odontoid screw fixation compared with posterior C1–2 fusion with screw fixation. However the mortality rate is probably lower with surgery than without surgery (10% versus 20%).

The author’s recommendation is that odontoid fractures in elderly patients are treated similarly to hip fractures. In healthy active patients with normal mentation, early surgery is indicated. In most cases this is achieved by a posterior C1–2 fusion with screw-based technique. Alternatively odontoid screw fixation can be performed in cases having adequate C2 bone stock and favourable fracture patterns. In patients with significant comorbidities, who are inactive, or have dementia, non-operative treatment in a collar is warranted. The goal is immediate immobilization and avoidance of complications. Such patients are not expected to heal their fracture but rarely will have long-term sequelae.

Type III

Type III fractures rarely require surgery. Surgical indications include instability despite non-operative treatment, and failure of fusion. Healing success with non-rigid immobilization and the halo vest are 92% and 94% respectively (see Table 12.39.5). Therefore this author recommends an attempt at immobilization in a cervicothoracic brace for Type III fractures. For failure of bracing, a posterior fusion is recommended.

Traumatic spondylolisthesis of the axis

Acute traumatic spondylolisthesis of the axis, also called hangman’s fracture, is caused by a fracture in the area of the pars interarticularis creating separation of the anterior and posterior aspects of the C2 vertebrae. Displacement increases the size of the spinal canal, accounting for the rare association of spinal cord injury expected in cases of severe displacement. Despite the injury’s ominous name, its overall prognosis is good with few patients requiring surgical treatment or having long-term disability.

The unique anatomy predisposes the axis to this injury. The axis is characterized by the dens or odontoid process which projects cranially from the C2 body around which the atlas rotates. The C2 body is connected to strong lateral masses by broad pedicles. The superior articular facet, which articulates with C1, is located on the cranial surface of the lateral mass. In all other vertebrae, the inferior facet is located directly under the superior facet but in the axis it is located posteriorly connected by a relatively small isthmus or pars interarticularis. This pars is a short tubular structure bounded by the C2 nerve root cranially and the vertebral artery caudally. Bending moments from hyperflexion or more commonly hyperextension are concentrated in the pars region between the inferior and superior facets, resulting in tensile fractures. In addition tensile forces are created in the C2–3 disc space which is commonly disrupted.

Classification

Several classification systems have been developed and all are based on displacement of the C2–3 disc and facet (Figure 12.39.12). These two factors should be considered when classifying and managing these injuries.
Classification of traumatic spondylolisthesis of the axis. (After Rechtine and Landsman.)

**Effendi**

Type I are non-displaced pars fractures. Type II have pars fractures with displacement or angulation of the C2–3 disc without facet subluxation. Several subtypes have been identified: those with only translations of the C2–3 disc and others with angulation, either in lordosis or kyphosis. Type III fractures are a pars fracture associated with dislocations of the C2–3 facet articulations with or without C2 body subluxations.

**Treatment**

Many treatment methods have been recommended for traumatic spondylolisthesis of the axis and they include collar immobilization, rigid immobilization with a halo vest, anterior plate fixation of C2–3, pars interarticularis screw repair, and posterior C1–C2–C3 or C2–3 fusion (Table 12.39.6). The choice of treatment is most commonly recommended based on the degree of stability of the fracture. Unfortunately no consensus exists to define stability.

The author's preferred treatment is in bold.

Almost all Type I and most Type II injuries heal with non-operative treatment although healing is often in a displaced position without clinical sequelae.

**Type I**

Immobilization of Type I fractures with a collar appears sufficient and healing is likely to occur in greater than 95% of cases.

**Type II**

There is no consensus regarding the treatment of Type II hangman's fractures. Successful non-rigid and rigid (halo vest) immobilization of Type II injuries have been reported. Multiple studies report greater than 95% healing with the halo vest. Anterior C2–3 interbody fusion with plate fixation and posterior fixation using either C2 pedicle screws or posterior C1–3, C2–3 instrumentation and fusion are also recommended. In the author's opinion, Type II hangman's fractures have an excellent prognosis and are best managed initially with a cervicothoracic brace. If this treatment option fails, a halo vest can be utilized. Surgical indications include failure to obtain or maintain fracture reduction, multiple injuries, and pseudoarthrosis. Either direct osteosynthesis with a C2 pedicle screw or anterior C2–3 fusion with plates and screws can be performed.
Type III

Type III injuries are unlikely to be reduced with traction and therefore open reduction and posterior C2-3 fusions is recommended. Stabilization of the pars fracture component can either be by transarticular C1-2 screws or by C2 pedicle screws.

C2 body fractures

Fractures of the C2 body exclusive of Type III odontoid fracture are heterogeneous in pattern although in general these injuries have a good prognosis. Fujimura classified these into four groups: extension avulsion from anterior-inferior corner of C2; low transverse fracture, comminuted body fracture, and sagittal plane fracture extending into the lateral mass.

Treatment

The majority of these injuries are stable, therefore non-operative treatment is appropriate. Non-rigid bracing is sufficient for non-displaced injuries (Figure 12.39.13). In displaced fractures, a halo vest should be considered. Surgery is indicated for failure of non-operative treatment, significant misalignment, and in spinal cord injured patients.

Conclusion

The stability of the upper cervical spine relies upon strong ligaments and unique osseous anatomy. Improved imaging with CT and MRI has enabled early diagnosis and an improved understanding of the pathophysiology of these complex injuries. Displacement of the occipitocervical or atlantoaxial articulations indicates disruption of key stabilizing structures and, in general, is an indication for surgery. More recent studies and systematic reviews have provided stronger medical evidence from which to base treatment decisions.

Further reading

Summary points

- The spine study group classification describes three families of fractures
- Clinical examination can exclude a cervical spine injury in a non-distracted conscious patient without pain and neurological deficit
- CT scan is the investigation of choice where fracture is suspected
- Pure ligamentous injuries are rare
- Priorities are immobilization and assessment, reduction of dislocations and then surgical decompression and stabilization.

Introduction

Approximately 150,000 spinal injuries present to the Emergency Rooms of the United States of America every year, and roughly, 7.5% of these present with a neurological injury. Improvements in on-site resuscitation and in the delivery of emergency medical care have significantly improved the survival of patients with spinal cord injuries. Multiple classification systems have been proposed to describe the different injury patterns, and the principles laid out by Allen and Ferguson, where injuries are classified according to the mechanism of failure, continue to be valid and widely accepted.

The interpretation of clinical findings and imaging studies to identify different injury patterns constitutes the first part of a successful treatment plan. Injury patterns reflect the biomechanics, the direction and severity of trauma, and the degree of instability of the cervical spine. The classification system adopted by the Spine Trauma Study Group describes three families of injuries according to the relationship of the vertebral bodies with one another: compression, distraction, and translation/rotation. Additionally, the presence of neurological injury and the integrity of the discoligamentous structures (intervertebral disc, anterior and posterior longitudinal ligaments, supra- and interspinous ligaments, facet joint capsules, and ligamentum flavum) constitute important indicators of the severity of the injury.

Initial evaluation and management (Box 12.40.1)

Management of cervical spine injuries starts at the site of the accident, following initial resuscitation guidelines described by the American College of Surgeons and includes protection of the spine and spinal cord during the primary survey. From the initial extrication and on-site management, it should be assumed that all trauma patients have a cervical spine injury until otherwise proven.

Patients with altered mental status or those presenting with distracting injuries are at a particular risk. Some authors have estimated that 3–25% of spinal cord injuries occur during extrication, acute resuscitation, and transport. For this reason, a rigid cervical orthosis must be used at all times, until the cervical spine has been formally cleared, which requires a reasonable certainty that the patient’s cervical spine is stable and free of significant injury. On the other hand, excessive use of a cervical orthosis can be associated with complications, including aspiration pneumonia, mandibular and occipital ulcers, limitations of respiratory function, and even possible increases in intra-cranial pressure. The protocol used in our institution for clearance of the cervical spine is described in Figure 12.40.1, and is further detailed as follows:

1. Alert and cooperative patients are cleared based on their symptoms and physical examination.
2. If the patient is symptomatic, imaging studies are requested.
traction. The purpose is two-fold: assessment is not reliable, as is the case of an obtunded or uncooperative patient, MRI is suggested prior to the onset of skeletal

be initiated on an emergent basis (Box 12.40.2). It is a matter of controversy and significant research efforts. Animal models support acute decompression of the spinal cord, and there is an increasing body of clinical data to support this as well. Nevertheless, there is a lack of prospective trials to support early or acute intervention. Finally, the role of high-dose steroids is controversial and will not be discussed in this chapter.

If the spine is dislocated, or if there is significant impingement of the spinal cord by bone fragments, reduction with traction should be initiated as soon as possible, and if reduction cannot be achieved, or if there are other compressing elements on the spinal cord, surgical decompression and stabilization is recommended as soon as the patient's condition has been optimized. The permanent use of a cervical orthosis is maintained until the patient is awake and cooperative.

An awake and alert patient is better able to cooperate with the clinical examination than an obtunded or unconscious patient. Also, the presence of other injuries, such as chest or abdominal trauma, or other musculoskeletal conditions, can distract from the symptoms of a cervical spine injury.

Clinical examination is sufficient to rule out a traumatic injury to the cervical spine in patients that present alert and awake, and have no complaints of neck pain or neurological deficit. The patient should be able to rotate the neck at least 45 degrees in each direction and have a normal neurological examination. This practice guideline is supported by Class I data, and has been extensively adopted in many institutions.

If the patient is awake and alert, and presents with neck pain or tenderness, there is a 2–6% chance of a significant cervical spine injury that would require specific treatment. In this scenario, clinical examination alone has a negative predictive value of 96.7%, but a sensitivity of only 66.7%. For this reason, radiographic examination is mandatory. Similarly, imaging studies are also mandatory for all patients who present with altered mental status, neurological injury, or other distracting injuries.

The basic trauma cervical spine series includes anteroposterior (AP) and lateral radiographic views, as well as an open-mouth odontoid view. Cervical spine radiographic series alone are associated with 15–17% false negatives. Because most of the misdiagnosed injuries are located in the occipitocervical or in the cervicothoracic junction, the addition of computed tomography (CT) scan increases the negative predictive value to 99.7% by improving the visualization of these areas. Despite the absence of osseous injury, instability can exist as a consequence of disruption of the spinal ligaments and other soft tissue components of the motion segment. These purely ligamentous injuries are of rare occurrence (0.1–0.7%). Flexion–extension radiographs can be safely used to rule out instability when the basic trauma cervical spine series is normal, only if the patient is awake and cooperative. Nevertheless, fluoroscopy and passive flexion–extension radiographs present risk of iatrogenic spinal cord injuries in obtunded and non-cooperative patients. Dynamic fluoroscopic examination is only able to detect surgically relevant injuries in 0.56% of patients not detected by CT scan. Finally, magnetic resonance imaging (MRI) is not recommended as a screening tool, but may provide important information when planning treatment. In a recent study, MRI showed abnormalities in 21.1% of patients with normal CT scan and normal neurological examination, nevertheless, any of these injuries required additional treatment.

Obtunded and uncooperative patients are temporarily radiographically cleared following review of cervical spine trauma series and CT. Particularly if the patient presents with high risk criteria (motor vehicle collision >35mph (56km), fall from heights >10 feet (3m), closed head injury, neurological deficits referable to the cervical spine, and pelvis/extremity fractures) cervical spine precautions including the use of a cervical collar and CT. May require other modalities to diagnose soft tissue injury.

Box 12.40.1 Diagnosis

- Must identify injury to treat correctly
- Allen and Ferguson classification
- Assume all trauma patients have a cervical injury initially
- CT scan negative predictive value 99.7%
- May require other modalities to diagnose soft tissue injury.

Skeletal traction and closed reduction

If the spine is dislocated, or if there is significant impingement of the spinal cord by bone fragments, reduction with traction should be initiated on an emergent basis (Box 12.40.2). This procedure is safe if the patient is awake and cooperative. If neurological assessment is not reliable, as is the case of an obtunded or uncooperative patient, MRI is suggested prior to the onset of skeletal...
traction. The purpose is two-fold:

1) To identify any disc or endplate material that could potentially be retropulsed into the spinal cord during reduction
2) To identify signal changes in the spinal cord suggestive of contusion or disruption.

Box 12.40.2 Traction

- Safe in conscious patient
- Otherwise need imaging first
- Increasing weights can be applied
- X-ray when weight increased.

Reduction is achieved by applying direct axial skeletal traction with skull tongs or a halo-ring. After an initial application of 5–10kg (10–20 pounds), incremental additions of 5kg (10 pounds) are applied until reduction is confirmed. The patient should be awake but lightly sedated so as to reduce muscle contractures and facilitate reduction. The head can also be positioned so as to facilitate the reduction, usually with some flexion of the neck. After 20–30min in traction, the neurological status of the patient is monitored, and a lateral cross-table radiograph is obtained. If the spine is not reduced, additional weights are added, a neurological examination is performed, and a lateral cervical radiograph is obtained, as previously described. Our typical protocol includes adding weights up to approximately one-third of the body weight, if needed. At higher weights, tongs may displace, and a halo ring is preferable. Another advantage of a halo ring is that it may facilitate better control of the position of the head and neck relative to the axis of traction. Traction is contraindicated in ankylosed spines, such as those suffering from ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis (DISH).

Non-contiguous cervical spine injuries occur in up to 15% of the cases and must be assessed before traction is initiated. Monitoring of plain films during reduction should also include evaluation for overdistraction at the level of injury. MRI is indicated to rule out the presence of disc material occupying the spinal canal if new or progressive neurological symptoms develop during the procedure.

Definitive management (Box 12.40.3)

Indications for surgery will depend on stability of the spine and the need for neural decompression. Understanding the principles and definitions of stability is fundamental for adequate management decisions. White and Panjabi have defined stability as the ‘ability of the spine under physiologic loads to maintain its pattern of displacement so that there is no initial or additional neurological deficit, no major deformity and no incapacitating pain’. In the event of a traumatic injury, it must be recognized if these properties have been lost. For this purpose, these authors have also provided a checklist to guide the clinician in the determination of spinal instability, which is based on both clinical and radiological parameters. Unfortunately, there are no means to accurately determine instability. Injuries of the cervical spine represent a continuum, and in some cases, there may only be a very tenuous difference between indicating unnecessary surgery and avoiding a disastrous omission. Careful review of the points in this checklist will help guide clinical decisions. If the criteria provide for a particular injury to be considered unstable, surgery is indicated for the purpose of recovering stability. This is usually designed to counteract the disruptive forces that have acted upon the spine.

Radiographic criteria are based on static and flexion-extension films (Figure 12.40.2). These criteria are based on biomechanical data obtained from serial sectioning of the ligamentous components of the spinal motion segment. These experiments showed that catastrophic failure could occur at physiological loads following sectioning of all posterior ligaments and one anterior ligament, or all anterior ligaments and one posterior structure. Furthermore, measurements made of intact motion segments showed a maximum displacement (measured between the posterior walls of adjacent vertebral bodies) of approximately 2.7mm and maximum angulation (measured between the inferior endplates of adjacent vertebrae) of 10.7mm. Only modest increases in displacement and angulation were observed before catastrophic failure occurred at physiological loads. The authors further suggested that to allow for variability in radiographic and measurement technique, measurements on a plain film lateral radiograph greater than 3.5mm of AP displacement or 11 degrees of angulation between adjacent vertebrae in excess of the angulation present in the levels above or below, imply potential instability in the clinical setting.

Fig. 12.40.2
Teardrop fracture of C4. Mid-saggital CT reconstruction (A), mid-sagittal T2-weighed MRI (B), and axial CT section through C4 (C) of an 18 year-old male who suffered an incomplete spinal cord injury following an accident while diving into shallow waters. An extensive signal change is observed in the spinal cord (B), as well as posterior soft-tissue disruption, reflecting damage through the posterior tension band. Characteristically, the posterior wall of the vertebral body of C4 is retropulsed, relative to C5 and C7. Also characteristic, in the axial CT image (C), are the coronal and sagittal fracture lines forming a ‘T’.
The number of cervical spine injuries without neurological impairment, or with incomplete spinal cord injuries arriving in emergency rooms, appears to be steadily increasing due to improved extrication and immobilization methods, on-site resuscitation, and improved trauma networks. The second most common reason for urgent surgery is in those patients with incomplete spinal cord injury with radiographic findings of ongoing spinal cord compression.

Box 12.40.3 Definitive management

- Establish whether spine is stable or unstable.

Common injury patterns (Box 12.40.4)

Three distinct categories of injury patterns are recognized based on the primary mechanism of injury: compression injuries, distraction injuries, and translation or rotation injuries.

Compression injuries

Simple compression injuries are defined by failure of the anterior column (anterior half of the vertebral body), with sparing of the posterior cortex of the vertebral body. They are usually not related to any form of neurological injury, and may be treated by the use of a cervical orthosis for 8–12 weeks. Early in the course of treatment, and as soon as the patient has developed reasonable comfort, flexion and extension films are taken to assess for patterns of instability. Additionally, serial radiographs are recommended to monitor for the potential development of progressive deformity (kyphosis).

Burst fractures are those where the structure of the vertebral body has failed under compressive loads, extending through the posterior cortex. As the energy dissipates into the vertebral body, bony fragments are ejected in all directions, including retropulsion of bone fragments into the spinal canal, frequently involving the spinal cord. Surgical decompression is indicated for ongoing spinal cord compression and is achieved by means of a corpectomy. Stability is achieved by the interposition of a strut graft and anterior locking plate.

Distraction injuries

Distraction injuries may occur with an extension or with a flexion moment. Hyperextension injuries are most likely to occur in a rigid, spondylotic spine. The energy is dissipated through anterior osteophytes, vertebral body, and into the posterior ligaments and facet joints. Hyperflexion injuries damage the posterior tension band, including the supra- and interspinous ligament complex, ligamentum flavum, and facet joint capsules, resulting in facet subluxation or perched facets. Varying degrees of damage to the posterior longitudinal ligament and posterior annulus also occur.

Ideally, reduction of uni- or bilateral perched facets should be obtained by skeletal traction with an awake and cooperative patient. If this fails, then surgical reduction and stabilization is considered. This can be achieved from either anterior or posterior approaches. We recommend a preoperative MRI in these cases. If there is evidence of extruded disc material, posterior to the body of the inferior vertebra, an anterior approach is recommended. This will allow for anterior decompression of the spinal canal, reduction of the dislocated facet joints and stabilization by means of an interbody graft and an anterior locking plate. If there is no evidence of disc extrusion, a posterior approach is preferred, as it provides for easier reduction of the dislocated facet joints. Although posterior fusion with lateral mass screw fixation provides superior biomechanical characteristics, progressive kyphosis is likely to develop, particularly in cases where the inter-vertebral disc has been disrupted.

Hyperextension injuries commonly occur in previously spondylotic spines with varying degrees of ankylosis (see Figure 12.40.2). These injuries are increasingly common in our increasingly active aging population. The spinal canal is commonly stenotic (Torg’s ratio <0.8), and the mechanism of hyperextension results in a pincer phenomenon, compressing on the spinal cord, between the postero-inferior margin of the superior vertebra, and the antero-superior border of the lamina from the inferior vertebra. This will result in spinal cord ischemia, frequently manifest as central cord syndrome. Furthermore, if the spine is extensively ankylosed, a significant lever arm is formed over the fracture site, resulting in a highly unstable injury pattern. An increased retropharyngeal soft tissue shadow, a widened disc space with high-signal intensity on T2-weighed MRI (otherwise degenerative disc spaces present with low-signal on T2), anterior osteophyte avulsion or avulsion injury of the anteroinferior vertebral body should be warning signs of this highly unstable injury.

These patients commonly present with persistent cord compression, which may or may not be accompanied by bone or disc-ligament injury. If the spine is stable and the neurological status is static or improving, initial non-surgical treatment with close follow-up is recommended. Delayed or late decompression may be required if symptom improvement is stagnant. Alternatively, some authors advocate early surgical decompression.

If surgery is indicated for spinal cord decompression and the spine is considered stable, then the approach will be determined by the alignment of the cervical spine, and the number of affected levels. A posterior approach with a laminoplasty is recommended for a lordotic spine with multiple levels of compression. If the spine is neutrally aligned or slightly kyphotic, and lordosis is obtainable on extension films, the same approach is accompanied by laminectomy and fusion with lateral mass screw fixation. Conversely, if the spine is focally kyphotic, and if the main compressive element is an anterior disc-osteophyte complex, then anterior surgical decompression and fusion is recommended.

Fractures through a previously ankylosed cervical spine require special attention. This may occur in ankylosing spondylitis, DISH...
(or Forestier’s disease), or in extensive multilevel cervical spondylosis. The injured motion segment is extensively ossified, including most, if not all of the spinal ligaments, facet joint capsules, and even the inter-vertebral disc (ankylosing spondylitis). As a consequence of this, the fracture through the ankylosed motion segment will compromise all of the stabilizing structures, rendering significant instability, similar to a long-bone fracture, with long lever arms acting on the injury and the spinal cord.

These injuries frequently occur in elderly, osteoporotic patients, and result from low-energy trauma. They are frequently missed, and initial diagnosis is based on a high level of clinical suspicion. Once recognized, these injuries must be immediately immobilized, and treated as highly unstable. The patient depicted in Figure 12.40.3A presented with neck pain after a fall at home, and the lateral film shows a fracture line through an extensively ankylosed spine secondary to DISH. He was immediately placed on cervical orthosis, and taken to MRI for further evaluation (Figure 12.40.3B), where the injury was recognized to be displaced. The patient was indicated for emergent surgical fixation. Skeletal traction must be avoided, as it only contributes to further displacement. Surgical treatment, in the form of a multisegment posterior instrumentation is recommended to provide stability to the long lever-arms and poor bone quality. Postoperative immobilization is mandatory, and should be maintained until the injury and fusion have completely healed.

### Box 12.40.4 Patterns of injury

- Compression fractures: brace
- Burst fractures: anterior fixation
- Facet subluxation/dislocation: traction and/or stabilization
- Ankylosis: very unstable fracture—may require decompression and/or stabilization
- Teardrop fracture: usually requires anterior/posterior fixation.

#### Fig. 12.40.3

Lateral radiograph (A) and sagittal T1-weighed MRI (b) of a 70-year-old male who consulted in the emergency room with complaints of neck pain after a fall in his patio. In (A), a non-displaced fracture line through an extensive area of ossification of the anterior longitudinal ligament is observed. Once the patient arrived to the MRI suite, the injury has displaced into extension (B).

#### Translation or rotation injuries

These injuries are recognized by the presence of translation of one vertebra relative to the adjacent one. Translation can occur in the sagittal plane, coronal plane, rotational plane, or combined. In bilateral facet dislocation, the mechanism is of pure anterior translation, whereas in unilateral facet fracture or dislocation, the mechanism is that of rotational translation with a fulcrum around the intact facet joint. Translation can occur as a product of disruption of disc-ligament structures or fracture of the articular process. There is a wide spectrum of injuries ranging from unilateral or bilateral dislocated facets, to the fracture-separation of the articular process, where the dissociation of the articular process (Figure 12.40.4) from the vertebral body and lamina affects the relationship to both the superior as well as to the inferior motion segments. In general, the more elements that are compromised with the injury, the easier it is to obtain closed reduction. Unilateral facet dislocation, are the most difficult injuries to reduce.
Facet fractures and dislocations are easily recognized on plain films. In unilateral dislocation, the AP film will reveal a loss of colinearity of the spinous processes at the level of the injury. The lateral films will add varying degrees of vertebral body translation. If this listhesis is 25% of the AP diameter of the vertebral body or less, unilateral facet joint fracture or dislocation is the rule (Figure 12.40.5), whereas with a listhesis of 50% or more is commonly associated with bilateral dislocations (Figure 12.40.4). Unilateral facet fractures or dislocations usually present with radiculopathy secondary to foraminal stenosis, whereas bilateral facet fractures or dislocations frequently present with spinal cord injury.

Management consists of emergent reduction with the use of skeletal traction, following the previously described protocol. Approximately 25–50% of patients will fail closed reduction and will require open reduction under general anesthesia. Once reduction is achieved, surgical stabilization is mandatory, and may be obtained by either anterior or posterior instrumented fusion. Prior to open reduction, we recommend an MRI to identify the presence of extruded disc material posterior to the body of the inferior vertebra. In such a case, an anterior approach is recommended. This will allow for anterior decompression of the spinal canal, reduction of the dislocated facet joints, and stabilization by means of an interbody graft and an anterior locking plate. If there is no evidence of disc extrusion, a posterior approach is preferred, as it provides for easier reduction of the dislocated facet joints. Posterior instrumentation with lateral mass screw fixation provides superior biomechanical characteristics when compared to anterior plate fixation and interbody graft. Nevertheless, in cases where the intervertebral disc has been disrupted, progressive kyphosis may develop. Furthermore, posterior fusion requires a more traumatic dissection and prone positioning, both of which are avoided in anterior fixation. Anterior fixation provides direct decompression, has similarly high fusion rates, and compares favorably in the restoration and maintenance of segmental lordosis. Nevertheless, if a fracture of the superior endplate of the vertebral body is associated with the translational deformity, anterior fixation alone is insufficient with early mechanical failure in two-thirds of the
cases. In this situation, combined anterior and posterior fixation is recommended, similarly to injuries with significant posterior ligament complex disruption, such as the case of teardrop fracture-dislocations.

The teardrop fracture is an injury pattern that results from axial loading and forced flexion of the cervical spine (Figure 12.40.2). This is common in injuries occurring when diving in shallow waters. It has also been termed burst fracture dislocation. A characteristic T-shaped fracture through the superior endplate of the vertebral body (Figure 12.40.2A) is associated with varying degrees of facet and articular process fracture as well as severe disc-ligament injury, affecting the facet joints, intervertebral disc, anterior and posterior longitudinal ligaments, and the ligamentum flavum (Figure 12.40.2B). The superior vertebra is not only axially loaded against the inferior vertebra, but also rotates over its axis, thus indenting its anteroinferior margin into the superior endplate of the inferior vertebra. This further displaces the posterior aspect of the vertebral body into the spinal canal, through a sagittal fracture line. The key feature is the displacement of the posterior vertebral body fragments into the spinal canal, both relative to the superior, as well as the inferior adjacent vertebral bodies. This finding must be recognized because it reflects a severe degree of discoligamentous complex injury, which results in continuous cord compression, as well as severe instability. Complete spinal cord injury is frequently present, and the recommended treatment includes decompression of the spinal canal through a corpectomy, and reconstruction with combined anterior and posterior instrumentation. Reduction by traction is rarely indicated, as the degree of disruption of the discoligamentous complex easily leads to overdistraction of the spinal canal and spinal cord.

Further reading

Whiplash-associated disorders

Summary points

- Whiplash costs UK economy approximately £3.64 billion per year
- Most occur after rear end vehicle collision
- Patients present with neck pain and stiffness, occipital headache, thoracolumbar back pain and upper limb pain and parasthesia
- Over 66% make a full recovery but 2% will be permanently disabled
- The outcome can be predicted in 70% after three months.

Definition

‘Whiplash’ is a collective diagnosis of the symptoms that follow indirect injury to the neck, spine, and adjacent structures. The term derives from one of a number of mechanisms of injury. The Quebec Task Force (QTF) on Whiplash-Associated Disorders (WAD) defined it as an acceleration–deceleration mechanism of energy transfer to the neck. The impact may result in bony or soft tissue injuries (whiplash injury), which in turn may lead to a variety of clinical manifestations (WAD).

Incidence (Box 12.41.1)

Since the introduction of compulsory seatbelts for the occupants of motor vehicles, the incidence of WAD has risen from 7.7% to 55%. Five per cent of the United Kingdom population have been involved in a rear-end collision. It is estimated that there are 300,000 claims for whiplash in the United Kingdom every year, losing 110 million man days at a cost of £3 billion to the United Kingdom economy, which includes NHS costs, social security costs, damage to property, and lost productivity. Of all personal injury claims, whiplash now accounts for 90% of the volume and 70% of the cost.

The incidence of acute whiplash injury is not known in many other countries, but a group of Norwegian neurologists reported that its incidence was much lower in Lithuania than in the United Kingdom or United States of America and attributed this to cultural differences. They demonstrated little difference in neck pain in car occupants involved in motor vehicle collisions than age- and gender-matched control subjects. Similar results were observed when controls were members of the same family. The difficulty with these studies was that they recorded rear-end collisions and because only 15% of patients involved in rear-end collision ever develop neck pain they were statistically underpowered. This was further compounded by the high prevalence of constitutional neck pain in Lithuania. This is 20% compared with 5% in Bristol and 7% in Belfast.

Box 12.41.1 Incidence

- 5% of the population have experienced WAD
- Annual cost £3 billion
- 90% of personal injury claims.

Biomechanics

The mechanism most commonly associated with whiplash injury is that of a stationary vehicle impacted from the rear, often with little or no vehicular damage. The speed of impact is important. Whiplash injury is unlikely to occur below 8–10km/h (5–7mph). The direction of impact also has an influence. In vehicles of a similar mass, front or side impacts require a higher velocity for tissue damage to occur compared with a rear impact.

Chronologically there are five stages during the transmission of force:

- Ramping: T1 vertebra moves supercateriorily immediately on the impact, producing an extension moment
- S-phase: the extension moment results in hyperextension of the lower cervical spine with compensatory flexion of the upper cervical spine
- Transition: where the upper cervical spine starts to extend
- Hyperextension: the whole cervical spine goes to hyperextension
- Flexion: forward acceleration of the head pushes the cervical spine into flexion.

The lower cervical spine exceeds the physiological limits of hyperextension at lower acceleration than upper cervical spine. Peak cervical spine flexion has not been shown to exceed physiological limits suggesting that the lower, and to a lesser degree, the
upper cervical spine are at risk for extension injury during rear impact probably in the s-phase, whereas pure flexion is a more unlikely mechanism of injury.

**Pathology (Box 12.41.2)**

The anatomical structures at risk are: intervertebral discs, paraspinal muscles, ligaments, and zygapophyseal joints.

*Intervertebral disc*: the high prevalence of disc disease in the asymptomatic population makes it difficult to ascertain the incidence of new disc injury in patients with WAD by magnetic resonance imaging (MRI) scan. A cadaveric study showed that shear forces of as little as 3.5g demonstrate excessive strain of the fibres of the annulus fibrosus, specifically at C5/6 level. Symptomatic cervical degenerative disc disease in patients suffering from WAD is both more common and occurs at a younger age compared to control population.

*Paraspinal muscles*: on MRI scans, the neck muscles of patients with WAD have significantly larger amounts of fatty infiltrate in all the cervical extensors than healthy control subjects particularly in the rectus capitis minor, rectus capitis major, and multifidi at the level of C3. These findings are independent of age, compensation status, body mass index (BMI), and duration of symptoms. It is, however, unclear whether the patterns of fatty infiltration are the result of local structural damage, nerve injury, or generalized disuse.

*Ligaments and membranes*: the findings of cadaveric studies are not truly applicable to underlying ligamentous involvement of WAD, as the latter has a different mechanism of injury with less energy transfer involved. High signal intensity is observed in alar ligament, transverse ligament and posterior atlanto-occipital membrane in individuals with chronic symptoms of WAD.

*Zygapophyseal joints*: if the whiplash mechanism is severe enough to injure the joint capsule, overstretching of the capsule of the facet is a potential cause of persistent neck pain. These data are reinforced by the therapeutic response of the zygapophyseal joints to intra-articular local anaesthetic blocks and radiofrequency neurotomy.

**Classification**

There are many published scoring systems for whiplash. Classifications commonly in use are the Gargan and Bannister which grades severity of symptoms (Table 12.41.1) and the QTF classification that also includes physical signs (Table 12.41.2).

<table>
<thead>
<tr>
<th>Table 12.41.1 Gargan and Bannister grading (1990)</th>

</tr>
</tbody>
</table>

The Gargan and Bannister grade is significantly associated with physical and psychological outcome measures and can be used as a self-administered questionnaire as it does not require physical assessment. It is a useful instrument for the evaluation of patients and an accurate method of classifying outcome and has a perfect interobserver (Cohen’s kappa coefficient = 0.82) and significant intra-observer reliability (intraclass correlation coefficient = 0.79).

**Box 12.41.2 Pathology**

- Speed of impact important
- 5 stages of transmission
- Injury can occur to disc, muscles, ligaments, and zygapophyseal joints.
The authors of the QTF classification concede it that was a consensus that required further work and it has neither been validated nor found particularly useful.

## Clinical evaluation

### History

Most patients will suffer their symptoms within 2 days, but they may be delayed by 12h or so. In up to 35% of patients the symptoms can be significantly delayed. The symptoms of whiplash are varied in their distribution and incidence (Table 12.4). In a prospective study of 504 patients from the south west of England who suffered a rear-end collision, 78% described neck pain lasting more than 1 week; 52% were still suffering neck pain at 1 year.

The incidence of depressive symptoms after whiplash injury is common. In Saskatchewan, 42% of patients with normal mental health before whiplash injury who had ongoing compensation claims or medical treatment demonstrated depressive symptoms within 6 weeks of their accident. The symptoms of depression occurred early in the disorder suggesting that depression is significant component of whiplash injury.

Although headaches are a generally accepted symptom of whiplash, the origin is less clear. The strongest predictor of headache following whiplash injury is pre-existing headache. Acute headaches after rear-end collisions may be stress related. There is a strong association between occipital headache and pain in the neck and trapezi with continuing symptoms 15 years after whiplash.

### Physical examination

The symptoms of whiplash are usually disproportionate to the physical signs. The most common sign is a reduced range of movement in a tender neck. The most common neurological deficit is decreased sensation. Significant irritation of the brachial plexus can be manifested by paraesthesia, coldness, discoloration, and hyperhidrosis of the upper limb. A positive Tinel’s sign over the scalene muscles, supraclavicular fossa, cubital tunnel or carpal tunnel may be found. These signs were associated with an unfavourable prognosis exactly as were the distribution of symptoms described by Squires et al. (1996).

As some 40% of patients with irritation of the brachial plexus had a positive Tinel’s sign in distal peripheral nerves, this suggests that proximal stretching may render the distal nerves more susceptible to subsequent compression. Alpar et al. demonstrated that carpal tunnel release in such cases relieved pain over the entire upper limb and reduced levels of substance P further reinforcing the concept of double-crush after whiplash. Paraesthesia occurs in 13–62% of cases and weakness in 18% (Table 12.41.4).

Investigations (Box 12.41.3)

There is no objective diagnostic test for WAD. Vertebral fractures are very rare. Therefore, in the absence of high-energy impact, the need for a radiograph is questionable; however, the association of more severe symptoms after whiplash in those with radiological changes in the neck has been recognized for decades.

There is no correlation between electromyography (EMG) and patients’ symptomatology, computed tomography (CT), and MRI findings.

The role for MRI is in patients with upper limb symptoms and signs. The difficulty with indiscriminate use of MRI is the high proportion of abnormalities unrelated to symptoms even in younger patients. Some clinicians have used MRI scans and clinical signs to target surgery. The fatty infiltrate in the cervical extensor muscles is specific in its presence and location in WAD patients and is independent of age, compensation status, BMI, and duration of symptoms.

Box 12.41.3 Investigations

Imaging and nerve studies of little use.

As we understand more about the organic pathology of WAD, imaging studies may become increasingly useful.

Treatment (Box 12.41.4)

A variety of methods are advocated for the treatment of WAD, many of them controversial or not supported by the literature. The following text summarizes the available level 1 evidence.

- **Collar and immobilization**: soft collar is widely used in the immediate phase, but there is little evidence to support it. In fact, its use should be discouraged as it slows down the recovery rate. Physiotherapy and mobilization is probably the best management. This reduces the pain and increases the range of movement 4 and 8 weeks after commencement of the treatment when compared with soft collar immobilization.
- **Education**: educational pamphlets do not help patients both in short (2 weeks) or long term (3 months). However, once it is delivered in the form of a video the reduction in pain and the increase in the cervical range of movement are significantly better in 1, 3, and 6 months’ follow-up.
- **Self-mobilization exercises**: active cervical exercises in the range limited by pain decrease whiplash symptoms 6 weeks following injury and maintain the improvement for a year. It is best commenced within 4 days.
- **Physiotherapy**: ice, active, passive, strengthening, and isometric exercises reduce the pain 6 weeks and 3 months postinjury. Maitland’s manipulation protocol and McKenzie’s principles are helpful if commenced within 4 days of injury. Magnetic field applied twice a day for 2 weeks combined with non-steroidal anti-inflammatory drugs (NSAIDs) is more effective than medications alone.
Little evidence for collar
Education
Exercises useful
Physiotherapy useful
Early steroids reduce symptoms
Botulinum little evidence
Radiofrequency neurotomy may help.

- **Self-mobilization exercises vs. physiotherapy:** there is controversy which is best
- **Chiropractic manipulation:** manipulation (a combination of high-velocity-low-amplitude thrust, muscle energy, and soft tissue techniques) in the acute phase is more effective than a single 30-mg intramuscular dose of ketorolac (NSAID) for immediate (1h) pain relief. Phasic exercises added to chiropractic manipulation increases the effectiveness of the delivered treatment on chronic WAD
- **Laser acupuncture:** laser acupuncture fails to improve the range of movement or reduce the pain when used in acute phase
- **NSAIDs:** 20mg of tenoxicam (a non-steroidal with a long duration of action) per day administered for 2 weeks, when started in the first 72h after accident effectively reduces the pain and increases the cervical range of motion at day 15. The observed difference in cervical range of motion was large enough to justify a clinically significant difference
- **Melatonin:** oral melatonin 5mg per day 5h prior to dim light melatonin onset does not reduce the pain, improve the sleep pattern or the quality of life (based on SF-36) in the chronic phase
- **Steroids:** intravenous methylprednisolone (30mg/kg in the first hour and 5.4mg/kg/h for 23h) started in the first 8h of the injury increases the short-term pain relief and reduces the long term sick leave
  - Injection of 1mL (5.7mg) of betamethasone into the zygapophyseal joints is not more beneficial than 1mL of bupivacaine 0.5% (local anaesthetic). The anatomical location of the painful joint should be confirmed on two separate occasions by pain relief following local anaesthetic injection. One should be aware that more than half of the patients report recurrence of pain after a week
- **Botulinum A toxin:** two different doses of botulinum toxin A has been tried in chronic WAD: 100 units. The injection sites are four to five ‘most tender’ spots in splenius capitis, rectus capitis, semispinalis capitis, and trapezius. In all three of these randomized controlled trials an improvement was observed in both the intervention and the control groups. None of these studies showed a significant difference between the two groups at the end of the trial (at 4–24 weeks). This might be due to the low number of patients in each arm
- **Percutaneous radiofrequency neurotomy:** percutaneous radiofrequency neurotomy of C3/4 to C6/7 facet joint capsule gives medium-term pain relief. The most commonly involved joint is usually the C5/6 facet joint. The median time for 50% of the pain to return is almost nine months
- **Cervical fusion:** there is no evidence to support surgical intervention for axial neck pain following suspected upper cervical ligamentous injury in WAD. In the case of radiculopathy, the evidence is not different from what is available for spondylosis and radiculopathy in general.

The following treatments are ineffective:

- Halter traction
- Kinaesthetic sensibility and coordination
- Cognitive behavioural treatment
- Pulsed electromagnetic therapy and transcutaneous electrical nerve stimulation
- Ultra-reiz current.

**Prevention**

The biomechanical principles to reduce whiplash injury are as follows:

- Decrease occupant acceleration
- Minimize relative spine movement
- Minimize forward rebound.

In the 1970s Saab introduced the fixed head restraint followed shortly after by Volvo. However, most head restraints are adjustable and 93% are poorly positioned.

Head restraints have been required by law since the 1970s, but to be effective they must be positioned behind and as close to the occupant’s head as possible. The major problem is that adjustable head restraints are less effective than a fixed version because they are often left in the down position, thus improperly positioned for many people.

Head restraints can and do reduce the incidence of whiplash injuries, especially among females.
Outcome (Box 12.4.1.5)

The established injury outcome of WAD is confounded by a diffuse literature that varies in its point of recruitment of patients. Only 54% of patients presenting in neurosurgical practice in Tennessee recovered, compared to 73% attending accident and emergency departments in the United Kingdom in the 1980, and 88% of patients filling insurance claims in Quebec, Canada.

Applying the Gargan and Bannister classification to series recruited from Accident and Emergency Departments in the United Kingdom and Sweden, 55% made a complete recovery, 22% recorded nuisance levels of discomfort, 16% had intrusive symptoms, and 7% were disabled.

Rate of recovery

The most comprehensive cohort study is a 4-year prospective review carried out for the Transport Research Laboratory in which symptoms reached a plateau at 2–3 years from injury. However the majority of patients reach their final state within 3 months.

Factors associated with outcome

Using univariate analysis, the literature identifies worse outcomes with the pre-accident variables of female gender, advancing age, known cervical spondylosis, previous whiplash injury, pre-existing neck pain, pre-existing back pain, excessive use of primary care services, and a history of anxiety/depression. Accident variables associated with worse outcome include rear end impact, lack of awareness of the impending impact, and position in the front of the vehicle. Response variables associated with worse outcome include onset of symptoms in less than 12h, pain radiating from the neck to other sites, and abnormal neurological signs.

Box 12.4.1.5 Recovery

- 50–75% recover
- Most of recovery within 3 months
- Many factors affect outcome, e.g. cervical spondylosis
- Psychological effects important.

Behavioural response to whiplash injury

From the mid-twentieth century, a psychoneurotic response was observed in patients presenting with whiplash injuries (52–85%). The behavioural response to whiplash is often disproportionate to the trauma sustained and the physical signs demonstrated. As whiplash injuries present more frequently in the medicolegal than clinical context there are inevitable suspicions that symptoms may be exaggerated for gain.

There are two conflicting theories about this psychological response to WAD.

The somatopsychic response

Cognitive deficits have been found in patients after whiplash injury that could not be explained by their psychological history before the accident. Distress is at similar levels in all patients at a week but significantly higher after 2 years in those who have developed chronic symptoms. The pain caused by the whiplash injury probably precipitates the syndrome that follows.

The biopsychosocial model

Cultural influence

An Australian occupational health physician, reported on patients with ‘late whiplash’ syndrome reviewed in the course of his professional duties. He compared 300 patients from South Australia with 20 from Singapore. Whilst the former reported high levels of disability, the only ones to complain in Singapore were emigrant Australians. The data were anecdotal but supported by further work from New Zealand. Another study in 1986 compared the incidence of whiplash injuries in Victoria, Australia and New Zealand. The population sizes and numbers of cars were comparable but in Victoria there were 3.5 times the number of rear-end collisions, ten times as many claims for compensation, and five times as many took more than 2 months off work. In 1987, legislation required that all whiplash injuries be reported to the police and that victims pay the first 317 Australian dollars of medical expenses. Although this is highly suggestive of social manipulation, 10% of Australians reported continuing symptoms after the 1987 legislation.

The effect of previous psychological problems

A biosocial model has been proposed based on symptom expectation, amplification and attribution, and prior knowledge of expected symptoms. Adverse social circumstances and a vulnerable personality count as risk factors for poor psychological outcome but not the physical outcome. Patients who were frequent attenders with their general practitioners before the injury have a worse outcome.
The effect of WAD on the patient’s psychological state

The initial reaction to RTA can be of anger, emotional shock, and frightened behaviour. These are usually temporary and settle with time. However, 1 year after the accident almost a third of the patients still show a form of psychological disorder, if looked for carefully by the employment of standard mental health diagnostic criteria, such as the diagnostic and statistical manual of mental disorders—fourth edition (DSM–IV).

The most common are as follows:

- **Travel phobia:** kinesiophobia, or fear of travel and movement, is more common in the victims of WAD (8% of patients) when compared to the patients with minor head injury. This phobia is associated with longer duration of neck symptoms.
- **Post-traumatic stress disorder (PTSD):** this includes avoidance, re-experiencing, and hyperarousal. Buitenhuis et al. showed that hyperarousal symptoms at 3 weeks following the accident was related to more severe WAD symptoms both at 6 and 12 months. Therefore this can be helpful as a outcome assessment tool at the time of initial evaluation.
- **General anxiety:** there is a strong correlation between chronic pain and anxiety. This is even more severe in males following WAD even though the coping strategies to counteract the effect of pain are virtually the same in both genders.
- **Depression:** more than 40% of patients with no history of previous mental health problems develop depression in the first 6 weeks from the injury and another 18% develop depression at between 6 weeks to a year following the accident. Of these 60% usually settle, but 40% become recurrent or persistent. Early depressive symptoms are also a risk factor for developing widespread pain and, therefore, anxiety.

Physical and psychological aspects of WAD are not separate. They interact and therefore sometimes make it difficult to attribute the proportion of disability following relatively mild injury. ‘Apparently disproportionate disability’ has been coined as a term for those patients with exaggerated symptoms and unexpectedly slow recovery. This is a subconscious psychosocial process. It is a useful term as it combines different physical, psychological, and social aspects of the injury.

Risk factors for poor psychosocial outcome can be divided to five distinct groups:

1. Pre-accident characteristics such as poor social circumstances and previous psychological problems
2. Accident trauma causing disproportionate distress and phobia
3. Patients erroneous beliefs on the chronicity and severity of the problem
4. Further postaccident factors such as a second accident, bereavement and frustrating legal proceedings
5. Quality of care. Inconsistent and ambiguous medical advice.

On the basis of these, appropriate medical care involves attention on psychiatric as well as chronic pain management. Patient education plays an important role. Prerecorded audiovisual material reduces the amount of pain and therefore anxiety 1, 3, and 6 months after injury.

Thoracic fractures

Summary points

- Thoracic fractures are associated with severe trauma in young patients
- Multiple injuries are common
- Early fixation of unstable injuries is recommended to prevent neurological deterioration
- Almost all surgery best carried out posteriorly
- Long implants can be used
- Anterior reconstruction may be required where the anterior column is deficient.

Incidence (Box 12.42.1)

Thoracic spine fractures (T1–T10) are relatively less common than thoracolumbar and lumbar fractures (T11–S1) and very little is published specifically on the subject.

There are two peaks of incidence. Firstly in young men associated with high-energy injuries with a second peak in elderly women with low-energy fragility fractures.

The annual incidence of thoracic spine fracture is approximately 21 per 100 000 population. In approximately 40% of cases there are other associated injuries with an overall mortality rate of about 4%. The reason for the high rate of associated injuries is because the thoracic spine is splinted by the ribs, and hence much greater forces are required to cause a fracture in the younger age group. In about 16% of cases a spinal cord injury will also be present.

Mechanism of injury

Most thoracic fractures are simple wedge fractures. They are particularly common in elderly women and are associated with osteoporosis. These fractures are generally caused by low-energy or minimal trauma and are stable.

Box 12.42.1 Incidence

- Less common than other spine fractures
- 40% associated injuries
- Mortality 4%.

Other patterns of fracture are generally caused by high-velocity or high-energy injuries, and these are more common in young males. However, pre-existing pathology such as ankylosing spondylitis may predispose to other patterns of fracture without severe trauma.

Axial compression is the most common mechanism of injury. Facet dislocation is rare in the mid-thoracic spine. This is probably because of the orientation of the facet joints and the relative stiffness of the thoracic spine compared with the spine at the thoracolumbar junction. Many of these fractures are the result of seatbelt injuries. Thoracic spine injuries are often associated with a lower cervical spine fracture. Injuries in the lower cervical spine are often overlooked, and a high index of suspicion is required.

Aetiology of fracture

Motor vehicle accidents are the most common cause of fracture by either direct injury, such as ejection from a vehicle, or indirect injury, such as a major deceleration injury. In the United States of America gunshot injury is a common cause of thoracic spine fracture and spinal cord injury, but this is much less common in Europe (Table 12.42.1).

Spinal cord injury

For a number of reasons the spinal cord is relatively sensitive to injury in the thoracic spine:

1) The blood supply to the thoracic spinal cord is relatively poor
2) The thoracic spinal canal is relatively small compared with the size of the spinal cord—this is most marked in the mid-thoracic spine
3) When fracture of the thoracic spine occurs, it is often due to very high forces. Translation or torsional injuries are more common, and these injuries are most commonly associated with spinal cord injury. Chest injury is also common after these fractures and occurs in about 24% of these patients. Chest injuries are not always apparent immediately after the injury, and in some cases a high index of suspicion is required to make the diagnosis.

In those with a spinal cord injury approximately 13% will not have a fracture of the bony elements. These fractures may be caused by stretching of the spinal cord, or vascular injury to the cord itself, so-called SCIWORA (spinal cord injury without radiological abnormality).

Not surprisingly, the more severe the fracture pattern the more likely it is to be associated with a neurological injury. In injuries involving the anterior and posterior elements three-quarters are associated with a neurological deficit and in those in whom a neurological injury is present all would have a dural laceration. The significance of a dural laceration is that the neural elements may become incarcerated in the lamina fracture itself and may benefit from decompression at the time of stabilization.

Surgical stabilization of patients with complete spinal cord injury probably reduces hospital stay, although the incidence of complications may be doubled in patients undergoing internal fixation.

Following a thoracic spine fracture the neural elements may be at risk particularly if the spine is unstable. Neurological deterioration has been well documented during hospital stay with the risk increasing the longer the spinal cord remains vulnerable.

Therefore it would appear that the optimum management of patients with unstable thoracic fractures and neurological damage is to protect the spine while resuscitating the patient and then to fix the fracture internally at the earliest opportunity to prevent the risk of neurological deterioration. In this respect, thoracic fractures are probably different from lumbar fractures, where no benefit has been found in urgent decompression and stabilization of unstable fractures in the absence of deteriorating neurology.

Diagnosis

Diagnosis of thoracic fractures is not always easy. In the majority of patients a clear history will be given and local tenderness will be found with radiological evidence of a fracture. However, in some circumstances distracting injuries make the diagnosis less straightforward:

- Proximal fractures (above T5)
- Fractures associated with head injury
- Hyperflexion most common mechanism of injury
- Commonest in elderly females (osteoporotic)
- Ankylosing spondylitis predisposes
- Spinal cord injury common
- Chest injuries common
- Unstable fractures are best stabilized acutely if possible.
- Fractures associated with patients who are intoxicated or on drugs
- Patients with multiple injuries
Patients with multiple injuries

- Confused elderly.

Risk factors for high energy thoracic fracture include back pain, a fall of 3m (10 feet) or more, a vehicle crash at 80km/h (50mph), Glasgow Coma Scale score less than 8, and neurological deficit. All these patients should be sent for radiography.

There should also be a high index of suspicion in elderly patients with low-energy falls or sudden-onset back pain in the absence of an obvious precipitant. Wedge compression fractures are common in the elderly with osteoporotic bone. Historically, if a fracture was identified, these patients would be treated expectantly with the vast majority going on to make a full recovery. However, other treatment options now exist for those who remain symptomatic.

All patients with suspected high-energy thoracic spinal injuries should be considered unstable until proved otherwise, and the patient should be protected from spinal cord injury by log-rolling and immobilizing the spine.

Unstable fractures are more commonly associated with the following:

- High-velocity injury
- Chest injury
- Multiple injuries
- Head injury
- Other pathology (e.g. ankylosing spondylitis).

### Imaging (Box 12.42.3)

In most patients anteroposterior and lateral radiographs will demonstrate the fracture, but further investigation with thin slice computed tomography (CT) scanning may be necessary to establish whether or not the fracture is stable.

CT scanning is the most widely used investigation for assessing the stability of fractures. It gives the best definition of the bone structure, and allows assessment of the anterior and posterior structures. It will also demonstrate the amount of canal compromise caused by displacement of the fracture or by intrusion of bone fragments into the canal. If fine cuts are used, reconstruction of the CT scan can be very helpful in assessing the injury, the amount of displacement, and the amount of canal compromise.

The usefulness of magnetic resonance imaging (MRI) in high-energy thoracic fractures is limited. It may be useful to establish the presence or absence of a posterior soft tissue injury associated with an anterior injury, or to establish the type of spinal cord injury in those with paraparesis or paraplegia. In late injuries, deteriorating neurological function should be assessed with MRI to examine the cord and to determine the presence or absence of a syrinx.

### Box 12.42.3 Imaging

- Most fractures shown on x-ray
- Thin slice CT helpful in management
- MRI to assess cord injury.

Ninety per cent of these fractures are stable.

MRI is of particular benefit in assessing fractures, particularly fragility fractures that remain persistently painful at a time when most would have settled or at least be symptomatically much improved (approximately 6 weeks).

Ongoing pain and high signal on STIR (short tau inversion recovery) sequence MRI are indicative of non-union of the fracture and such fractures are amenable to operative intervention.

### Associated injuries

Associated injuries are relatively common after thoracic fractures, particularly displaced fractures. This is because they are mainly caused by high-velocity or high-violence forces (Table 12.42.2).
Table 12.42.3 Incidence of associated injury

<table>

</tr>
</tbody>
</table>

Head injuries are more common in fractures of the thoracic spine than in fractures elsewhere in the spine. This may be because of the high violence involved with so many of these injuries, and it is also possible that many of those with cervical injuries die before they can be transferred to hospital. It has been demonstrated that up to 40% of patients may have no tenderness at the site of a spinal fracture, and one of the risk factors for this is head injury. It is best to assume that those with a significant head injury have an unstable thoracic fracture until radiographs have excluded this.

Associated injuries are more common in thoracic fractures compared to thoracolumbar and cervical fractures.

A classic combination of injury in those with thoracic fracture is the association between sternal fracture, thoracic fracture, and rupture of the arch of the aorta. The sternal fracture is usually self-evident, but it is easy to miss one of the other two injuries because they can both cause serious back pain. The injury commonly occurs following high-velocity trauma in a road accident where the patient has been wearing a seatbelt. About 40% of those with thoracic fractures have associated chest injury, usually in the form of rib fractures. Haemopneumothorax is common and usually requires drainage with a chest drain. A chest radiograph and radiographs of the thoracic spine are mandatory in these patients, and an arch aortogram is required if there is suspicion of an aortic injury.

Other injuries associated with thoracic fractures include scapular fractures (2%), clavicle fractures (5%), rupture of the bronchus, subclavian injury, brachial plexus injuries, cardiac tamponade, rupture of the diaphragm, and intra-abdominal injury.

Multiple-level injuries occur in 10–15% of those with spinal fractures, and are common in those who fall from a height and in those subjected to high-violence injuries.

Non-operative management (Box 12.42.5)

Virtually all stable thoracic fractures can be treated non-operatively. Significant late deformity is very unusual, and most of these fractures can be treated with pain relief and bed rest initially, followed by mobilization and physiotherapy. Depending on the severity of their symptoms, many patients will not even require a period of bed rest. There is no evidence that bracing controls or limits the amount of kyphosis seen after simple wedge fractures, but the patient may be more comfortable in a three-point brace until the pain has settled down. The elderly do not tolerate brace-wear well, but it may be in these patients that the brace is best able to prevent progression of kyphosis after fracture. The standard orthosis is of little use in thoracic fractures above T6, and in these patients a thoracolumbar spinal orthosis with a cervical extension may be used. Below T6 a standard thoracolumbar spinal orthosis can be used.

Box 12.42.4 Caveats

- Head injury
- Sternal fracture, thoracic fracture, and aortic injury.

Box 12.42.5 Management

- Little evidence for bracing
- Brace ineffective in high fractures
- Some unstable fractures best treated non-operatively.

Box 12.42.6 Insufficiency fractures

- Usually treated with pain relief and/or bracing initially
- Must exclude underlying pathology, e.g. malignancy
- Consider vertebroplasty/kyphoplasty where symptoms >6 weeks.
Some unstable fractures may be managed non-operatively. For example, patients with complete spinal cord injury and without wide displacement of their fracture may be managed with bed rest followed by orthotic treatment for up to 3 months. The treatment used will depend on the preference of the treating physician.

Axial load or extension injuries over multiple levels are best treated non-operatively. Initial bed rest followed by immobilization in a brace for 6 weeks is best. However, if there is a neurological injury, the spine is probably unstable and surgical management is recommended in most cases.

### Surgical management

#### Low-energy fractures

Treatment options now exist for the management of fragility fractures of the thoracic spine that remain symptomatic. Whole spine MRI is mandatory in this group of patients to exclude malignancy as the underlying cause of fracture or pain. If doubt exists, then vertebral body biopsy should be undertaken. Investigations should demonstrate concordance with pain, changes in plain radiology, and high signal on STIR sequence MRI at the same vertebral level.

It is not uncommon to find multiple vertebral compression fractures on plain x-ray in this patient group but not all may be symptomatic hence the need for MRI (Figure 12.42.1). The vast majority of these fractures heal without ongoing sequelae. However, symptomatic fractures of greater than 6 weeks’ duration can be treated with cement augmentation. A variety of systems are available ranging from products that are aimed at restoring the height of the vertebral body either using a balloon or metal stent to elevate the endplates with a delivery system to then fill the residual void with bone cement (kyphoplasty). If height restoration is not considered feasible than simple filling of the vertebral body may suffice (vertebroplasty). Bone cements used include PMMA, calcium phosphate, and combinations of both. These products exert their effect either by stabilizing the fracture or reducing noicceptive stimuli through the exothermic reaction of the cement.

![Fig. 12.42.1](Click to view larger)

Vertebroplasty demonstrating one of the complications, extravasation of cement, into the venous system which on rare occasions may result in cement embolus.

#### High-energy fractures (Box 12.42.7)

Since the advent of the Harrington instrumentation there have been great advances both in the type and complexity of spinal instrumentation and in the surgical expertise of the modern spinal surgeon. Instrumentation and techniques now mean that fractures may be stabilized anteriorly, posteriorly or both and in some circumstances percutaneously or by minimally invasive means.

The approach to surgical stabilization of thoracic fractures depends on a range of factors:

- Fracture pattern
- Presence or absence of neurological injury
- Associated injuries.

The posterior approach to the thoracic spine is most commonly used. This is the traditional approach to the spine and most surgeons carrying out spinal surgery feel comfortable with it. In surgery to stabilize the thoracic spine after fracture, the advantages of the posterior approach outweigh the disadvantages in most cases:

- Long-segment fixation is easier via the posterior approach

---

**High-energy fractures**

- Posterior surgery most common
- Long constructs
- Can reconstruct anteriorly from behind
- Deteriorating neurology absolute indication for emergency decompression/stabilization.
The posterior approach does not compromise lung function which may already be impaired after injury. Most fixation devices for thoracic fractures are designed for posterior use. Fracture reduction, where necessary, is easier.

The importance of short instrumentation and fusion in the lumbar spine, in order to maintain its motion, has been emphasized. In the thoracic spine longer-segment instrumentation or fusion does not compromise the spine in the same way (Figure 12.42.2). The thoracic spine is relatively immobile compared with the lumbar spine, with most motion being in rotation. Patients tolerate a stiff thoracic spine much better than a stiff lumbar spine. Careful biomechanical consideration needs to be given to the type of construct required for fixation. There is no consensus on the optimal fixation technique. Constructs range from long to short and employ fixation methods from screws, hooks and wires although the trend is increasingly toward a pedicle screw based system. Most of the short-segment fusion devices depend on pedicle screw fixation for their stability. With this type of construct mobile segments may be preserved (Figure 12.42.3). At best a single mobile segment may be spanned and fused (ultra short segment fixation), if the injured vertebra is intact enough to support a screw. Alternatively two mobile segments may be spanned with fusion of the injured segment. This leaves the option of removing the metalwork with restoration of movement of the non-injured segment.

Fig. 12.42.2
High thoracic fracture at T5 associated with fractures of C5 and C7. A) and B) Sagittal and axial CT demonstrating acute kyphosis at level of the fracture with retropulsion of the posterior wall into the canal. C) and D) Demonstrates intraoperative images following pedicle screw placement before and after ligamentotaxis to reduce the fracture.

Fig. 12.42.3
Patient pedestrian versus cars, admitted with head injury and soft tissue Chance fracture of the thoracic spine. A) Sagittal CT demonstrating minor endplate fractures of adjacent vertebral bodies. B) Sagittal T2-weighted MRI demonstrating the fracture and increased signal in the intervertebral disc with increased signal in the posterior elements. C) STIR sequence demonstrating vertebral body oedema. D) Dynamic plain x-ray (sitting lateral) demonstrating gross ligamentous instability. E) Reconstruction of the posterior tension band utilizing a pedicle-based instrumentation system.

Non-pedicle screw constructs require a longer area of instrumentation (usually two segments above and two segments below the fracture) in order to achieve adequate stability.

Fracture patterns resulting in complete loss of anterior column support biomechanically would benefit from restoration of this support. This can be achieved from the posterior approach with a corporectomy via a costotransversectomy approach with or without sacrificing a thoracic nerve root. A reconstruction cage can then be sited to replace the fractured vertebral body. This combined with posterior column reconstruction gives a biomechanically robust construct, minimizing the risk of late kyphotic deformity or implant failure. A recent evolution in this construct, minimizing the surgical insult is to support the anterior column with bone cement through an open transpedicular approach using a hydraulically inflated balloon to reduce the fracture fragments and create a void to fill with bone cement, a technique known as balloon kyphoplasty.
In the neurologically compromised patient or the patient with deteriorating neurology it may be necessary to decompress the neural elements. Although this can be achieved with modern posterior instrumentation and ligamentotaxis, a more thorough decompression is achieved with an anterior approach. Following decompression anterior instrumentation is used to reconstruct and stabilize the anterior column. With associated major posterior ligamentous disruption this may also need to be augmented with additional posterior instrumentation.

The absolute indication for surgery is the patient with an unstable thoracic fracture with deteriorating neurology. Failure to stabilize these patients early on is likely to result in further deterioration and possibly paralysis. As discussed earlier, there is a high incidence of neurological deterioration in patients with unstable thoracic fractures, and they should undergo early stabilization to prevent neurological damage. This applies whether the patient is neurologically intact or has a partial neurological injury at presentation. In those with a complete and irreversible spinal injury there is not the same urgency for treatment. However, stabilization of a grossly unstable fracture in the presence of multiple injuries will help in the management of the patient; for example, it will allow the patient to be sat up and moved without danger.

Further reading

Thoracolumbar, lumbar, and sacral fractures

DOI: 10.1093/med/9780198550647.003.012043

Summary points

- High-energy trauma often results in serious spinal fractures. The junctional zone between the relatively stiff thoracic spine and the more mobile lumbar spine is particularly susceptible to injury.
- The role of decompression in spinal cord injury remains uncertain at level three or four evidence.
- Unstable fractures may be stabilized using modern fracture fixation methods enabling easier nursing care in polytrauma and earlier mobilization than non-surgical treatment.
- There is level two evidence that stable thoracolumbar fractures have similar outcomes with surgical and non-surgical treatment.
- There are many fracture classification systems that are not validated or have poor inter- and intraobserver error. Recent modern validated systems may in the future assist in the rational planning of interventions for spinal injury.

Introduction

A spectrum of injury can occur from the trivial to the devastating. The mobile junctional zones of the cervicothoracic and thoracolumbar junctions are more susceptible to injury than the deeply set lumbosacral junction. The relatively stiff thoracic spine is supported by the thoracic cage, the ribs and sternum.

In terms of nomenclature a fracture of the thoracolumbar spine involves any combination of the T11, T12, and L1 vertebral bodies.

At the thoracolumbar junction the spinal cord segments control lower limb and bowel and bladder sphincter function. Neurological dysfunction at this level can have devastating consequences for the patient.

A lumbar fracture is of the L2, L3, L4, and L5 vertebral bodies.

A sacral fracture is to any part of the sacrum between the superior endplate of S1 and the sacro-coccygeal junction and laterally to the sacroiliac joints.

Historical perspective

The development in care of spinal cord-injured patients owes much to the tragedies of the world wars. The reduction in morbidity and mortality of cord injured patients came about as a result of the political embarrassment of crippled soldiers dying from avoidable complications and poor nursing care. Centralization into specialized spinal injury units resulted in dramatic improvements for these patients. Powerful single personalities such as that of Guttmann at Stoke Mandeville in the United Kingdom influenced the whole of spinal rehabilitation for many generations.

The early mining industry with tunnel collapses produced spinal column injuries with regularity. The original Holdsworth classification of stability of spinal fractures into anterior complex and posterior complex was generated with the injuries sustained in the Nottingham coal mines.

Early surgical fixation devices such as the Harrington rod have no place in modern fracture management and are of historical interest only.

Aetiology and epidemiology

Motor vehicles in the form of cars and motorbikes are world wide the most common causative agent for thoracolumbar injury. Sports injuries from horse riding, mountain biking, climbing, and some extreme sports also contribute.

Earthquakes, particularly at night, are major natural disasters that can paralyse many thousands in a matter of minutes. The tremor wakes the population, they sit up in bed, flexed at the moment of ceiling collapse. In Oct 2005 in Northern Pakistan, 194 paraplegics were observed from a population of 600; 62% had lumbar level injuries, 25% thoracic, 9% thoracolumbar, and 4% were cervical or sacral.

A significant challenge is the patient group of ‘jumpers’. They fall into two psychiatric categories: the psychotic that jumps under impulse or because of delusional voices. They have a high rate of recidivism; the depressed or those with a situational crisis rarely repeat after the cathartic injury. Significant lower limb injuries contribute to the complexity of management.

The ageing population increases the pool of those vulnerable to fragility fractures secondary to osteoporosis. The incidence of vertebral osteoporotic fracture is high worldwide. In the United States of America there are an estimated 700 000 osteoporotic vertebral body compression fractures each year. The natural history is one of resolution of pain. Modern treatment strategies aim at preventing future fractures with treatment after assessing bone mineral density. Vertebroplasty and kyphoplasty involve the injection of the vertebral body with bone cement. This can be an effective treatment for pain. There are no published randomized controlled...
trials comparing this technique to natural history. There is level two, three, and four evidence to support this treatment.

## Stability (Box 12.43.1 and Box 12.43.2)

This term is commonly used but poorly defined.

An injury to the spine must be assumed ‘unstable’ until clinical data from examination and imaging enables an evaluation of stability.

There is a spectrum of stability and the two main questions relate to immediate stability and long term stability. Neurological features and mechanical or structural features need consideration in this assessment.

- Question 1: Is this spine so ‘unstable’ that there is immediate risk to neurological structures?
- Question 2: Is this spine ‘unstable’ such that over the expected time frame of healing of the injury the spine will deform or displace to an extent that may impair function or structure of the spine?

In simple terms, neurological involvement, no matter how trivial, implies that at the moment of injury there was sufficient displacement of the fracture to produce damage to neurological tissue. Immediate stability is likely to be jeopardized, and long-term displacement has a high probability.

In the absence of neurological symptoms or signs immediate stability must be assessed in terms of probability of displacement in the short term producing neurological deficit and long-term increasing displacement producing pain, deformity, or embarrassment of neural function.

A simple fracture of a transverse process is an obviously stable injury. A burst fracture with rotation at the thoracolumbar junction with partial neurological involvement is obviously unstable.

Fracture classification systems assist in the assessment of stability.

There are insufficient series or tested protocols to recommend a classification system for children.

## Clinical features

The spinal injury should be assessed as a part of the routine Advanced Trauma Life Support (ATLS) protocol: Primary and secondary surveys should occur. Modern imaging systems combined with clinical skills enable accurate assessment of stability at an early stage.

In the same way that repeated neurological assessment of patients with head injury is mandatory, so it is with patients who have a spinal column injury. An obtunded or consciousness-impaired patient must be assumed to have an unstable injured spine until evidence is available to ‘clear’ the spine.

### Box 12.43.1 Key points in assessment and documentation

- Immediate mechanical stability
- Long-term stability
- Neurological stability.

Assessment should be context specific for polytrauma or isolated an injury.

### Inspection and palpation

It is not possible to properly examine the spine of a supine patient. A ‘log-roll’ or spinal lift are the only two ways to move a patient before ‘stability’ has been established. A gibbus is a kyphotic deformity at the site of the fracture. It can only be seen on log rolling the patient. At this ‘look, feel, move’ moment, interspinous point tenderness and haematoma can be detected.

### Neurological examination

The use of the ASIA (American Spinal Injury Association) chart (Figure 12.43.1) reduces observer error and makes recording of sensory and motor deficits easy. The chart itself has helpful reminders regarding the Medical Research Council (MRC) grading of muscle strength. It enables diagrammatic recording of the dermatome and myotome of neurological deficit.
### Differential diagnosis

The diagnosis of a spinal fracture is confirmed with imaging. The energy transferred during acceleration or deceleration causes a structural failure of the components of the spinal column. The greater the energy the greater the injury. Whenever there is disproportionate tissue destruction or damage, suspect a secondary pathology. Pathological fractures secondary to metastatic or even primary tumour can occur with low-energy trauma.

Osteoporosis and osteomalacia have many causes. In older patients suspect fragility fractures as the cause of spontaneous spinal pain.

Osteoporosis produces decreased trabeculae thickness and strength. In the older spine the posterior elements are often osteoarthritic and so have sclerosis and falsely high bone mineral density. Loading of the osteoporotic vertebra results in fracture of the anterior superior aspect of the body, where there is greatest bone loss.

Pathological fractures occur as a result of metastatic spinal disease. Screening for metabolic bone disease to include plasma electrophoresis must occur in all patients with a pre trauma history of new back pain.

### Clinical imaging

Consider:

- X-ray, coned view:
  - Plain AP and lateral
  - Sometimes enables greater definition of detail, redundant with computed tomography (CT) scanning

- Standing weight bearing x-ray: useful to determine stability in less severe injuries

- Flexion extension x-rays: used to detect abnormal dynamic movement

- CT scan: 5mm or thin slice 2–3mm give clear definition of bone. Abdominal scans for trauma should be viewed for fracture

- Magnetic resonance imaging (MRI) scan: used to assess posterior ligament and disc. Predictive role not yet clear and a high false positive rate

- Bone mineral density scan: use for assessment of osteoporotic fractures and consider prior to fracture fixation particularly in alcoholic or other at-risk groups.

### Box 12.43.2 Stability

- Compression fractures and stable burst fractures are treated non-surgically
- Unstable injury patterns are treated surgically. Flexion distraction, fracture dislocation, and unstable burst
- The separation of stable and unstable burst fractures remains problematic.
The ideal classification system for thoracolumbar fractures awaits development. A classification system essentially compartmentalizes an analogue spectrum of injuries into discrete packages and creates arbitrary boundaries. This makes comparison, pattern recognition and treatment algorithms easier for those involved in the analysis of treatment options.

The ideal classification system provides the following functions:

- Language for communication
- Decisions about treatment
- Evaluate prognosis
- Compare results.

It should also be reliable, reproducible, all-inclusive, mutually exclusive, logical, and clinically useful.

As imaging technology has advanced so has the complexity of commonly used classification systems.

The early ‘two complex’ concept was superseded by the three columns. These were based on pain x-rays and subsequently CT scans.

The load sharing concept is a classification system that describes the loss of structural integrity of the anterior spinal structures and implies a need in certain circumstances to reconstruct the anterior complex of the spine. The system has good reliability but remains unproven in prediction of mechanical failure. The study is a retrospective evaluation of imaging and patient outcomes.

Denis three-column concept (Figure 12.43.2 and Box 12.43.3)

The three-column concept is in common use and has a practical value. It was developed from a retrospective review of 412 plain x-rays, 53 CT scans, and 120 patient records.

The fractures fall into four main categories, which have an interobserver agreement with a kappa of 0.606, which is moderate:

- Burst
- Seat belt type
- Compression
- Fracture dislocation.

The 16 subcategories have a poor interobserver error with a kappa value of 0.173.

The AO system has a comprehensive classification. The type A, Type B and Type C fractures are subdivided into three sub groups and each of these into a further three subgroups, a total of 27 types. The kappa scores of 0.475 for the main three groups of A, B, and C suggest fair reproducibility.

Box 12.43.3 The three anatomical columns

- SLL, supraspinatus ligament
- PLL, posterior longitudinal ligament
- ALL, anterior longitudinal ligament.

A specific study looking at reproducibility of the two most common classification systems used 33 sets of imaging and 19 observers. The Denis and the AO system for the classification of spine fractures have only moderate reliability and repeatability.

The tendency for well-trained spine surgeons to classify the same fracture differently on repeat testing is a matter of some concern.

Fracture pattern is frequently the dominant or only factor forming the basis of spinal injury classification.

The Thoracolumbar Injury Classification and Severity Score

The Thoracolumbar Injury Classification and Severity Score (TLICS) is a system in evolution being validated and improved by the American Spine trauma study group. The three components held by a consensus of clinicians to be important in fracture management decision processes are included. They are

- Fracture morphology determined by radiographic appearance
- Integrity of the posterior ligamentous complex
- The neurological status of the patient.

The three main categories are similar to the AO system, that is, A) compression or burst B) translation or rotation C) distraction. The integrity of the posterior ligament complex is assessed and scored, and medical uncertainty is permitted as the ligament may be intact, suspected or indeterminate, or injured. A spectrum of neurological status is recognized and graded. There is clinical utility to the research by this active group.
The three anatomical columns: SLL, supraspinatus ligament; PLL, posterior longitudinal ligament; ALL, anterior longitudinal ligament.

**Treatment (Box 12.43.4 and Box 12.43.5)**

There is prehospital care, in-hospital care, and rehabilitation. In-hospital care must involve consideration of the risks of venous thromboembolic disease. Early mobilization improves outcomes. Rehabilitation and avoiding long-term disability is an important treatment goal.

Simple measures such as an early graded medical return to the workplace have significantly reduced the social morbidity of long-term impaired function. Reassurance by the physician is an important tool in this process. ‘Mixed messages’ and negative messages from health care professionals confuse patients and can act as obstacles to recovery. Most fractures have a favourable prognosis and spinal fractures are no exception. The outcome of many spinal disorders can be influenced by positive messages.

Non-surgical treatment can require greater supervision with serial assessments. If the fracture is deemed stable then early mobilization and return to activity as pain allows is the treatment of choice. Early aggressive pain control with appropriate support and early discharge is the most common treatment for stable injuries.

‘Trunk’ stability is when the patient can sit comfortably without support. A proportion of patients find bracing beneficial as a means of pain reduction. A Jewitt brace is small and lightweight. It has three-point fixation to reduce flexion. A custom moulded thoracolumbar orthosis provides a greater degree of structural support.

Early surgery may have advantages in trauma over delayed surgery with reduced morbidity.

Stable fractures can be treated without surgery or with surgery. The principles of fracture stabilization are

- Short segment fixation to preserve motion segments (Figure 12.43.4)

**Treatment options**

- A Jewitt brace: three-point fixation to reduce flexion.
- A thoracolumbar orthosis: greater degree of structural support
- Stable lumbar fractures: non-surgical treatment
- Vertebroplasty and kyphoplasty involve the injection of the vertebral body with bone cement
- Sacral or posterior pelvic fracture: displacement of >1cm is considered to be unstable
- Stable fractures treated without surgery or with surgery.

**Principles of fracture stabilization**

- Short segment fixation to preserve motion segments
- Anterior reconstruction and posterior fixation if loss of anterior column support
- Posterior fixation two levels above and two levels below fracture if fitness for anterior reconstruction doubtful.
Consideration of anterior reconstruction as well as posterior fixation if there is loss of anterior column support.

- Posterior fixation two levels above and two levels below fracture if fitness for anterior reconstruction doubtful.

A randomized controlled trial (level two <80% FU) compared surgery to non-operative care in stable thoracolumbar burst fractures without neurology. There was no difference in outcome. The surgical group had an average Oswestry disability index of 20 points, the non-operative only 10 points, suggesting a better outcome for non surgical treatment in this group.

**Medical uncertainty**

The role of early decompression of spinal fractures that have a stable neurological deficit has not been confirmed.

The assessment of neurological status before ‘spinal shock’ has resolved is not absolute.

Clinical outcomes of anterior decompression and stabilization compared to posterior decompression and stabilization in the presence of an unstable injury and neurological deficit has insufficient evidence, but there is a trend for better results with anterior decompression and stabilization where there is evidence of anterior compression of the spinal cord or nerve roots.

**Likely developments over the next 5–10 years**

Current research centres on establishing predictive value to treatment algorithms that are based on classification systems.

Biological means of improving the outcome of neurological deficit with stem cells or olfactory glial cells are in development.

**Sacral fractures**

Sacral fractures are often identified late. Local crepitus, deformity, or sacral de-gloving may be found. Rectal examination and assessment of sphincters and perineal dermatomes is essential. Five principals of assessment have been described:

1) The presence of active bleeding
2) The presence of an open fracture
3) Neurological injury
4) The pattern and stability of the injury
5) The systemic injury load.

A) Compression or burst. B) Translation or rotation. C) Distraction. The integrity of the posterior ligament complex is assessed and scored, and medical uncertainty is permitted as the ligament may be intact, suspected or indeterminate, or injured. A spectrum of neurological status is recognized and graded. There is clinical utility to the research by this active group.
The fracture may be difficult to image with plain x-rays. CT scan is the imaging modality of choice. Radiological features such as a fracture of the L5 transverse process may be associated with sacral fracture.

There are a number of classification systems, the most widely used is that of Denis. The three zones described in his retrospective series have an ease of use simplicity.

- Zone 1: completely lateral to the neural foramina
- Zone 2: involves the neural foramina but not the spinal canal
- Zone 3: extend into the spinal canal and may have associated fracture lines.

Any sacral or posterior pelvic fracture-displacement of greater than 1cm is considered to be unstable. Fracture fixation can be considered if the fracture configuration and patient fitness permits. Insufficiency fractures in metabolic bone disease may not be amenable to fixation.

Further reading

Summary points

- The commonest site for post-traumatic kyphosis (PTK) is the thoraco-lumbar junction
- Symptoms of PTK may include pain, progressive deformity, neurological deficit and unacceptable cosmesis
- Localized kyphotic deformity greater than 30 degrees increases the risk of chronic pain
- Surgical options for the correction of PTK depend on the magnitude and location of the deformity and whether the deformity is fixed or mobile.

Incidence

In the United States of America approximately 50,000 fractures of the spine occur each year. Between 7000 and 10,000 of these are associated with neurological deficit. The thoracolumbar junction (T10–L2) is the commonest site for such injury. This predilection may be explained by virtue of its unprotected position between two rigid lever arms formed by the upper thoracic and lower lumbar spine.

Post-traumatic kyphosis (PTK) is a common sequel to fractures in this region, particularly following neglected flexion–compression, flexion–distraction, and burst fractures. The resultant late deformity may result in pain, neurological deficit, or unacceptable cosmesis requiring complex reconstruction of the spine.

Anatomy

The spine has a characteristic alignment in the coronal and sagittal planes. In the coronal plane the spine is straight. In the sagittal plane, the spine is lordotic in the cervical and lumbar regions and kyphotic in the thoracic region. The normal cervical lordosis is 30–50 degrees, with the majority occurring at the C1–C2 level. The normal thoracic kyphosis is 10–40 degrees. The normal lumbar lordosis is 40–60 degrees with up to 75% occurring between L4 and S1. The thoracolumbar junction measured between the superior endplate of T10 and the inferior endplate of L2 usually measures 0 degrees.

In stance, the C7 plumb line should pass within a few millimetres of the posterosuperior corner of S1. The lordotic and kyphotic segments of the spine must ultimately balance the occiput over the sacropelvic axis for posture to be energy-efficient.

Classification

PTK may occur in the cervical, thoracic, or lumbar spine. Loss of cervical lordosis and lumbar lordosis may occur following posterior spinal decompressive procedures. The commonest site of PTK however is thoracolumbar junction. The thoracolumbar junction is the biomechanical transition zone between the relatively rigid thoracic spine and the highly flexible lumbar spine and is relatively unprotected.

Several classification systems for thoracolumbar injuries have been described. However, these often lack validity and reproducibility, serving only as descriptors of injury and not necessarily as predictors of outcome. The thoracolumbar injury classification severity score (TLICS) attempts to address this by assessing the fracture morphology, the integrity of the posterior ligamentous complex, and the neurological status of the patient. Careful use of this classification may improve the diagnostic accuracy of such injuries, resulting in more aggressive early treatment, potentially minimizing the risk of PTK.

Assessment

History (Box 12.44.1)

The present site and severity of pain should be ascertained. Pain may be localized to the original fracture site. It may result from a pseudarthrosis or failure of the fracture to heal, or it may be secondary to adjacent level intervertebral disc degeneration or facet joint degeneration. Alternatively, the pain may be remote from the fracture site. Malcolm et al. highlighted the problem of low back pain resulting from muscle fatigue as the posterior spinal muscles attempt to correct the sagittal imbalance produced by a more cranial PTK.

Patients may complain of loss of height or progressive deformity. Others will complain of discomfort when sitting in hard-backed chairs when the gibbus makes contact with the back of the chair. Others still will complain of unacceptable cosmesis. Neurological dysfunction may be evident with radicular-type symptoms suggestive of individual nerve root compromise or in more severe cases there may be spinal cord involvement with lower limb weakness, bladder, bowel, or sexual dysfunction.

Box 12.44.1 Presenting symptoms of PTK
♦ Pain
♦ Progressive kyphosis
♦ Instability
♦ Increasing neurological deficit
♦ Unacceptable cosmesis.

**Examination**

The patient should be examined in the standing position with attention paid both to frontal and sagittal alignment. The spinal balance should be formally assessed with a plumb line in both posterior and lateral views. The site and size of the gibbus should be noted. This will become more obvious if the patient is asked to bend forward. The range of motion in the spine should be assessed. An attempt should be made to ascertain whether the deformity is fixed or flexible. This may be done, for example, by asking the patient to lie on a flat couch to see if the deformity corrects. A complete neurological examination including abdominal reflexes and rectal examination should be carried out.

**Investigations (Box 12.44.2)**

**Plain radiographs**

Standing anteroposterior and lateral radiographs of the whole spine will allow assessment of the focal kyphosis by measurement of the Cobb angle. This is the angle subtended by a line drawn over the superior endplate and a line drawn over the inferior endplate of the vertebral body above and below the level of injury. These standing radiographs will also allow for an assessment of the global sagittal balance. The C7 sagittal plumb line should pass on average 40mm anterior to the posterosuperior margin of the S1 endplate. A hyperextension film over a bolster placed at the apex of the deformity will allow for an accurate assessment of the flexibility of the deformity (important in planning the surgical strategy). Serial lateral standing radiographs will allow assessment of progression of the deformity over time.

**Computed tomography**

Computed tomography with fine cuts (1–3mm) will allow a detailed evaluation of the bony architecture and fracture geometry. Sagittal and coronal reconstructions may confirm the presence of a pseudarthrosis at the site of the original fracture and also allow for detailed planning including the need for spinal osteotomy.

**Magnetic resonance imaging**

Magnetic resonance imaging is invaluable for assessing the integrity of the posterior ligamentous complex, the surrounding intervertebral discs, and subtle neural compression and changes within the spinal cord, such as myelomalacia or the presence of a post-traumatic syrinx.

**Provocative discography**

This is useful to confirm the source of pain. Under conscious sedation, the intervertebral discs adjacent to the injured vertebra are cannulated using a two-needle technique, followed by injection of radiographic contrast. If such an injection produced concordant pain reproduction, there would be a strong argument for inclusion of this level in the proposed fusion.

**Box 12.44.2 Investigations**

♦ Plain radiography:
  • Standing lateral views
  • Flexion/extension films
♦ Computed tomography: sagittal/coronal reconstructions
♦ MRI to assess:
  • Posterior ligamentous complex
  • Adjacent intervertebral discs
  • Degree of neural compromise
♦ Provocative discography: to assess pain source
♦ Baseline SSEP: to allow spinal cord monitoring

**Somatosensory evoked potentials**
Baseline somatosensory evoked potentials (SSEPs) are important to assess before surgery. If reproducible, they will allow the use of continuous intraoperative spinal cord monitoring to detect intraoperative spinal cord dysfunction before it becomes irreversible.

Management (Box 12.44.3 and 12.44.4)

The treatment of PTK depends primarily on the location and magnitude of the deformity, its stiffness on hyperextension films, and the anatomical source of pain. Conservative measures including non-steroidal anti-inflammatory medication and physiotherapy (aimed at optimizing the spinal extensor muscle activity and postural readjustment) should be given a fair trial before surgery is considered.

Indications for surgery include pain, progressive neurological deficit, progressive spinal deformity, and unacceptable cosmesis. Patients who have a localized kyphotic deformity of greater than or equal to 30 degrees have been noted to have an increased risk of chronic pain at the site of the kyphosis.

Goals of surgery include correction of the deformity, restoration of sagittal balance, provision of immediate stability, improvement of neurological function, and reduction in pain. In so doing, it is important to recreate a load-sharing and tension band system and to fuse only the damaged segments.

The basic principles used in the treatment of fractures still apply, however the surgical technique differs. This is because the kyphosis is often fixed, correction is more difficult to achieve than is the case for acute fractures because of the presence of osseous deformity, soft tissue retraction, and elongation. Also there is a higher risk of neurological impairment because of dural adhesions. Very rarely is only one segment damaged, in the majority of cases two segments are involved.

In any surgical correction it is important to use spinal cord monitoring during the procedure. The combination of SSEPs and transcortical magnetic stimulation motor-evoked potentials (MEPs) are extremely useful in detecting spinal cord lesions before they become irreversible. Prompt intervention during loss of spinal cord monitoring can lead to a return of normal spinal cord monitoring, thereby preventing a permanent neurological deficit.

A number of different surgical procedures have been described, depending on the magnitude and location of the deformity and whether the deformity is fixed or mobile.

**Posterior-only instrumented fusion**

This is particularly useful for flexible multisegmental deformities which lack focal angular kyphosis. Multiple extension (Chevron) osteotomies with segmental fixation may allow return of a normal sagittal contour. In this type of surgery, the importance of a comprehensive resection of the facet joints or fusion mass cannot be overemphasized.

**Anterior-only instrumented fusion ± decompression**

This technique requires either a thoracotomy or a thoracoabdominal approach, depending on the level of the PTK. For fixed kyphotic deformity, the anterior-only approach provides a less reliable and sometimes incomplete correction.

Benil et al. (2007) treated 40 patients with PTK with a mean age of 44.7 years (range 18–65 years) with anterior vertebrectomy, decompression and anterior fusion with costal or iliac crest bone graft. The preoperative kyphosis measured 51.4 degrees ± 13.8 degrees compared to a postoperative kyphosis of 7.0 degrees ± 7.6 degrees. At a minimum of 5-year follow-up, the mean loss of correction was 1.4 degrees ± 1.8 degrees. These authors reported complete resolution of pain in 36 patients with partial resolution of pain in the remainder. For those patients with neurological deficit before surgery (24 patients), all noted an improvement following surgery. Improvements in pain and functional assessment were noted, as well as total SRS-22 scores and each individual domain score (pain, function, mental status, self-image, and satisfaction).

Gertzbein (1992) in a study of 1019 acute spinal fractures noted that anterior surgery was more beneficial in improving complete bladder impairment to partial impairment when compared to posterior surgery. For those patients with an incomplete neurological deficit, several authors have reported significant neurological recovery after anterior decompressive procedures even as late as two years after injury.

**Pedicle subtraction osteotomy**

This is an excellent posterior technique ideally suited for localized kyphosis requiring a large magnitude correction. Surgery below the conus medullaris (circa L1) is generally regarded as safer than that above the conus.

The technique involves removal of a posteriorly-based wedge involving the spinous process, pedicles and vertebral body followed by segmental fixation (Figure 12.44.1). This is a closing-wedge osteotomy thereby shortening the neuraxis. For this reason arguably it is safer than an opening-wedge osteotomy, which is now rarely performed.
Fig. 12.44.1

Wu (1996) treated 13 patients with rigid PTK by pedicle subtraction osteotomy. All patients were male between the ages of 20 and 45 years. The initial fractures were all between T12 and L4. The mean kyphosis before correction measured 40 degrees (range 30 –60 degrees), reducing to a mean kyphosis of 1.5 degrees (range −5 degrees to +5 degrees) postoperatively. The authors reported no neurological deficit, no implant failures, no infections and bony union was said to occur in all 13 cases at the osteotomy site.

Three-stage surgery (back–front–back)
Harms describes surgery consisting of three stages, usually performed in one operation. The first stage consists of a posterior release via a transversotomy. This consists of resection of the ligamentum flavum and undermining of the upper neural arch (to avoid posterior compression of the cord during and after the reduction), resection of the facet joints. Only rarely is a complete laminectomy required. Pedicle screws for segmental fixation are inserted at this stage. The second stage involves an anterior release consisting of excision of the anterior longitudinal ligament and intervertebral discs, along with a vertebrectomy if required. The anterior release is then followed by reduction of deformity, grafting and anterior instrumentation. The third stage involves return to the posterior approach for completion of the posterior instrumentation. The structure is loaded in compression to restore the tension band (Figure 12.44.2). Only in those cases where the bending films show full reduction without neural compromise, can the surgery be performed in two approaches (anterior and posterior).

Fig. 12.44.2
This technique provides exceptional correction of sagittal plane deformity through segmental and progressive release/excision. The initial posterior approach allows an aggressive facetectomy ± osteotomy followed by anterior decompression/release allowing for a comprehensive correction of the kyphotic deformity. Finally the posterotension band is restored through an instrumented posterior arthrodesis. Disadvantages of this procedure are the prolonged anaesthesia, significant blood loss, and it may well be tiring for the surgeon.

Been et al. (2004) compared an anterior procedure alone (10 patients) with a one-stage combined anterior and posterior procedure (13 patients) for post-traumatic thoracolumbar kyphosis after simple type A fractures. The main indication for this surgery was pain. No significant difference was observed in the clinical or radiological outcome between the two techniques. The authors concluded that monosegmental correction with an anterior procedure alone was preferable to the more complex combined procedures.

Complications of post-traumatic spinal reconstruction include approach-related complications (e.g. pneumothorax, diaphragmatic hernia, paralytic ileus, chylothorax, retrograde ejaculation, dural laceration), neurological deficit (spinal cord, cauda equina, individual nerve roots), bleeding, infection, pseudarthrosis, and implant failure.

Kyphosis often fixed
Often multisegmental damage
Correction difficult because of osseous deformity and soft tissue retraction
Higher risk of neurological impairment.

Posterior only instrumentation ± Chevron osteotomy
Anterior only instrumentation ± decompression
Pedicle subtraction osteotomy—single stage
Anteroposterior surgery for fully flexible PTK
Three-stage surgery (back-front-back) for rigid PTK.

One study reported an overall complication rate for PTK surgery at 48%. Postoperative neurological deficit was observed in 8.3% of patients and 12.5% suffered a pseudarthrosis. Forty-two per cent reported a loss of correction of more than 10 degrees and 2% had further problems with instrumentation.

In PTK, the spinal cord is often draped over the anterior vertebral column. Pre-existing spinal cord injury, neural scarring, and cord tethering will all potentially increase the risk of neurological injury. Intraoperative neural injury to the spinal cord may occur as a result of traction, correction, mechanical damage or vascular events. Nerve roots or cauda equina may be injured as a result of a misplaced pedicle screw or inadequate decompression prior to reduction. Dural laceration is not infrequently reported and may relate to previous scarring. Major vessel injury has been reported involving the aorta and inferior vena cava caused by too vigorous retraction. Posterior screws that are too long may perforate the anterior cortex and cause vessel injury.

PTK is a common occurrence following fractures of the thoracolumbar and lumbar spine, the presence of which often indicates a failure of initial treatment. The resultant pain, progressive deformity, progressive neurological deficit or unacceptable cosmesis may offer compelling indications for surgical intervention. With careful planning and meticulous technique these symptoms can be
treated with a degree of success, justifying such invasive and complex surgery.

Rehabilitation of spinal cord injuries

Summary points

- Fragmentation of care is the greatest threat to the treatment of patients with spinal cord injury
- Level of injury defines disability
- Early care critical to prevent late complications
- Tertiary spinal cord injury may occur (e.g. syrinx of the spinal cord)
- Complications affect almost all body systems directly or indirectly.

Introduction

Prior to the Second World War most spinal cord-injured patients died soon after injury. The establishment of systems of comprehensive care, pioneered by the National Spinal Injuries Centre in Stoke Mandeville Hospital, changed this situation.

Spinal cord injury affects every system of the body. Successful rehabilitation depends on the effective management of all aspects. Failure of care in any area results in unnecessary morbidity and mortality. A multidisciplinary approach is essential if the optimum rehabilitation outcome is to be achieved.

The greatest threat to the successful rehabilitation of the patient is fragmentation of care. To avoid this, systems of care were initially developed in the United Kingdom, and later in Australia, New Zealand, the United States of America, and Canada, where all aspects of treatment could be addressed by those with the required training. Those systems where all facets of medical care following the accident and emergency department phase are dealt with in one centre have fewer complications than those that involve acute care in one hospital followed by subacute and chronic care elsewhere.

Definitions

A spinal cord injury is complete if there is no somatic motor or sensory function below the level of injury. If the arms are spared the patient has paraplegia. If they are involved the patient has tetraplegia. The level of injury is the lowest intact spinal cord segment. If there is residual function several segments below this then the injury is incomplete and the patient has either paraparesis or tetraparesis.

Box 12.45.1 Spinal cord injury

- 0–50/million/year
- Road accidents commonest cause
- Diving, rugby, and horse riding commonest sports.

Epidemiology (Box 12.45.1)

The incidence of traumatic spinal cord injury is between 10 and 50 per million in the population each year. The figure in the United Kingdom is towards the lower end of this range.

Prevention (Box 12.45.2)

The two components relevant to rehabilitation are prevention of the injury, and avoidance of the secondary deleterious effects that are the consequence of poor care.

Spinal cord injury is most commonly caused by motor vehicle accidents. Seat belts, both front and rear, side impact support systems, and inflation bags reduce the incidence and severity of injury.

Sports-related injuries are uncommon. In the United Kingdom the most common are, in order of frequency, diving, rugby, and horse riding.

Diving-related injuries can be partly prevented by good education, appropriate pool design, adequate poolside signs, and appropriate supervision by attendants trained in safe methods of retrieval.

Rugby injuries can be reduced by adherence to the rules of the game, the avoidance of participants playing out of position, and ensuring that players are suitably fit. Where complete tetraplegia is caused by cervical dislocation, relocation within 4h of injury
can produce full recovery in two-thirds of cases.

Box 12.45.2 Prevention

♦ Vehicle design and road safety measures
♦ Sports training
♦ Stabilization of acute injuries.

Avoidance of the secondary deleterious effects that are a consequence of poor care is dependent firstly on the recognition that a spinal injury may have occurred, and secondly on knowledge of, and expertise in the correct actions to take. Ten per cent of unstable spinal injuries in the United Kingdom are missed. Of these, circa 50% deteriorate neurologically due predominantly to inappropriate movement at the injury site, compared with less than 5% of those managed appropriately. Common sites where fractures are overlooked include the cervicodorsal junction and spinal fractures below the major fracture. If there are reasonable grounds for believing that there is an unstable spinal injury, appropriate steps must be taken to immobilize the spine until the diagnosis has been confirmed or refuted. The more the spinal cord is damaged the less complete its recovery and the worse the rehabilitation outcome.

Clinical management

Optimum rehabilitation outcome depends on good management of all facets that affect the spinal cord-injured person.

Management of associated injuries (Box 12.45.3)

Associated injuries must be well treated to ensure optimum rehabilitation outcome. Amongst the more important are the following.

Brain

Successful rehabilitation following spinal cord injury is dependent on the total involvement of the disabled person. Good executive function enables the spinal cord-injured person to lead a safe and well-integrated life. Relatively minor impairments of personality, memory, concentration, and intellect can interact with the other problems associated with spinal cord injury to make safe independent living and successful employment more difficult.

Limb joints and bones

People with spinal cord damage are more dependent on their arms than prior to injury. Joint damage, and to a lesser extent long-bone fractures, can severely impair transfers and wheelchair skills. Contractures are frequently very disabling.

Problems in arm joints commence at an earlier age after spinal cord injury because they are put under stress by the routine activities of wheelchair life. The onset of these difficulties is accelerated by damage sustained at the time of injury.

Peripheral nerve injuries, especially brachial plexus

Peripheral nerve and brachial plexus injuries occasionally occur in association with the spinal cord damage. Paraplegics require both arms for most activities. The affected arm cannot cope so well with transfers and wheelchair control.

Chest and abdomen

Chest and abdominal injuries, though life-threatening at the time of injury, are seldom important in rehabilitation terms.

Box 12.45.3 Associated injuries

♦ Treat brain injury
♦ Avoid contractures especially upper limb.

Neurology

The level, degree of completeness, and pattern of the spinal cord injury are of central importance in determining rehabilitation outcome and prognosis. There is no level of neurological disability, including ventilator dependency, that is incompatible with life in the community.

Methylprednisolone is seldom given in the United Kingdom as the harmful effects of the very high doses of steroids required outweigh the relatively small rehabilitation benefits.

Preserved sensation below the injury makes the paralysed person aware of complications such as pressure sores, fractures, and intra-abdominal events, thereby improving life expectancy through earlier diagnosis.
The neurological level of injury is the most important determinant of rehabilitation outcome. Each segmental level in the cervical region in particular is of vital importance.

Complete C3 and above patients usually require a greater or lesser degree of ventilatory support.

C4 level patients can almost always breathe independently but are otherwise almost totally dependent. Electric wheelchair mobility and high-technology control of the environment is achievable using retained head and neck control.

C5 level patients have good shoulder control as well as elbow flexion. With aids, such as feeding straps, limited function is possible. Assistance is required with every activity.

C6 level patients have good wrist dorsiflexion. Elbow extension can be achieved by means of trick movements. By locking the elbow, transfers are sometimes possible. Wrist dorsiflexion is associated with passive tenodesis of the fingers and the thumb. Upper-limb reconstructive procedures can be of great benefit at this level of injury. Active elbow extension can be achieved by the Mobberg posterior deltoid to triceps transfer operation. Stronger hand key and grasp grips can be achieved by tendon transfers around the wrist, such as insertion of extensor carpi radialis longus into flexor digitorum profundus and brachioradialis into flexor pollicis longus. These procedures do not usually increase transfer capability. They improve upper-limb control and lead to improved quality of life.

C7 and C8 level patients lack fine intrinsic hand muscle control but have sufficient upper-limb function to achieve partial independence in transfers and activities of daily living.

Box 12.45.4 Neurological level

- C3 and above ventilator dependent
- C4 breathe spontaneously but otherwise totally dependent
- C5 limited function, assistance with every activity
- C6 can sometimes transfer
- C7/8 can transfer, some independence of activities
- T2–6 poor trunk control, difficulty transferring, poor trunk control
- L1 very limited ambulation sometimes
- Mid-lumbar younger patients can ambulate.

Upper-thoracic (T2–T6) level patients lack the abdominal and lower paraspinal muscle control required for good truncal balance. Wheelchair control and transfers are impaired as a result. Spontaneous spasms can cause problems in transfers. Ambulation is difficult and requires both long-leg orthoses and truncal braces.

Lower-thoracic (T7–T12) patients have greater abdominal and paraspinal muscle control and hence better truncal balance. Higher kerbs can be negotiated because of better wheelchair control.

L1-level patients frequently achieve ambulation using long-leg orthoses though this is seldom of functional benefit.

Mid-lumbar level patients have good quadriceps control. This usually allows functional ambulation in younger patients through using below knee orthoses.

Longer-term neurological consequences (Box 12.45.5 and Box 12.45.6)

The incidence of tertiary spinal cord change is commoner than had previously been recognized. These changes continue to develop throughout the life of the spinal cord-injured person. The most important is the spinal cord syrinx. The previously quoted incidence of syrinx formation of 2–4% was largely based on clinical diagnosis. It is now clear that the incidence of syrinx is much greater because the majority do not have clinical features. The incidence of syrinx at 5 years postinjury is 9%. In those injured over 20 years it is 20%.

The presence of a syrinx has important consequences for rehabilitation. Lifestyle should be altered to avoid those abrupt stresses, strains, and other events that could cause serious spinal cord deterioration. Falling from the wheelchair in a poorly executed transfer, for example, can be associated with loss of the use of a hand. The aetiology and management of syringes remains controversial. Surgery is not usually required. Continued review is essential.

A neurosurgeon with a specialist interest in the spinal cord-injured patient is an essential member of the multidisciplinary team.

Spine

Following the acute event, spinal problems are not usually an issue. Degeneration may occur at an earlier stage in the mobile motion segments above and below the injured one. This can give rise to increased spinal pain, stiffness, and altered neurological function. This contributes to the greater dependence that arises with aging. Deformities such as gibbus are seldom functionally important.
Long spinal fixations can be very disabling. A young person with paraplegia and a long fixation is usually totally independent in their younger years but when they are older their loss of truncal mobility cannot be so readily compensated by increased movement in his hips. This brings forward the stage at which dependence increases. Long fixations in the cervical region prevent the tetraplegic person from looking around, making driving a car more difficult.

Around 10% of spinal injured patients have fractures at multiple levels. Those below the level of the main injury are important if they cause neurological damage or deformity. For example, a complete cervical spinal cord-injured person with an L1 fracture must have the latter carefully treated if reflex bladder, bowel, and sexual functions are to be retained.

Progressive skeletal deformity is a particular problem in children. Regular careful review of their spinal position is required until skeletal maturity. Whereas gibbus does not significantly increase disability, scoliosis can be a significant problem. Sitting posture, the pattern of pressure on the ischial areas, cardiorespiratory function and transfers are impaired by scoliosis.

An orthopaedic spinal surgeon with a specialist interest in the spinal cord-injured person is an essential member of the multidisciplinary team.

Pain
Musculoskeletal and neurogenic pains are common following spinal cord injury. They can be intractably disabling. Treatment is frequently difficult.

Sometimes the pain makes it necessary for patients to shift from one position to another or to lie down at intervals during the day. Employment can be difficult for this reason and also because of the effect on concentration of the pain itself and its associated medication.

Neurosurgical intervention is rarely required. Behavioural approaches usually offer the best prospect for the patient learning to cope with the pain. An anaesthetist with a specialist interest in the spinal cord-injured person is an essential member of the multidisciplinary team.

Bladder

Lower urinary tract
Bladder sensation and control are impaired by spinal cord injury. All methods of bladder care are associated with events that can be distressing and inconvenient. With intermittent self-catheterization there is incontinence. Toilets are frequently inaccessible. With automatic drainage the urinary sheath occasionally disconnects causing soaking. Penile problems can prevent application of the sheath forcing bed-rest or an indwelling catheter. High voiding pressures can compromise renal function.

When partial bladder control remains there is often urgency and frequency that seriously impairs quality of life. Journeys depend on accessible toilets. Anticholinergics or intravesical botulinum toxin may help.

Bladder management in females is particularly difficult. There are no satisfactory external collecting appliances. The risk of incontinence and the smell of urine impair self-confidence and femininity.

A variety of urological procedures exist that benefit certain groups of patients. The more commonly used include augmentation cystoplasty, surgical or botulinum toxin distal urethral sphincterotomy, the artificial urinary sphincter, and sacral root stimulators. Many patients elect to have indwelling suprapubic or urethral catheters because their improved quality of life outweighs the increased risks of infection, bladder stones, intravesical bladder change, urethral discharge, catheter blockage and autonomic dysreflexia.

Upper urinary tract
Continued vigilance of the upper urinary tract is required throughout the life of the paralysed person. Asymptomatic upper tract problems such as calculi and dilatation can occur. An annual evaluation will usually suffice to ensure early diagnosis and treatment. Improved urologic techniques, such as lithotripsy, have reduced the morbidity of upper tract stones.

Experienced nurses are important sources of advice and help with incontinence aids and appliances.

A urological surgeon with a specialist interest in the spinal cord-injured person is an essential member of the multidisciplinary team.

Box 12.45.5 Consequences 1

◆ Up to 20% syrinx
◆ Long fusion can be very disabling
◆ Progressive deformity common in children
◆ Pain common
◆ Bladder and bowel function seldom normal.
**Bowels**

Upper gastrointestinal problems are seldom significant. Faecal evacuation is usually a major problem. Most patients require suppositories or digital stimulation. Some require aperients. A disciplined pattern of bowel control is essential.

Episodes of incontinence can be very distressing. They are minimized by discipline and avoidance of precipitating factors such as hot curries.

Most paraplegics are able to manage their bowels independently by transferring onto the toilet followed by suppository insertion or digital evacuation. The rectum needs to be checked after bowel emptying to ensure that no faeces remain.

Most tetraplegics need assistance. Bowel evacuation whilst seated on a shower chair over the toilet and followed by a shower is usually effective.

Bowel problems are common in chronic spinal cord injury. Faecal evacuation may take a progressively longer time. Aperients become less effective. The life of the paralysed person can be greatly disrupted. Colonic irrigation or colostomy is sometimes required.

Nurses are the key team members advising on bowel care following spinal cord injury.

**Joints**

Wear and tear of upper-limb joints is increased. As paraplegic patients get older, episodes of upper-limb joint pain and stiffness occur with increasing frequency, especially in the shoulder girdle.

Heterotopic ossification can occur in the early stage following injury. Hip mobility can be severely impaired. Transfers and activities of daily living become more difficult. The ossification process eventually becomes quiescent. Surgery is rarely required. It should only be undertaken after ascertaining that there is no residual heterotopic activity. There is a small place for radiotherapy immediately following excision of abnormal tissue.

Contractures interfere with independent living, mobility, and transfers. They give rise to pain and disability. In tetraplegics, contractures of the shoulders, elbows, and wrists are a particular problem. In paraplegics, lower-limb contractures prevent ambulation and interfere with transfers.

Therapy to joints is essential at all stages following spinal cord injury, and especially in the acute phase. Splinting of hands and correct positioning of shoulders and elbows can prevent unnecessary upper-limb joint morbidity. Therapists should establish the treatments that should be continued by the patient, carers, and family.

In the chronic spinal cord-injured person long-bone fractures occur following relatively minor trauma. Internal fixation often fails because of the osteoporotic bones, infection, and the development of pressure sores. Immobilization in casts must be carefully supervised to avoid pressure sores.

**Spasms**

Spasms and spasticity usually occur in spinal cord injury. They are sometimes helpful but more usually a problem. They can cause embarrassment, hinder transfers and driving, impair sleep of both paralysed person and partner, and throw the legs and trunk out of position.

Treatment of spasms includes eradication of any precipitating cause, in particular intravesical and bowel-related pathology, good physiotherapy including standing, systemic drugs such as baclofen, tizanidine, and dantrolene, local injections such as botulinum toxin, and, occasionally, operative intervention such as insertion of an intrathecal baclofen infusion system.

Systemic medication for spasticity has adverse effects. Baclofen causes drowsiness and interferes with concentration, affecting both quality of life and employment. The intrathecal drug delivery systems can have complications such as tube dislodgement and kinking.

For the management of spasticity to be effective there must be expertise in the spinal cord injury centre in all relevant physiotherapeutic, medical, and surgical techniques. Intrathecal pump insertions should only be carried out by those with experience.

**Respiratory system**

Permanent ventilator-dependent patients can live safely in the community provided that they have sufficient care. A trained carer must at all times be ‘in-line-of-eye’ of the ventilated person. This carer must be able to carry out tracheal suctioning, tracheostomy replacement, ventilator reconnection, and bagging. Alarms to summon help immediately are required. With a portable ventilator and other suitable devices, good mobility including aircraft travel can be achieved. High tetraplegic ventilated patients value their lives even though these are impoverished in physical terms.

Mid- and low-cervical patients have good diaphragmatic control but no intercostal or abdominal muscle function. Their cough is weak.

Respiratory impairment is the most important increased risk to life in tetraplegics. Carers need to be carefully instructed in the relief of choking, the assisted cough, postural drainage of the chest, the cough assist machine, and clearance of secretions.
Mid-thoracic paraplegics lack a good cough because their abdominal muscle control is absent. They require help with chest infections in their older years.

For the management of respiratory problems to be fully effective there must be a chest specialist available who has a special interest in the respiratory problems of the spinal cord-injured. Expert anaesthetic support is required to make domiciliary ventilation as safe as possible.

**Box 12.45.6 Consequences 2**

- Upper-limb arthritis problem in older patients
- Heterotopic bone
- Contractures may occur
- Spasms common
- Ventilatory problems highest risk for life
- Autonomic dysreflexic episodes can be very troublesome.

**Cardiovascular system**

Postural hypotension is a common problem in the early stage following spinal cord injury. It is seldom disabling thereafter. It can cause muscle neck and shoulder girdle ischaemic muscle pain that is mistaken for spinal column pathology.

Autonomic dysreflexia is a serious potential problem in all patients with injuries at T6 and above. It can be precipitated by any stimulus arising below the level of injury. The most common are those from the bladder and the bowels. Some events, such as rectal electrostimulated semen emission and vibrator-induced ejaculation, are particularly potent stimuli.

During autonomic dysreflexic episodes the arterial blood pressure can rise to dangerously high levels. Cardiac dysrhythmia may occur. Patients may describe their heads bursting open with pain. Sweating may be so profuse that a change of clothes or bedding is necessary.

Because tetraplegics cannot deal with the factors that precipitate autonomic dysreflexia, care must be available to ensure that when such attacks occur they are dealt with promptly and safely. It is essential that staff, patients, family, and carers are fully conversant with the diagnosis and treatment of this unpleasant and dangerous complication.

Despite immobility and leg dependency, deep venous thromboses and pulmonary emboli are uncommon except in the early stage following injury. Anticoagulation is rarely required following the acute stage. In contrast, cardiac and arterial problems are common. Cardiovascular exercise through FES (functional electrical stimulation) cycling or rowing, treatment of dyslipidaemias, cessation of smoking, and attaining an ideal weight are essential.

Peripheral oedema and superficial vascular skin changes are common. Careful attention must be paid to the feet so that cellulitis and other complications are avoided. Chiropody is sometimes helpful. Cardiovascular risk factors need to be regularly reviewed.

**Skin (Box 12.45.7)**

Immobility and loss of sensation contribute to the risk of pressure sores. Careful discipline and good care will largely prevent their development. The insensitive skin must be inspected morning and evening. The minor red marks and skin abrasions that occur during transfers are best treated by rest in bed until the skin has returned to normal.

With aging, the skin and its underlying tissues become less resilient and the risk of pressure sores increases. Patients may go many years without a pressure sore and then develop a serious one.

During the acute stage following injury turning every 2h in bed is necessary. In the later stages such frequent turning is rarely required. Prone lying is an excellent way of maintaining the hips, minimizing spasticity, and preventing pressure sores.

Paraplegics are usually able to turn in bed independently in their younger years. They require increasing help as they get older. Various aids such as monkey poles are helpful. Tetraplegics usually require assistance with turns. The required time between turns in bed at night depends on the individual. A risk assessment will indicate if one or two people are required for turns.

Variable height beds make transfers easier. The ability to elevate the head of the bed aids independence. Rotating beds are seldom popular. Most patients prefer double beds that they can share with their partners. Beds that appear normal are preferred to beds with a hospital appearance.

Specialist mattresses increase the time between turns and reduce the burden on carers. They can make turns more difficult.

Different types of cushions are available. The appropriate one for the individual must be selected. A spare cushion is required in case the main one is damaged. Good posture is as important as cushions in the prevention of pressure sores. A Jay Back may be required to correct posture. The Jay Protector enables patients to go up and down steps on their bottoms and to travel more safely in vehicles when other methods for buttock support are not available.

The nursing staff of the centre must be conversant with teaching techniques for lifting and turning to patients, families, and carers.
A posture and seating clinic is essential to ensure that the optimum seating system for the patient is defined.

**Sexual function**

Sexuality is severely impaired following spinal cord injury. Men sometimes feel incomplete because not only is normal sexual intercourse impossible but also they feel they cannot be full husbands, fathers, and breadwinners, or be involved in ‘masculine’ activities.

Women can lose their self-respect. Wearing attractive clothes such as skirts is limited by the leg-bag and the wheelchair. Urinary incontinence reduces self-confidence and produces a smell of urine.

Although many approaches are available to achieve erections, including oral medications, implants, intracavernosal injections, and external aids, the spontaneity, sensation, and orgasm of normal intercourse are lost. Oral phosphodiesterase inhibitors such as sildenafil produce effective erections in approximately 70% of impotent males.

Fertility in spinal cord-injured men is usually severely impaired. Obtaining semen is the first problem. Methods for achieving this include the penile vibrator, rectal electrostimulated semen emission, and microepididymal sperm aspiration. The second and more important problem is oligoasthenospermia.

Fertility centres are usually required for parenthood to be achieved. Their contribution includes preparation of the semen and treatments of the female partner to increase her fertility. Of the current techniques, intracytoplasmic sperm injection has the highest success rate. Men without any motile sperm, such as those who were prepubertal at the time of injury, can now become fathers.

Female intercourse is possible but passive. Orgasm does not occur except in women with lower levels of injury. Fertility is usually unimpaired.

---

**Box 12.45.7 Consequences 3**

- Pressure sores prevented acutely by 2-hourly turns
- Specialist pressure relieving equipment may be needed
- Sexual function severely affected in men
- Affects male fertility
- Causes stresses in family life.

---

Both male and female spinal cord-injured people face limitations in their parental roles. Relationships and marriages are under greater stress following spinal cord injury. The prospects for maintaining and developing lasting relationships are reduced, particularly in young women.

The spinal cord injury service must have doctors, nurses, and therapists who are knowledgeable in the sexual problems that follow spinal cord injury. Sexuality and fertility clinics are important. A gynaecologist with a special interest in the particular problems of the spinal cord paralysed woman is essential. Close liaison with a fertility clinic is mandatory if optimum live birth rates are to be achieved for couples where the male partner is spinal cord-injured.

**Mobility (Box 12.45.8)**

Wheelchair selection requires expert therapist assessment. Different wheelchairs are necessary for different purposes. A sports wheelchair, a lightweight wheelchair, and an outdoor electric wheelchair may be required by the same person for use at different times.

The pattern of wheelchair requirement varies with the individual. It also changes with age. A young tetraplegic can cope with a lightweight manual wheelchair on level surfaces and up shallow slopes. In their older years they will require an electric wheelchair instead.

The range and type of wheelchairs that are available is enormous and constantly changing. Before the appropriate wheelchair for an individual is selected it must be evaluated in a practical setting. The most sophisticated wheelchairs allow control of the environment through systems built into the wheelchair. These chairs can also take portable ventilators. They can provide stand-up or reclining facilities.

The wheelchair must be integrated with an appropriate car for satisfactory mobility out of doors. The selection of the appropriate vehicle and its controls requires careful assessment in a specialized centre. The individual characteristics of the patient must be considered. Tall tetraplegics are restricted in the vehicle that they can use whilst seated in their electric wheelchair. Swivel seats aid transfers.

In general, tetraplegics at the level of C5 and below are able to drive. Those at C5 usually require a joystick control. Some at C6 and most at C7 and below can cope with vehicles with hand controls, automatic transmission, servo-assisted brakes and power-assisted steering.

Ambulation is seldom a functional form of mobility for paraplegics or tetraplegics but it can be useful as a form of exercise. For
those with poor truncal balance, such as low tetraplegics and higher-thoracic paraplegics, orthoses that provide truncal support are necessary. With lower thoracic and upper-lumbar levels of injury, knee–ankle–foot orthoses usually suffice. Those with good quadriceps control usually ambulate with ankle–foot orthoses alone. The majority of spinal cord-injured patients who learn to ambulate soon cease to do so. Few regret having mastered the technique.

**Box 12.45.8 Transport**

- Public transport difficult
- Air travel possible
- Many can drive.

Public transport, such as buses and trains, is difficult. Air travel is usually feasible.

Recreational mobility equipment, such as the quadbike for mobility over rough ground, can be helpful.

A portable ramp is useful when visiting places where ramped access is not available.

**Transfers**

This refers to the way in which a paralysed person gets from one position to another.

Nearly all paraplegics become independent in level transfers. Most achieve the more difficult split-level transfers such as from easy chair to wheelchair and out of the bath. The most difficult transfers, such as getting from the floor into the wheelchair, are achieved by only the most able.

There is great individual variation between paraplegics in their capability with transfers. Factors associated with reduced ability include increasing age, poor truncal balance, spasticity, spasms, obesity, joint contractures and upper-limb problems such as muscle strains and nerve injury. Those with a low arm to trunk length ratio, for example, achondroplastics, seldom achieve independent transfers.

A few low-level tetraplegics become totally independent in transfers, usually with the aid of a sliding board. Most require help.

The minimum pattern of help required by each individual is best determined by a risk assessment after a course of rehabilitation in a spinal cord injury unit. Hoists are important transfer aids. Portable hoists are versatile but ceiling mounted ones take up less room.

**Activities of daily living (Box 12.45.9)**

This refers to the normal activities of daily life that the able-bodied take for granted. The occupational therapy department is vital in this area.

Paraplegics are usually independent. Tetraplegics are usually partially dependent, especially in lower-half activities such as washing, dressing, and personal hygiene. Obesity, poor truncal balance, increasing age, upper-limb musculoskeletal problems, spasms, spasticity, and short arms reduce the ability to carry out activities of daily life.

Higher-level tetraplegics benefit substantially from environmental control systems. Provided that a single muscle can be voluntarily moved in an accurate and predictable manner then the environment can be controlled, such as closing curtains and using the telephone. An expert is required to advise which system is appropriate to an individual’s needs.

Most paraplegics and tetraplegics benefit from remote control door-openers.

**Box 12.45.9 Activities of daily living**

- Paraplegics are usually independent.
- Tetraplegics are usually partially dependent.
- Multiple adjustments to home usually required.
- Recreational activities limited.

Paraplegics are usually able to manage wall-mounted shower seats. Higher-level paraplegics and low-level tetraplegics find the shower chair system more helpful.

Most paraplegics can manage a normal bath whilst they are young. This becomes more difficult with aging. A bath-board may then help. Eventually a specialized bath is required.

**Psychology**
The effects of sudden paralysis, potential double incontinence, impotence, infertility, loss of personal relationships, and all the other manifestations of spinal cord damage insinuate into every facet of life. The impact can be devastating. Despite this, depression is not a major consequence of spinal cord injury. Most paraplegic and tetraplegic people who have experienced a spinal cord injury unit have learned to minimize the effect of their disability. They seldom concentrate on what they cannot do. Children in particular adapt well. Counselling may be helpful at various stages though it is usually resisted.

The psychologist in the multidisciplinary team has an important role not only in diagnosing and treating patients but also in assisting family and staff in dealing with the psychological and emotional strains that surround spinal cord injury. A psychiatrist with a special interest is essential because first the risk of suicide is increased and second psychiatric conditions such as depression and schizophrenia can result in traumatic spinal cord injury.

**Family**

The enormous impact of paralysis on the family including parents, siblings, spouses, and children must be considered. Relationships can be destroyed. The old age of parents can be shattered by paralysis in their children. The ability of the spinal cord-injured person to be a complete father, mother, husband, or wife is severely impaired. The adverse effects on the family rebound on the patient who sometimes feels guilty for the suffering caused.

It is no longer widely accepted that family members should look after their spinal cord-injured relative. It is better for normal relationships to be retained. A wife should remain wife, mother, and lover, rather than become nurse and carer.

Family teaching days are essential. Chronic spinal cord-injured patients and their families provide invaluable insights based on experience to the families of those who have recently been injured.

**Home**

The accommodation in which most spinal cord-injured people live at the time of their injury is seldom suitable for life in a wheelchair. Early housing assessment is required.

Incomplete paraplegics who can ambulate and cope with stairs in their younger years find this increasingly difficult as they grow older. Many eventually become wheelchair dependent. Crutch and rollator walking take up more space than normal ambulation. Doorways and corridors need to be wider to take account of this.

Tetraplegics and complete paraplegics are safer in ground-floor wheelchair accessible accommodation. This is seldom achieved in the United Kingdom because most houses are two-storey, and most spinal cord-injured people like to remain in their own area. Accordingly, through-floor lifts and stair-lifts are usually required.

The precise housing requirements following spinal cord injury depend on the person concerned and the pattern of disability. It is seldom possible in the United Kingdom for all needs to be met by statutory authorities so compromise is almost always required.

There should be a covered way for the car and from the car to the front door together with adequate space for the patient to get in and out of the vehicle under cover. There should be appropriate, usually ramped, access to the house. Doorways and corridors should be of sufficient width to accommodate the wheelchair base and turning circle. Adequate storage space should be available to avoid equipment cluttering up corridors and living space. The main bedroom should be of sufficient size for ready wheelchair mobility and with adequate storage space for catheters, urinary sheaths, and other personal equipment. There should be an en suite toilet and bathroom to the main bedroom. For tetraplegics, and paraplegics in the later years of their lives, carer accommodation is required.

Paraplegic and tetraplegic people are less able to maintain their body temperature. Adequate heating is required. The temperature control of tetraplegics is compromised by their altered sympathetic nervous system, so air conditioning is required.

**Recreation**

Recreations possible before injury are seldom practicable afterwards. A home computer system is often helpful. High tetraplegics benefit from page-turners. Although some paraplegics and tetraplegics enjoy wheelchair sports, the majority are no more sporting that the rest of the population. Access to places of public enjoyment such as theatres and cinemas is often difficult.

Regular holidays help to maintain morale and family relationships. They are usually more expensive. Extra help is required.

Occupational therapists, and specialist clubs and societies can provide information. Many recreations such as skiing, scuba diving, piloting aeroplanes, sailing, abseiling, and various sports are possible.

**Employment**

This most important rehabilitation goal is often not achieved. The opportunities for employment following spinal cord injury are greatly reduced.

Many universities have facilities where spinal cord-injured people can study. Most succeed in obtaining good degrees. However, there is a great difference between obtaining a qualification and achieving employment. In general, the wheelchair dependent are disadvantaged when there is competition.

Those who had physical outdoor manual employment prior to injury, and in particular those with poor academic backgrounds, usually remain unemployed.

Academically capable patients and those who succeed in retraining in clerical skills still face many problems. It takes longer for
them to get up and get going in the morning. At work the car must be under cover and with access from it to the place of work. The latter must be wheelchair accessible. Getting from one floor to another and from one building to another is usually difficult and sometimes impossible. There must be facilities at work to allow for episodes of incontinence. Employers have to accept that complications such as red marks and urinary tract infections will result in time off work. Drugs such as baclofen interfere with concentration and mental agility.

Although many paraplegics and some tetraplegics achieve some form of employment, it is more likely to be part-time than full-time, and intermittent rather than continuous, and involve early retirement.

**Continuing medical care**

In the chronic stage following spinal cord injury, complications such as pressure sores and urinary tract infections can arise. Some can be successfully treated at home. When hospital admission is required, this should be into a spinal cord injury centre. Annual comprehensive review in a spinal cord injury unit is required.

**Aging**

It is essential that the effects of ageing are taken into account when planning a spinal cord injury service. There is no stereotypical pattern for aging. Some people are intrinsically more able than others. Others have the effects of aging brought forward by problems such as contractures.

**Community care**

Low-level paraplegics are usually independent when young apart from domestic activities, shopping, certain obstacles out of doors, gardening, and home maintenance.

Mid-level paraplegics may require assistance with the standing frame, bath and car transfers, and lifting the wheelchair in and out of the car. Spasticity, spasms, intrinsic ability, obesity, truncal balance, and age are important.

Most low-level tetraplegics require some assistance. For example, they can feed themselves but not cut meat. They can drive a car but not transfer into it or lift in the wheelchair. Someone should be on hand to deal with an emergency such as autonomic dysreflexia or choking on food.

Whilst in general it is not appropriate for family members to be involved in the care of their relations, they frequently choose to do so and provide extremely good care.

In general, carers can carry out straightforward physiotherapy activities provided that they are initially trained and subsequently monitored by specialist physiotherapists.

### Conclusion

The successful rehabilitation of a spinal cord-injured person is dependent on a full understanding of the particular individual including past history, current situation, and future aspirations. Treatment should be in a spinal cord injury centre that can manage all acute, subacute and chronic aspects.

The clinical service specifications of a modern United Kingdom spinal cord centre have been laid out. They include cooperation in the efficient retrieval and early admission of acute spinal cord-injured patients for specialized care, the provision of all necessary treatment in the acute, subacute, and chronic phases, life-long surveillance, readmission when required, and outreach services at all stages.

Pelvic ring fractures: assessment, associated injuries, and acute management

DOI: 10.1093/med/9780199550647.003.012046

Summary points

- The contribution of the soft tissue and bone in each fracture pattern must be understood
- A large proportion of pelvic fractures will have significant associated injuries
- Successful management of haemodynamically unstable pelvic fractures requires advance planning.

Introduction

Pelvic ring fractures within the developed world are reported as having a yearly incidence of 23 per 100,000 population. Of 23 patients there will be three prehospital deaths, ten high-energy injuries, and ten low-energy injuries. Only high-energy injuries are discussed here. These are potentially life-threatening injuries and their outcome is very dependent on the early management.

Anatomy

The pelvic ring is formed by the sacrum and two innominate bones. The innominate bones are formed from the ilium, ischium, and the pubis. These bones are connected by the triradiate cartilage of the acetabulum which is fused by approximately 16 years of age.

Axial load is transmitted between the innominate bones and the sacrum via the sacroiliac (SI) joints. The SI joint has an irregular surface and a relatively small synovial cavity. There are small rotatory movements during gait. Posteriorly the joint is spanned by the interosseous and posterior SI ligaments that originate from the posterior iliac crests and insert across the entire sacrum. The sacrum effectively hangs between the innominate bones supported by the very strong posterior ligament complex; this is analogous to a suspension bridge (Figure 12.46.1B). The orientation of the SI joints contributes little to the mechanical stability. The majority of stability comes from the posterior SI ligaments. The anterior SI joint ligaments are weak in comparison.

The anterior part of the pelvis is formed by the pubic rami and a symphysis that is composed of hyaline cartilage, fibrocartilage, and ligament.

The pelvic floor is spanned by the sacrotuberous and sacrospinous ligaments (Figure 12.46.1A) and in combination they resist external rotation and shearing forces. The sacrotuberous ligament also resists flexion (sagittal plane rotation) (Figure 12.46.1C). To understand the contribution of these structures it is important to appreciate the orientation of the pelvis in the anatomical position. The muscles of the pelvic floor contribute little to the stability of the pelvic ring.

In single-leg stance the anterior part of the pelvic ring acts as a strut resisting compression. In double-leg stance the anterior part of the pelvic ring and pelvic floor ligaments are under tension.

The L5/S1 disc provides the connection between the pelvic ring and the lumbar spine this is augmented by the iliolumbar and lateral lumbosacral ligaments that connect the transverse process of L5 to the iliac crest and sacral ala, respectively.

When the pelvic ring is disrupted, the abdominal wall helps to limit pelvic volume; this is breached during a laparotomy.

Pelvic stability

Stability is defined as the ability of the pelvic ring to withstand physiological forces without abnormal deformation. This is a key concept in the management of pelvic injury.
When a force is applied to the pelvis, both the bone and ligaments fail sequentially in a predictable order. As the pelvis functions mechanically as a ring, disruption of one part necessitates disruption elsewhere. However, that disruption is not always complete and mechanical continuity can be maintained by the ligaments. The transition from stable to unstable patterns is dependent on the integrity of both the bone and ligamentous structures that make up the posterior part of the pelvic ring (Box 12.46.1).

**Box 12.46.1 Pelvic ring injuries**

- Stable
- Partially or rotationally unstable
- Completely unstable.

A pelvic injury is described as completely unstable when a hemipelvis is unable to resist deformation in any plane. For this to occur there must be a complete disruption of the anterior and posterior pelvis (bone, joint, or ligament) resulting in a mechanical disconnection of the lower limb from the axial skeleton.

Pelvic injuries can also be considered partially or rotationally unstable when there is incomplete disruption of the posterior complex and pelvic floor ligaments. Vertical stability may be maintained, however there is loss of stability in the horizontal plane, e.g. internal or external rotation.

There are a group of stable pelvic ring fracture patterns that do not compromise the mechanical integrity of the pelvic ring. This group also includes include avulsions (e.g. avulsion of rectus femoris with anterior inferior iliac crest) or direct blows (e.g. transverse sacral fractures below the sacrogluteal arch and iliac crest fractures). The management of these injuries will be dealt with in the next chapter (Chapter 12.47).

How the pelvis fails during loading is dependent on many factors such as bone density, rate of loading, contact surfaces, etc. The direction of force, however, is the key factor in determining injury pattern and allows us to understand the residual stability.

**Classification (Box 12.46.2)**

Many classifications have been proposed; however, the two dominant concepts are stability and direction of force. The evolution of a classification based on direction of force has culminated in the Young and Burgess classification. The degree of residual stability has been used in the comprehensive classification system. The most recent version has been produced after collaboration between the AO group and the Orthopaedic Trauma Association (OTA) in 2007.

In addition, the Denis classification is commonly used to describe the sacral component of the pelvic fracture.

**Young and Burgess pelvic ring fracture classification**

The Young and Burgess classification system groups injuries according to the direction of force; anteroposterior compression (APC), lateral compression (LC), vertical shear (VS), and combined mechanism (CMI). APC and LC injuries are further subdivided according to severity. This classification has been used to correlate injury patterns with blood loss and associated injury.
The force is applied directly to the pelvis or through the flexed hip, along the femoral axis, in an anteroposterior (AP) plane. Failure occurs initially at the anterior ring through the symphysis or through vertically orientated fractures of the pubic rami. Direct AP blows may result in fracture of all four pubic rami. This can be seen in ‘straddle’ type of injuries where the rest of the pelvic ring and floor remains intact. More commonly with AP loading the hemipelvis externally rotates resulting in diastasis of the pubic symphysis.

An APC I injury occurs when the pelvic floor ligaments are stretched but maintain their mechanical integrity. With further external rotation the ligaments of the pelvic floor and SI joint start to stretch and then fail from anterior to posterior. With displacement of the symphysis in excess of 2.5cm it can be expected that the anterior SI and ligaments of the pelvic floor will have ruptured, resulting in an APC II injury. The integrity of the posterior SI ligament in isolation will prevent vertical displacement and therefore retain stability in this plane. With further external rotation the last structure to fail in this mechanism is the posterior pelvic ligament complex (interosseous followed by posterior SI), resulting in an APC III injury. Although vertical displacement may not be apparent on the diagnostic imaging this injury is unstable in both the horizontal and vertical plane. Pure AP compression injuries may result in external rotation bilaterally.

**Box 12.46.2 Classification systems**

**Young and Burgess**

- **APC:**
  - I—stable
  - II—rotationally unstable
  - III—completely unstable

- **LC:**
  - I—stable
  - II—rotationally unstable
  - III—LC ipsilateral and APC contralateral, ‘roll over’

- VS: completely unstable

- CM: combined mechanism

**AO/OTA classification**

- A: stable
- B: rotationally unstable
- C: completely unstable

**Denis**

- Zone I: lateral to foramen
- Zone II: involving foramen
- Zone III: extends into spinal canal.

**Lateral compression**

Lateral compression is the most frequent mechanism (up to 80%) and is seen with side impacts and crush. Failure of the anterior ring tends to occur through transverse orientated fractures of the pubic rami (ipsilateral, contralateral, or bilateral) (Figure 12.46.3). The most frequent method of failure posteriorly in a lateral compression fracture involves an impacted crush of the sacrum. Due to the impaction, intact posterior pelvic ligament complex (that spans the fracture posteriorly) and pelvic floor ligaments LC I injuries retain both vertical and horizontal stability.
In the case of LC II injuries there may be complete disruption of the posterior pelvis either through the SI joint, posterior ilium, or both. SI disruption occurs when the anterior sacrum acts as a pivot and the lateral compressive force produces a complete disruption of the posterior ligament complex. The ‘crescent’ fracture pattern is a fracture/dislocation through the anterior part of the SI joint and the posterior ilium. The ‘crescent’ refers to the posterior superior iliac crest that remains attached to the superior part of the posterior ligament complex. There is no impaction and therefore these injuries are rotationally unstable, the integrity of the pelvic floor ligaments provides ‘relative’ vertical stability. With significant internal rotation of the hemipelvis there is also the potential for superior rotation and subsequent leg length discrepancy.

LC III injuries are associated with more extreme internal rotation with associated external rotation of the contralateral hemipelvis and increased instability. This injury often results from a rollover type mechanism rather than falls and lateral impact motor vehicle collisions that are seen commonly in LC I and II injuries. The pattern of associated injuries is also different with less head, chest, and upper abdominal injury.

Lateral compression can also cause isolated extra-articular fractures of the ilium (Duverney fractures).

Vertical shear
Axial loading, directly or through an extended leg, results in superior displacement of the hemipelvis and indicates complete disruption of both the anterior (pubic symphysis or vertically orientated pubic rami fractures) and posterior pelvic ring (sacrum, SI joint, or ilium) with rupture of the (pelvic floor) sacrospinous and sacrotuberous ligaments, (Figure 12.46.4). This injury mechanism is usually due to a fall from height or motor vehicle collisions and results in complete instability of the hemipelvis. Vertical displacement is usually apparent on the original x-rays.

Combined mechanism
The direction of force may not be readily apparent in some circumstances either due to a combination of sequential forces (e.g. ejection from vehicle followed by landing) or resultant force acting in a different plane. Common patterns include lateral compression/vertical shear and AP/vertical shear.

Comprehensive pelvic ring classification (OTA/AO)
The comprehensive classification is an alpha-numerical code used for coding throughout the body. In relation to pelvic injuries they are categorized according to residual stability of the pelvic ring. The code for pelvic ring is 61 and subdivided into A, B, and C. Group A represents stable pelvic ring injuries. Group B represents partially unstable injuries and Group C represents complete instability. Subclassification further describes the injury.

Details of the classification can be found at: http://www.ota.org/compendium/compendium.html

Denis fracture classification
The Denis classification describes the relationship of the sacral fracture to the sacral foramen and has been correlated with neurologic injury (Figure 12.46.5). Zone 1 injuries are defined as fractures restricted to the sacral ala lateral to the sacral foramina.
Zone II injuries involve the sacral foramina but do not extend medially into the sacral canal. Zone II injuries may also result in instability at the lumbosacral junction. This is dependent on the relationship of the vertical fracture line with the L5/S1 facet joint. Fractures running lateral to the joint are not associated with instability, however fractures running into or medial to the facet joint have the potential for instability at L5/S1 as the facet joint is either defunctioned or separated from the axial skeleton.

Any fracture that extends into the sacral canal is defined as Zone III. Zone III fractures also include pure transverse fractures and complex fractures with a transverse component (e.g. 'U', 'Y', 'H' and 'Λ' patterns) (Figure 12.46.6). These complex fractures result in complete discontinuity between the spine and pelvis.

Associated injuries

Pelvic fracture should be considered a marker for high-energy injuries and associated injuries are very common. All of these associated injuries can have a significant impact on morbidity and mortality.

Vascular injury

In addition to the bleeding from fracture surfaces, significant blood loss may arise from venous and arterial vascular injury. Venous bleeding is much commoner than arterial bleeding. Significant arterial bleeding source is identifiable in 4–15% of cases, and is commoner with more severe injuries of the pelvis. The superior gluteal is the most frequently injured in unstable posterior injuries and the pudendal and obturator vessels are the most commonly injured vessels as a result of the anterior ring injuries.

Genitourinary lesions
The frequency of associated injury to the bladder and urethra is reported at 7–25%. Injuries to the urinary tract are frequently multifocal and the overall frequency and anatomic distribution of urinary tract injury is similar in both APC and LC injuries. Although the fracture pattern is not predictive of urinary tract injury, the type of injury is related to the pelvic fracture pattern.

Bladder injury has been reported with a frequency of 9–16%, of these 60% are extra-peritoneal, 30% intraperitoneal, and the remainder are a combination of both. Extraperitoneal injuries result from a shearing force and commonly involve the anterolateral and base of bladder. Intraperitoneal ruptures tend to occur at the dome as the result of blunt injury to a distended bladder. Due to the high energy involved, pelvic fractures associated with bladder rupture have increased mortality rates. Perforations can also occur directly from the fractured bone ends.

Partial and complete urethral injury (Figure 12.46.7) is seen in approximately 10–22% of males and usually involves the posterior part of the urethra, below the level of the sphincter. Female urethral injury is rare and is often secondary to laceration from fracture fragments. Injury involving the bladder sphincter can result in incontinence.

Abdominal and thoracic injury

The frequency of associated abdominal injury is 15–26%, and in unstable pelvic fractures the frequency of abdominal injury is up to 55%. Although the incidence of abdominal injury is high, only a proportion will require laparotomy, this can create difficulty in identifying, prioritizing and managing ongoing blood loss. Pelvic fracture with a liver injury requiring packing has been associated with a 60% mortality rate.

The rectum is held within the muscular pelvic floor, and when the pelvic floor is torn it is at risk of injury.

Abdominal compartment syndrome should be considered in patients with pelvic and abdominal injury, this may be secondary to visceral oedema or ongoing bleeding resulting in a tense abdomen, respiratory compromise and renal dysfunction.

Approximately 20% of pelvic fractures will have a thoracic injury greater than AIS (Abbreviated Injury Scale) 2.

Neurological injury

Pelvic fractures are frequently associated with central and peripheral neurological injury. In the United Kingdom, AIS scores higher than 2 for head injuries have been identified in 17% of cases. Head injury is particularly common in lateral compression injuries. This has been related to frequently occurring motor vehicle side impacts. Head injury has a significant influence on mortality and outcome.

Up to 25% of high-energy pelvic fractures will have an associated spinal injury.

Peripheral nerves are also susceptible to injury. The anterior lumbar, sacral, and coccygeal rami form nerves which traverse the pelvis providing motor and sensory function to the pelvic viscera, perineum, and lower limbs. Neurological deficit may be subtle and has been reported in up to 21%. The sacral nerve roots and lumbosacral trunk are at risk from posterior pelvic ring disruption either as a result of being crushed within sacrum or stretched due to pelvic or sacral displacement. The location of the sacral injury influences the risk of neurologic deficit: zone I, 5.9%; zone II, 28%; and zone III, 57% (within this group, bowel, bladder, and sexual dysfunction occurs in 76%). In transverse sacral fractures there is a higher incidence of bladder dysfunction at the S1–3 level compared with S4 and below.

Assessment of a pelvic injury should be conducted along ATLS® principles. With appropriately trained personnel many of the steps
can be performed simultaneously rather than sequentially.

The following elements of the assessment are particularly pertinent to pelvic trauma:

- Haemodynamic assessment and response to resuscitation
- Evidence of other sources of bleeding
- Full blood count, clotting, acid-base, lactate, and cross-match
- AP pelvic x-ray as part of the primary series. Pubic symphysis diastasis greater than 2.5cm is suggestive of horizontal plane instability and more than 1cm distraction of the SI joint is suggestive of complete posterior instability. Pubic rami fractures displaced more than 1.5cm are suggestive of complete disruption of the obturator membrane and inguinal ligament. Occasionally unstable pelvic fractures may look relatively normal on the AP x-ray when a pelvic binder has been applied in the prehospital setting. Radiographic findings such as posterior fracture gap (rather than impaction), avulsion of L5 transverse process, lateral border of sacrum (sacroiliac ligament), or ischial spine (sacrospinous ligament) or SI displacement of 5mm in any plane should alert the clinician of the potential for instability
- Temperature
- Rectal examination to identify abnormal rectal tone or sensation, high-riding prostate, or fresh blood suggestive of a rectal tear. Rectal examination can be performed with the patient supine
- Vaginal examination to assess for tears
- Evidence of genitourinary bleeding. Blood at the meatus (98% sensitive for urethral injury). If positive a retrograde urethrogram and cystogram (with pre- and postdrainage films) should be considered
- Evidence of significant soft tissue injury:
  - Degloving (Morel—Lavallée lesion)
  - Open fractures
- Evidence of abnormal leg position and limb length discrepancy
- Tenderness, palpable gaps, and crepitus both anteriorly and posteriorly. Posterior tenderness over the SI joint is suggestive of injury to the posterior ligament complex
- Evidence of neurological deficit in the lower limbs. Particular attention to entire motor and sensory distribution of the lumbosacral plexus including anorectal/bladder and gluteal muscle dysfunction
- Lower extremity pulses
- Log roll and physical assessments of stability should not be performed in the haemodynamically unstable patient. Radiographic findings are usually sufficient and the primary clot should not be jeopardized.

Further assessment and management

The appropriateness and urgency of further assessment and management is dependent on the haemodynamic stability.

Haemodynamically unstable pelvic fracture

There is controversy regarding optimum management. However, there is evidence and consensus that the outcome is improved if the treatment plan is protocol driven. Optimum management will be dependent on the institution and is best considered as a series of standard steps:

- Identify the patient at risk (Box 12.46.3)
- Resuscitate (Box 12.46.4)
- Identify source of bleeding (Box 12.46.5)
- Haemostasis (Boxes 12.46.6 and 12.46.7).

Box 12.46.3 Identifying patient at risk

- Haemodynamically unstable patient with suspected pelvic fracture should be transferred to an appropriate facility:
  - 30% increased incidence of survival
- Pregnant
- Elderly
- Systolic BP <90mmHg
- Response to resuscitation
  - BP <90mmHg after 2 units packed red blood cells (73% positive predictive value for arterial bleeding)
  - Haemodynamic instability associated with >40-60% mortality
- Base deficit:
• >5mmol/L associated with significant bleed
• 9mmol/L = average in non survivor group
• >12mmol/L associated with 50% mortality rate

♦ Abnormal clotting
♦ Blood transfusion:
  • ≥6 units of blood in 12h associated with >40% mortality rates

♦ Triage Revised Trauma Score (T-RTS—based on Glasgow Coma Scale, systolic BP, and respiratory rate).
  • T-RTS ≤8 associated with a mortality rate of 65%.

Box 12.46.4 Resuscitation

♦ Activate trauma team (preferably prior to patient arrival) and early involvement of all additional involved specialties (blood bank, theatres, neurosurgery, urology, obstetrics, etc.), this will facilitate decision-making and avoid time wasting
♦ ATLS to deal with associated immediately life-threatening injury
♦ Pelvic binder/sheet—to reduce pelvic volume and stabilize clot
♦ Pack open pelvic wounds—to help formation of clot
♦ Avoid disturbing the clot with unnecessary movements
♦ “Permissive hypotensive/’balanced’ resuscitation, until evidence of haemostasis (unless head or spinal cord injury)
♦ Aggressive correction and prevention of coagulopathy
♦ Maintain core temperature
♦ In the event of an early transfer ensure that resuscitation can continue.

Box 12.46.5 Identify source of bleeding

♦ ATLS primary survey
♦ FAST + DPL to be considered (confidence in result?)
♦ Can the patient survive CT with contrast in your institution?

Box 12.46.6 Indirect haemostatic techniques: decision making

♦ No useful comparative clinical trials available
♦ Any stabilization applied quickly is likely to be better than none
♦ How quickly can embolization be performed in your institution?
♦ Is the fracture pattern amenable to stabilization with a binder/sheet and will an external fixator provide improved reduction and stability in the short term?

Box 12.46.7 Direct haemostatic techniques: decision-making

♦ Mortality is related to the rate of bleeding and the speed at which it is stopped
♦ Is there evidence of ongoing haemodynamic instability despite adequate resuscitation and indirect methods? If yes, proceed with direct haemostatic technique ASAP:
  • Patients who respond to initial resuscitation with ongoing manageable resuscitation requirements are good candidates for AE—can the patient survive the time required to set-up, transfer, and perform AE in your institution?
  • If the patient has failed to respond to 2L of crystalloid and 2 units of packed red blood cells it is recommended that EPP is considered
  • In the patient with multiple potential sources of bleeding the operating theatre is the best environment to prioritize, treat, and reassess
  • If laparotomy is required, perform external fixation ± packing ± minimal internal fixation
  • If EPP is to be performed notify interventional radiology team, they will have time to set up during the operative procedure in the event that EPP fails
Quick, minor interventions can be life saving during the early phase as the majority of pelvic fractures will be amenable to simple interventions performed efficiently. Ongoing bleeding that does not stop with splintage and resuscitation will require surgical or angiographic control and this will take time to organize.

An early decision should be made with regard to transfer. This a contentious issue which requires senior input and a common sense approach. Transfer to an appropriate facility has been demonstrated to increase the probability of survival by 30%.

Identify the patient at risk

This should start in the prehospital environment and should influence the choice of appropriate receiving facility, avoiding medical ‘speed bumps’. Many haemodynamically compromised patients will have achieved haemostasis by the time of presentation and will respond appropriately to resuscitation. The group that requires early identification are those patients who are haemodynamically unstable due to ongoing active bleeding. They will present as transient or non-responders to fluid resuscitation and are more likely to require early intervention. Identification of the ‘sick patient’ is the priority as this sets the tempo, direction and location of further aggressive management. 60% of deaths with pelvic fractures occur in the prehospital environment.

A post injury median survival time of 55min has been reported in pelvic fracture fatalities (54% <1h; 11% 1–2h; 16% 2–6h). In general the primary survey (including diagnostic peritoneal lavage (DPL) or focused assessment with sonography for trauma (FAST)), and temporary stabilization of the pelvis should be achieved within 15min and the decision with regard to requirements for haemostasis within 20–30min.

Using physiological signs and readily available investigation will allow the correct management decisions to be made in a timely fashion. Pulse, blood pressure (BP), and respiratory rate allow an estimation of blood loss. The response to fluid resuscitation is also useful to determine adequacy of resuscitation and ongoing losses.

Lactate, pH, and base deficit (BD) are useful indicators of hypovolaemic shock and when monitored will also reflect the response to treatment. Retrospective clinical review has identified BD as a better prognostic indicator than pH and is a sensitive marker for injury severity, blood transfusion requirements within the first 24h, incidence of multiorgan failure (MOF) and death. Patients with a BD higher than 5mmol/L should be considered at risk of having a significant bleed. Lactate levels are also reliable indicators of morbidity and mortality in pelvic trauma. One study demonstrated that survivors had significantly lower initial lactate levels (4.2 ± 1.8mmol/L) in comparison to those early deaths within a few hours (8.6 ± 2.5mmol/L).

The presence of coagulopathy early in the presentation of a trauma patient is a poor prognostic sign. Prothrombin time (PT) and partial thromboplastin time (PTT) are independent predictors of mortality. Initial abnormal PT increases the adjusted odds of death by 35% and an initial abnormal PTT by 326%.

Resuscitation

‘Permissive hypotensive’ or ‘balanced’ resuscitation, maintaining a systolic BP of 80–100mmHg and haemoglobin of 7–9g/dL, is appropriate in the initial management to minimize blood loss and the risk of rebleeding. This must only be used as a temporizing measure until the source of bleeding is controlled. This is not appropriate in patients with head injury or spinal cord injury and care should be used in the elderly patient. Under these circumstances it is important to maintain perfusion pressure.

To help control bleeding, a pelvic binder/sheet should be considered and open pelvic wounds should be packed.

The choice of resuscitation fluid is still an area of ongoing development; however, there is increasing evidence to suggest that early resuscitation with blood products is associated with improved outcome. The use of packed red cells (PRC) and fresh frozen plasma (FFP) in a 1:1 ratio is favoured by many trauma centres and the military.

Consideration must also be given to prevention and correction of coagulopathy. Platelets should be administered to maintain a platelet count in excess of 100 000/µL. Clotting can be further promoted with tranexamic acid and Factor VIIa. Factor VIIa is most beneficial when used before the patient becomes acidic. Fibrinogen levels should be maintained >1g/L with cryoprecipitate.

In addition, it is also important to address hypothermia. A 1° decrease in core temperature is associated with a 10% decrease in coagulation function. All intravenous fluid must be warmed.

Identify source of bleeding

In polytrauma, having identified a patient at risk, it may not be clear what contribution the pelvic fracture has made to the haemodynamic status. Accurate assessment is essential as it avoids unnecessary time wasting procedures. Significant bleeding from limb fractures is easily identified through clinical and radiological examination; blood loss volumes can be estimated. Bleeding from open injuries is less easily quantified. The majority of thoracic bleeding can be excluded with the presence of a normal chest x-ray. One of the biggest dilemmas is differentiating between ongoing pelvic and abdominal bleeding. DPL, FAST, and computed tomo graphy (CT) can help to determine the source of bleeding but they all have limitations.

The recorded sensitivity of DPL, FAST, and CT for detecting intra-abdominal injury is 1.0, 0.92, and 0.97 respectively. However, it is the lack of specificity that results in negative laparotomies, reported in one-third of cases. This has the potential to delay treatment of a pelvic bleed.
CT has high sensitivity and specificity but requires the patient to be transported to the CT scan. Emergency CT is extremely valuable in all high-energy pelvic injuries as in addition to information on the fracture pattern it allows the identification of visceral and spinal injury. In addition, CT can identify pelvic haematomas and contrast extravasation. Pelvic haematoma volumes higher than 500mL are associated with a 0.45 probability of ongoing pelvic arterial bleed. Contrast extravasation can indicate ongoing arterial bleeding demonstrable at angiography (positive predictive values 45–80% and negative predictive values of 85–99.6%). Although the negative predictive value is extremely high, a small number of these cases will require embolization and therefore the clinical situation must be monitored.

Although there is no reason for anything other than brief interruptions to resuscitation and monitoring, CT scanning may delay the necessary time critical intervention to stop the bleeding, and this must be balanced against the patient’s physiology. If the patient’s haemodynamic situation requires early intervention and does not permit CT, then DPL and FAST can be used to help in the decision-making and treatment priorities. However, they have greater limitations with regard to specificity.

FAST depends on availability and technical expertise and in general it has a reported sensitivity of 0.92 for detecting intraperitoneal fluid. However, in the context of a patient who is hypotensive (<90mmHg) from abdominal bleeding the sensitivity has been reported as 1.0. In practical terms if a patient is hypotensive, secondary to bleeding in the abdomen, and the FAST scan is negative an extra-abdominal source of bleeding should be sought.

If neither FAST nor CT are available then DPL can be considered, it has been reported as having a sensitivity of 1.0 with poor specificity (false positive rates for DPL have been reported as high as 29%). The accuracy can be improved with suprarenal placement and good technique. In a hypotensive patient unless gross bleeding is identified on the DPL, bleeding is likely to be originating from an extra-abdominal source.

**Haemostasis**

Treatment should be directed at promoting and maintaining clot formation. The quicker a haemostatic technique is adopted the more likely it is to work. All interventions directed towards controlling pelvic bleeding will fail unless coagulopathy is aggressively corrected.

**Indirect**

In addition to the correction of coagulopathy clot formation is enhanced by reducing the pelvis. Reducing the pelvis reduces pelvic volume, increases stability, and apposes pro-thrombotic surfaces. This can be achieved by using non-invasive or invasive external compression devices. Stabilization of the pelvis has been proven to be clinically effective in reducing mortality rates and transfusion requirements. Once stabilization has been achieved the patient should be moved with caution to avoid clot disruption.

Non-invasive external pelvic compression

This includes pelvic binders, bean bags, and sheets that can be applied to generate non-invasive circumferential pressure (Figure 12.46.8). The principal aim is to minimize movement and clot disruption at the fracture site. To further supplement stability the lower extremities can be held together with padded bandages applied to the thighs and ankles. These devices need to be used correctly (centred on the greater trochanters), with care to avoid neurological, vascular, visceral, and skin injury through over-reduction. They are quick to apply in the prehospital or resuscitation setting and avoid the problems of pin sepsis. It is not advisable to maintain them for long periods of time due to concerns about skin breakdown. The benefit of this technique has yet to be fully quantified and the limited studies available are not conclusive.
iliac crests is a familiar technique that can be performed quickly (in the emergency department, operating theatre or angiogram suite) without image intensification. Anterior external fixation has been associated with poor reduction and stability of the posterior ring. Any form of external fixation can be complicated by pin site colonization and sepsis. Ideally pin placement should avoid areas of degloving and if possible the position of future surgical incisions; however, these are secondary considerations in the emergency setting (discussed further in Chapter 12.47).

![Fig. 12.46.9](Click to view larger)
Pelvic binder replaced with anterior external fixator.

**Posterior external fixation**

A pelvic c-clamp can be used for emergency treatment of posterior ring disruption. Pins are applied against the outer table of the posterior ilium, overlying the SI joints. The entry point for these pins is at the intersection of the femoral axis and a vertical line running through the anterior superior iliac spine. Posterior external fixation has the potential to reduce and stabilize the posterior ring more effectively than anterior fixation. The c-clamp must be applied with care to avoid placement of the pins in the sciatic notch and is contraindicated in iliac fractures. Over compression or pin perforation risks vascular, visceral, and neurological injury.

**Internal fixation**

Certain fracture patterns and situations may warrant consideration of early internal fixation. In the presence of an open book injury undergoing a laparotomy it would be appropriate to consider plating the pubic symphysis. Posterior injuries could be considered for percutaneous SI screw placement; however, this is technically demanding and should not be undertaken if there is a risk of incurring an unacceptable time delay. Both of these options need to be considered before draping.

**Direct intervention**

Despite resuscitation, correction of coagulopathy and pelvic stabilization a small proportion of pelvic fractures will have persistent hypotension due to ongoing arterial and venous bleeding. They will require rapid direct haemostatic intervention for survival. In extremis, temporary occlusion of the aorta can be considered by clamping the aorta or insertion of a balloon catheter. Ligation of the internal iliac is of limited benefit due to the retroperitoneal haematoma and considerable anastomoses linking the right and left sides of the arterial and venous circulation.

**Extraperitoneal packing (EPP)**

This procedure involves tamponade of the pre-sacral and paravesical vessels by placing packs into the extraperitoneal space of the true pelvis. This is achieved through a low midline incision. Once the extraperitoneal space is accessed little additional dissection is required due to the injury and the expanding haematoma. Large swabs are placed, from posterior to anterior, either side of the pelvic viscera. For maximum benefit it has been recommended that EPP should be performed within 30min. In those amenable fracture patterns, external fixation is added in conjunction with EPP. The packs are usually removed at second look surgery within 48h.

Routine post-EPP angiography has demonstrated an 80% incidence of ongoing arterial bleed. However, in another study, angiography was only performed in 17% when it was clinically indicated.

Packing has been shown to have a significant effect on haemodynamic status, reduced postpacking blood transfusion, and is suggestive of improved survival rates. It also allows other sources of bleeding to be dealt with by surgical intervention in the same location. It can be performed quickly during the time required to set up for angiography.

This technique requires the immediate availability of an operating theatre and necessitates an open procedure that has implications with regard to infection and abdominal compartment syndrome. It is likely to be less effective with bleeding from larger arteries and under these circumstances may only function as a temporizing measure to limit blood loss. Packing is associated with a 25–29% mortality rate.
Angiographic embolization (Figure 12.46.10)

AE is an attractive technique for controlling pelvic arterial bleeding with an 85–100% success rate. However, it does not limit venous bleeding. The angiography suite should be equipped and staffed to allow optimum continuation of all the components of resuscitation. In extremis a balloon catheter can be rapidly inserted and used to occlude the aorta. A catheter is passed through the femoral artery at the groin or the left axillary artery if the groin is not accessible. Angiography can also look for sources in the chest and abdomen. Large vessel injury including the thoracic aorta is present in approximately 6% of those requiring embolization of pelvic arteries. Selective embolization techniques can be performed, however non-selective bilateral embolization procedures, including embolization of the internal iliacs, has been reported with good outcome. In some hospitals it is feasible to perform angiography in the operating room.

Review of the literature would suggest only 5% of all pelvic fractures are likely to benefit from embolization. However, there are subgroups that have been identified with an increased incidence of ongoing arterial bleeding: contrast extravasation and large haematoma volumes on CT, hypotensive patients (<90mmHg) who are transient or non-responders to resuscitation have a 44–76% incidence; BD of more than 6mmol/L (when used as a trigger it identified arterial bleeding in 100% of cases); over 60 years of age (over two-thirds of this group of patients will present with normal vital signs). Venography has been recommended if there is no improvement following AE as significant venous injuries have been identified. It is also appropriate to consider placement of an inferior vena cava filter (discussed further in Chapter 12.47). If hypotension or a BD persists following any intervention, repeat angiography should be considered. Re-embolization has been required in 6–7.5% of reported cases.

The technique is both resource and time consuming, even in expert hands it requires time. It should be expected that AE will take an average of 90min, in addition to the transport and set-up time; however, this is very dependent on the institution. Successful embolization has not been seen to always result in an immediate improvement in haemodynamic status and reduced requirements for blood products. Not all identifiable small arterial bleeds (seen on CT and angiography) will require embolization. These factors have yet to be fully quantified. The extent of ischaemic complications related to AE is believed to be less with selective embolization techniques. However it is difficult to separate the effect of AE from the injury. Risks include:

- Gluteal muscle necrosis (<5%)
- Skin necrosis (may be sign of gluteal muscle necrosis)
- Visceral necrosis
- Lower limb paresis
- Urogenital dysfunction (has not been clearly demonstrated)
- Nephrotoxicity from the contrast agent.

The cumulative reported mortality rate is 43%.

Haemodynamically stable pelvic fracture

When the patient is haemodynamically stable, with or without intervention, further assessment is required prior to definitive management. Further imaging is required to define the injury. First-line investigation in most centres still involves inlet and outlet views. The inlet view is taken with the patient supine; with a 40-degree cranial tilt of the beam so that it is perpendicular to the pelvic brim. The beam is then rotated to a 45-degree tilt towards the feet to achieve the outlet view (Figure 12.46.11). In some circumstances obturator and iliac oblique films are useful to define the fracture pattern and exclude acetabular involvement. CT (1–2-mm cuts) is a more sensitive tool for identifying occult injury and with improving technology (e.g. three-dimensional reconstruction) and access, the requirement for inlet and outlet views will become more dependent on surgeon preference.
Under some circumstances, to determine stability, examination under anaesthesia and stress views can be used. Dynamic assessment is contraindicated in haemodynamic instability (wait 3–5 days), lumbosacral plexus injury, ipsilateral vessel injury, and lower limb fractures that prevent axial loading of the hemipelvis.

Provisional reduction and stability is important for pain relief and to facilitate definitive surgery. This can be achieved using the methods previously discussed with or without skeletal traction (skin traction is inadequate) to reduce vertical displacement. If external fixators are considered, application should be discussed with the surgeons performing the definitive fixation.

Management of associated injuries

Genitourinary lesions

A history of inability to void, blood at the urethral meatus, haematuria, high riding prostate, and inability to catheterize are suggestive of genitourinary injury. In the presence of these findings urethral catheterization is contraindicated and requires further investigation. Retrograde urethrogram can be performed through a Foley catheter with the balloon sited in the urethral meatus. The presence of a urethral injury demands a urological opinion and may necessitate a suprapubic catheter. Potential bladder ruptures are diagnosed with a retrograde cystogram. The bladder is then emptied and the x-rays are repeated if necessary. Small extraperitoneal bladder ruptures are treated with suprapubic catheter drainage alone, to prevent the accumulation of urine and the risk of sepsis. The majority of tears will be healed by 10 days, the remainder within 4 weeks. Large tears and intraperitoneal tears require surgical repair.

Male urethral tears can be managed with early realignment with a urethral catheter maintained for 4–6 weeks or urinary diversion using a suprapubic catheter for 3–6 months followed by reconstruction. Urethral tears are frequently complicated by stricture formation. In females with proximal urethral tears, early urethral realignment or reconstruction is recommended.

Surgical correction of impotence should be delayed 12–18 months due to delayed return in function.

A vaginal laceration in association with a pelvic fracture should be considered an open fracture. All vaginal injuries should be explored and debrided under a general anaesthetic.

Abdominal injury

In addition to the associated visceral injury seen with polytrauma involving pelvic fractures it is important to identify rectal injuries that may be in continuity with the pelvic fracture. These fractures should be considered as open due to the contamination of the fracture site by faecal organisms. The only evidence of this injury may be fresh rectal blood identified at PR. Rectal tears may not always be identifiable using standard investigations (proctoscopy, sigmoidoscopy, and contrast studies). However, the consequences of a missed rectal injury are serious. Therefore when there is a high index of suspicion, the general surgeons should be encouraged to perform a complete defunctioning colostomy with distal washout. A double barrelled colostomy is not acceptable as it does not completely divert the faecal stream. The colostomy should be placed sufficiently high on the abdominal wall to avoid interference/contamination of future pelvic surgery. This can be reversed at a later date.

In the haemodynamic unstable patient with pelvic and abdominal bleeding, damage control principles may be appropriate with minimal surgical intervention, packing of the abdomen and pelvis and application of an external fixator. These patients should be monitored for abdominal compartment syndrome. Further pelvic or intra abdominal bleeding may be amenable to AE.

Soft tissue injury (Figure 12.46.12)

Open fractures including those involving the rectum and vagina constitute 2–4% of all pelvic fractures. The mortality rate for open pelvic fractures is greater than 50%. In an open fracture there is less potential for tamponade and blood loss is limitless. In addition there are the problems with deep sepsis. Early studies (pre-1992) report infection rates of approximately 30%, compared with a 15% incidence in the modern literature. Although the reported incidence of infection has improved the mortality rate of open
fractures remains high, 67%.

This problem should be managed, at presentation, according to the guidelines of all open fractures with early antibiotics, tetanus, and wound dressing followed by debridement, stabilization, and early soft tissue coverage. Defunctioning colostomy is required in those patients with an open injury involving the rectum or significant perineal wounds that are at risk of contamination.

Closed degloving injuries (Morel-Lavallée lesions) are associated with necrotic fat, fluid collection and bacterial colonization. These injuries may involve the planned surgical field and must be treated before fixation. Open and percutaneous techniques have been used successfully at both the same operation and as a separate procedure.

Mortality

Pelvic fracture should be considered a marker of severity and as demonstrated earlier in the chapter there are significant associated injuries. Many of these associated injuries will be fatal. The incidence of pelvic fracture as the sole cause of death (based on postmortem studies) is very low, 3.7%, and approximately 50% of pelvic fracture deaths will have other potential causes of haemorrhage. In general the pelvic fracture is felt to contribute evenly to both early and late deaths.

Generalized inpatient mortality rates, from large studies in the modern literature, are quoted at 3–20% (cumulative data 12.4%). These figures are dependent on the cohort, usually reflecting the referral pattern for the institution, and care should be taken when comparing figures. These figures are of little value in the clinical setting as the true lethality of this injury can be under appreciated. Haemodynamically unstable fractures have a much higher mortality rate, 40–60%.

In the polytrauma patient it is the cumulative physiological burden of the multiple injuries that often contributes to death. An ISS higher than 25 has been determined as an independent determinant of mortality. The level of physiological burden that can be survived is dependent on age with increased mortality rates seen in the over 40 age group. Pelvic injuries occurring in those over 65 years is an independent determinant of mortality.

Pelvic fracture in pregnancy is rare but fetal mortality rates of 35–80% have been reported; many of these deaths occur prehospital.

Summary

An understanding of the pathoanatomy of pelvic fractures will allow accurate classification and appropriate treatment. A significant proportion of pelvic fractures will be at additional risk of morbidity and mortality from extravasation and associated injuries. The management of these patients is an area of evolution. However, the treatment principles will remain the same and there will always be a requirement for protocol driven treatment to minimize delay. The indications and thresholds for current and future treatment modalities will need to be refined and ideally this will be based on assessment tools that are practical and can be used with minimal delay in the emergency department.

Further reading

Pelvic fracture: definitive management

Summary points

♦ Pelvic fractures must be actively managed to avoid peri-operative complications
♦ Understanding stability is the key to pelvic fracture management. Fixation is used to compensate for instability until healing occurs
♦ Long term disability can occur despite optimum fixation.

Introduction

The aim during definitive management is to produce a stable, pain-free pelvis with minimal functional limitations and avoidance of complications.

Ideally optimal treatment in the acute and definitive phases of treatment should be complementary but can, however, conflict. This can be problematic if definitive treatment is to be performed in another facility. Even if the admitting facility is not involved with definitive management it is important that definitive treatment options are understood.

Interim management (Box 12.47.1)

During the period between early and definitive management the patient must be actively managed and steps should be taken to avoid complications.

Timing of definitive fixation needs to consider the disadvantages of early and late surgery. In the physiologically unstable patient, definitive fixation can be associated with higher levels of blood transfusion, organ failure, multiple organ failure, and death. Long operations have a greater physiological impact and are associated with a worse outcome. It is therefore appropriate to postpone definitive fixation until the patient is fit for surgery. Problems associated with the ‘second hit’ are believed to be minimized if surgery is delayed until after day 4. Fracture stability is part of the optimal treatment of open fractures and this will influence timing and method of fixation. Prolonged delay to surgery increases the risks associated with immobilization. It also increases the technical difficulty of achieving anatomical results and this has been associated with worse outcome. The technical difficulties of delay can be mitigated to a degree by holding the pelvis in a reduced position with external fixation and skeletal traction in the case of vertical displacement.

Venous thromboembolism (VTE) is a significant problem in pelvic fracture patients as they frequently have many of the well established risk factors:

1) Injury severity score higher than 15
2) Age greater than 40 years
3) Lower extremity fracture
4) Severe head injury
5) Vertebral fracture
6) Spinal cord injury
7) Delay to surgery.

The presence of any of these risk factors in association with pelvic fracture results in a significantly higher incidence of VTE. In addition, these patients may not have received appropriate thromboprophylaxis due to haemodynamic instability. Deep venous thrombosis (DVT) has been reported with an incidence as high as 61% in pelvic fractures that have not received DVT prophylaxis. With DVT prophylaxis the incidence is reported as 2–33%. Pulmonary embolus (PE) is reported as occurring in 2–13%. Fatal PE is reported with an approximate incidence of 1%. Early thromboprophylaxis is important as 6% of PEs occur within the first 24h.

Box 12.47.1 Interim management

♦ Active medical management
♦ Maintain temporary pelvic stabilization
♦ Thromboprophylaxis:
  • Mechanical
  • Chemical
  • IVC filter
♦ Avoid sepsis
Pressure area care
Laxatives.

Strategies to minimize the problems associated with VTE include early mobilization, screening, mechanical and chemical prophylaxis, and inferior vena cava (IVC) filters.

Although the majority of DVTs originate in the legs, in pelvic fractures approximately half involve the pelvic veins. Ultrasound and venography are poor investigations for deep pelvic vein thrombosis and magnetic resonance (MR) venography has been reported as the gold standard. There is no consensus at present with regard to screening.

Where possible, chemical thromboprophylaxis with low-molecular-weight heparin should be used; however, this can be problematic in this patient group due to both the acute haemorrhage and the need for operative intervention. Pulsatile compression devices are an alternative in those patients in which chemical thromboprophylaxis is contraindicated. Their use is limited in the presence of lower extremity injury and the benefit, on their own, has not been conclusively proven.

IVC filters can be used in high risk patients, those with established DVT and as an alternative to chemical prophylaxis (Figure 12.47.1). A review of studies (1983–2005) reporting on IVC filter use reports a 13% complication rate. Complications include malposition, migration, insertion site thrombosis, difficulty removing the device, and occlusion. Occlusion has been reported as 15%, but can be reduced to 8% with anticoagulation.

Pressure areas must be protected particularly in the unconscious patient and those on traction. Wound care will minimize the risk of sepsis from wounds and pin sites prior to definitive surgical treatment. Constipation should also be avoided as faecal loading causes discomfort and can greatly limit intraoperative image intensifier visualization.

Rationale for treatment (Box 12.47.2)

Treatment strategies need to consider residual pelvic stability, strength of fixation, deformity, pain and neurologic deficit.

Stability is the key to managing pelvic fractures. Stability can usually be interpreted from the clinical assessment, x-rays and CT (see Chapter 12.46). Where stability, in the vertical and horizontal planes, has been maintained, non-operative treatment can be considered with immediate full weight bearing as tolerated.

Where stability is deficient, fixation can be used to compensate until sufficient healing has occurred (pubic rami 4–6 weeks, sacroiliac (SI) joint 12 weeks). It is important therefore that the fixation used is capable of performing the task. Bone quality and the condition of the soft tissues will have a significant impact on the choice of fixation technique.

In displaced rotationally unstable fractures where vertical stability is maintained, as a result of the intact posterior ligament complex, anterior fixation alone is adequate. Posterior fixation is usually required in pelvic injuries with complete instability of the posterior pelvic ring.

Deformity also influences the treatment strategy. In lateral compression (LC) injuries significant internal rotation of the hemipelvis is also associated with rotation in the sagittal plane and subsequent relative leg length discrepancy (Figure 12.47.2). Significant leg-length discrepancy and internal rotation are indications for operative intervention. Thresholds for acceptable displacement will be dependent on the patient and it has been recommended that operative intervention should be considered for rotation greater than 10 degrees and leg-length discrepancy of more than 0.5cm. When the rotation deformity is sufficient to prevent external rotation it will prevent normal gait. Prominence and asymmetry of the pelvic bony prominences can also cause problems. Fractures involving the relative height of the ischial tuberosities will affect sitting stability.
Pain is a factor in both short- and long-term goals. Stabilization of fractures reduces pain and allows for easier and earlier mobilization. There are occasions in patients with minimally displaced stable pelvic ring injuries where a short period of temporary stabilization, provided by an anterior external fixation, for pain relief will be of benefit. Pubic rami fractures can heal quickly and allow the frame to be removed.

**Box 12.47.2 Rationale for treatment**

- Early mobilization
- Restore stability
- Avoid complications of displacement and consider intervention if:
  - Leg-length discrepancy >0.5cm
  - Reduced hip rotation >10 degrees
  - Sitting stability
  - Bony prominence
- Reduce early and late pain:
  - Dyspareunia >5mm pubic rami displacement in females
  - SI joint displacement >5mm associated with increased pain
- Decompression of sacral nerve roots.

In the long term, pain significantly affects outcome. Pubic rami fractures may cause dyspareunia and displacement of more than 5mm has been demonstrated to be problematic in females. Pain is particularly problematic in pelvic fractures involving disruption of the SI joint. Anatomical reduction of the posterior ring (<5mm displacement) is believed to correspond to a better outcome. However, this appears to be more significant in injuries involving the SI joint.

Treatment must avoid causing neurological deficit and there are certain circumstances and techniques that may place neurological structures at risk. Percutaneous techniques in particular SI screws require experience and adequate intraoperative imaging. Sacral fractures may result in neurological compromise as a result of compression at the time of injury or treatment.

The indications and outcomes of sacral nerve root decompression have not been fully established. Denis zone II and III fractures with identifiable compression may benefit from open reduction and decompression; delays of 2–3 days are believed to be acceptable. It is reported that there will be an overall improvement in at least 30% of cases regardless of treatment. Higher rates of recovery have been reported following decompression.

**Treatment options**

The categorization provided by classification systems helps to establish the residual stability of the pelvic ring. It is this understanding which allows the correct treatment decisions to be made.

**Stable pelvic ring injury**

These fractures do not compromise the stability of the pelvic ring and the vast majority can be treated non-operatively.

**Avulsion fractures**
Fractures of the anterior superior and anterior inferior iliac spines occurs as a result of avulsion of the sartorius and rectus femoris muscles, respectively. This most frequently occurs in adolescents. Treatment is symptomatic.

**Transverse sacral fractures**

Transverse fractures of the sacrum, below the level of the sciatic buttress, occur as the result of a direct blow. Operative treatment is considered when there is significant angulation particularly in association with a neurological deficit, but this is rare.

**Iliac wing fractures**

These fractures also occur as a result of a direct blow and may be associated with significant overlying soft tissue injury. Treatment is usually non-operative. When there is gross displacement that is likely to result in unacceptable cosmesis or gluteal muscle dysfunction, operative intervention can be considered (Figure 12.47.3). These injuries can be very painful.

Fig. 12.47.3

This fracture was treated with open reduction and internal fixation to avoid problems with bony prominence and gluteal dysfunction. Full range of pain free movement and weight bearing was achieved at 6 weeks.

**Anterior posterior compression Type I**

When displacement of the symphysis pubis is less than 2.5cm the ligaments of the pelvic floor and the integrity of the posterior ring is likely to be intact. Non-operative treatment is appropriate with weight bearing as tolerated.

**Lateral compression Type I**

These fractures are associated with horizontally orientated pubic rami fractures and an impaction fracture of the sacrum. The pelvic floor and posterior ligaments remain intact. This is a stable fracture pattern that can usually be treated non-operatively. The patient can weight bear as tolerated.

**Bifocal fracture of anterior arch**

These fractures can occur without disruption of the posterior pelvic ring and are associated with straddle injuries, e.g. fuel tank of motorcycle. As pelvic ring stability has not been compromised the injury can be managed non-operatively; however, operative fixation should be considered with significant displacement.

**Rotationally unstable, vertically stable pelvic ring injury**

**Anterior posterior compression Type II (Figure 12.47.4)**

This fracture pattern is seen in APC injuries with disruption of the pelvic floor ligaments and displacement greater than 2.5 cm. The hemi-pelvis externally rotates on a hinge (intact posterior SI ligaments) and maintains vertical stability. Plating the symphysis restores stability of the pelvic ring in the horizontal plane and facilitates healing of the soft tissues in an anatomical position. Late plate failure as a result of fatigue is frequently seen, however at this stage stability has usually been achieved by the healed soft tissues. An external fixator can be considered instead of a plate if the soft tissues are not appropriate. The anterior fixation will be under tension in double leg stance and compression in single leg stance. Following operative fixation weight bearing is protected for 6–8 weeks although some authors have advocated weight bearing as tolerated.

**Lateral compression Type II**

This fracture pattern is seen with lateral compression associated with complete disruption of the posterior ring. Horizontally orientated pubic rami fractures are associated with a fracture line that runs through the posterior ilium and often involves the SI joint. In both circumstances it is only the pelvic floor ligaments that remain intact, providing ‘relative’ vertical stability. Fractures of
the ilium with significant displacement resulting in significant leg-length discrepancy or internal rotation should be considered for operative intervention. When a fracture/subluxation involves the SI joint, it is described as a 'crescent fracture' (Figure 12.47.5). This refers to the posterior ilium that remains attached to the posterior SI ligaments. These fractures are more unstable than lateral compression with anterior sacral crush and are usually treated operatively. Anterior fixation is usually achieved by plating, external fixation or percutaneous screw fixation of the superior pubic rami. Posterior fixation is required to anatomically reduce the SI joint and this can be achieved using closed or open techniques.

![Click to view larger](Fig. 12.47.4)
APC II injury treated with symphyseal plate.

![Click to view larger](Fig. 12.47.5)
LC II 'crescent fracture' treated with posterior open reduction and internal fixation and anterior supra-acetabular external fixator.

**Completely unstable pelvic ring injury**

These fractures are vertically and rotationally unstable as a result of complete disruption of the anterior and posterior parts of the pelvic ring. Posterior disruption occurs through the ilium, SI joint, or sacrum. These fractures require both anterior and posterior fixation to restore stability.

In SI joint disruption, treated with open reduction, some surgeons will routinely fuse the SI joint.

**Bilateral pelvic ring injury**

Consideration and treatment is directed towards the individual components, as described earlier. However as the contralateral side cannot be relied upon to ‘anchor’ the fixation additional posterior fixation may be required to restore stability e.g. LC III or CMI (Figure 12.47.6).
Lumbosacral injuries

Complex fractures through the sacrum, with vertical and transverse components, or traumatic spondylolisthesis from bilateral L5/S1 fracture dislocations may result in complete mechanical discontinuity between the lumbar spine and pelvis. These are rare high energy injuries that are frequently fatal. More frequently, vertical sacral fractures running through or medial to the L5/S1 facet joint may cause instability between L5 and S1. Sacral fixation in isolation may be inadequate and lumbopelvic fixation should be considered (Figure 12.47.7).

Non-operative treatment

In the majority of pelvic fractures the optimal treatment will be non-operative. There will also be a small group of patients who will have indications for operative management but due to other circumstances are managed non-operatively. The aim is to mobilize early. The main limitations are pain and sufficient upper body strength to mobilize partial weight bearing. The patient will require adequate analgesia, a short period of bed rest followed by progressive mobilization with walking aids. Pain is a good indicator of healing and should be used as a guide to determine the progression from bed rest to mobilization with weight bearing as tolerated.

Operative treatment (Box 12.47.3)

External fixation

Anterior external fixation can be used in isolation or in conjunction with posterior internal fixation. Anterior external fixation is insufficient to maintain posterior reduction. Pins are placed into the iliac crest (Fig 12.47.8A) or supra-acetabular bone (Fig
During the course of treatment external fixator pin sepsis may be problematic and both sites may be used consecutively.

**Fig. 12.47.8**

A) Optimum placement of pins in iliac crest takes advantage of the thick strut of bone extending from the crest to the hip joint. B) Optimum placement of supra-acetabular pin is similar to that of the LC II screw. C) Poor placement of pins and obesity predispose to skin necrosis and sepsis.

External fixation using convergent pins placed in the thick strut of bone running from the anterior iliac crest to the acetabulum is relatively quick and familiar to most orthopaedic surgeons. Three pins are placed between the inner and outer table of the iliac crest. It is preferable to only drill the outer cortex and use 5-mm pins. The use of self-drilling pins increases the risk of breaking out of the inner or outer table. An appreciation of the anatomy of the iliac crest is important to ensure correct pin placement, pins are commonly placed too vertical in both the sagittal and coronal planes. As the iliac crest overhangs the outer table there is also a tendency for the entry point to be too lateral. A K-wire placed on the inside of the inner table can provide a useful guide.

Considerations must be given to the surrounding soft tissues. When an external fixator is used to reduce an open book fracture the position of the optimum skin incisions will change. To accommodate the change in position it is often helpful to place the skin incisions perpendicular to the iliac crest directed towards the umbilicus. It is very common for the abdomen to swell following pelvic fracture and if this is not anticipated, problems with skin necrosis and infection arise (Figure 12.47.8C).

The main purpose of anterior external fixators used in isolation is to restore horizontal stability in a rotationally unstable pelvis. Biomechanically this reduction is best achieved with supra-acetabular pins placed adjacent to the anterior inferior iliac spine directed posteriorly into the thick bone of the sciatic buttress. One or two pins can be linked with a simple frame to achieve this goal. Placement of these pins requires the image intensifier and therefore is rarely suitable in the acute management of haemodynamic instability.

External fixation, either used temporarily or definitively, is associated with a significant incidence of sepsis and aseptic loosening.

**Internal fixation**

**Anterior**

Fixation of the pubic rami or symphysis pubis can restore the anterior pelvic ring. Not all pubic rami fractures will require fixation and those fractures with up to 1.5cm of displacement will have sufficient retained soft tissue stability that fixation may not be necessary. In vertical shear posterior injuries the risk of failure is related to the anterior fixation, plate fixation is stronger than external fixation and has been associated with less late displacement.

The approach used will depend on the position of the fracture. Disruption of the symphysis pubis and medial pubic rami fractures can be obtained through a Pfannenstiel approach. Access to the superior aspect of the pubic symphysis is achieved by a split between the distal rectus abdomini. This allows access to the extraperitoneal space. Often the recti are torn and some of the dissection will have already been accomplished by the injury. A limited amount of sharp dissection of the rectus abdominis insertion will improve exposure. Reduction can be achieved with reduction forceps. In rotationally unstable injuries a single 3.5-mm reconstruction plate is usually sufficient when the bone quality is adequate (see Figure 12.47.4). Specialized plates are available that avoid leaving a stress riser (unfilled screw hole or thin part of the plate) directly over the symphysis. In completely unstable injuries double plating, with an additional plate applied anteriorly, can be considered in addition to the posterior fixation; however, some surgeons believe a single plate is adequate.

An alternative to plating the pubic rami fractures involves using pubic rami screws that can be inserted percutaneously in an antegrade or retrograde direction. Their trajectory is similar to that described for anterior column screws (see Chapter 12.49).

**Posterior**

Many methods and combinations have been described. The technique used will depend on the fracture position, configuration, and...
displacement. In addition the surgeon must also take into account the soft tissues, neurological deficit, patient positioning, available equipment, and experience.

Open or closed reduction techniques have been described. Open reduction techniques have the benefit of reducing under direct visualization but incur the risk of the open approach. Posterior approaches use either a midline incision or a longitudinal incision 2.5cm lateral to the posterior superior spine. The gluteus maximus and multifidus muscles can then be mobilized. Posterior open approaches have been associated with a high incidence of wound problems and infection (3–27%).

Mechanical differences have been identified between the fixation techniques. In general, two points of fixation are preferable and none of the techniques are sufficiently strong to allow unrestricted weight-bearing. Two SI screws or one SI screw and anterior SI plating have been shown to be the strongest constructs most commonly used. A lumbopelvic triangular construct can also be considered, however this is overtreatment for many fractures.

**SI screws**

SI screws are commonly placed through the posterior aspect of the ilium into the body of S1. If space permits, two screws can be placed in S1 or alternatively a second screw can be placed in S2 (Figure 12.47.9). The screws can be placed with the patient supine or prone. The percutaneous technique is very dependent on operator experience and good image intensification. The technique requires using the image intensifier to obtain good quality inlet, outlet and lateral views. Inaccurate placement is associated with the risk of injury to L5, sacral nerve roots (within the foramen and canal), iliac vessels, superior gluteal nerve and vessels. The risk has been shown to increase significantly when the sacral fracture is incompletely reduced or there is sacral dysmorphism. Nerve injury has been reported as less than 1%; however, it must be appreciated that this complication rate is not transferable.

**Sacroiliac plates (Figure 12.47.10)**

Anterior SI plating can be performed through the lateral window of the ilioinguinal approach (see Chapter 12.49) using two orthogonal plates passing from the sacral ala to the anterior aspect of the posterior ilium. It has the advantage of being performed with the patient supine using an incision with low morbidity. In addition it facilitates direct visualization of the reduction, direct placement of fixation and allows the SI joint to be debrided to facilitate fusion if required. However, it is restricted as it can only be used in a pure SI joint injury with an intact sacral ala. Only one screw in each plate can be inserted into the sacral ala due to the close proximity of the L5 nerve root which runs over the sacral ala approximately 1cm from the anterior aspect of the SI joint.
SI bars plus tension band plate (Figure 12.47.11)

These devices require posterior incisions that are associated with problems of wound breakdown; however, minimally invasive techniques have been described. Metal work prominence can be problematic in thin patients. Posterior plating can be used in conjunction with neural decompression and can maintain distraction in fracture patterns associated with compression.

Spinopelvic fixation

This is considered to provide the highest mechanical stability. Pedicle screws can be placed into L4 and L5 and linked to screws placed into the posterior ilium (see Figure 12.47.7). Cross links create a triangular construct. This can be used in lumbosacral injuries and can be considered in Denis II and III fractures.

Crescent fracture

The posterior ilium retains attachment to the posterior SI ligament complex. Anatomical reduction and fixation of this fragment to the rest of the ilium restores posterior stability. The choice of fixation techniques is dependent on the size of the crescent fragment. Large fragments are suitable for open or percutaneous fixation. Open techniques use the lateral window of the ilioinguinal approach (described in Chapter 12.46) with direct visualization of the fracture and SI joint. Anterior plating techniques can be used. Closed techniques have also been described. Following closed reduction one or two partially threaded ‘LC II’ screws can be passed through the supra acetabular corridor (similar to supra acetabular external fixator pin) across the sciatic buttress into the crescent fracture (Figure 12.47.12).

Smaller fragments may necessitate a posterior approach with fixation performed directly using plates and screws or closed reduction and SI screws to stabilize the SI joint (Figure 12.47.5).
### Box 12.47.3 Fixation techniques

  - SI bars
  - Tension band plate
  - Iliac plates and screw fixation
  - LC II screws
  - Lumbopelvic fixation.

### Postoperative management

Open reduction and internal fixation can be painful and this is often best managed during and after the operation with epidural analgesia. The epidural catheter is usually removed over the following 3 days so that the patient can start to mobilize.

Weight bearing as tolerated can be considered for fractures that retain horizontal and vertical stability. Fractures that require posterior fixation require protective weight bearing until sufficient healing has been achieved (8–12 weeks). The patient should be instructed by the physiotherapists to only touch weight bear (equivalent of the weight of their leg). Bilateral injuries will necessitate wheelchair mobilization until full weight bearing on one limb can be tolerated.

X-rays (AP, inlet, and outlet) should be performed postoperatively and if there are concerns about hardware placement a CT scan may be required. Further x-rays should be performed frequently if there are concerns about stability, otherwise routine follow-up at 6-weekly intervals until the fracture is united.

In addition to mobilization, physiotherapy should help with breathing exercises, hip range of motion exercises, and general conditioning.

### Outcomes

Complications related to specific problems and techniques have already been discussed. General problems are discussed below.

#### Infection

Infection rate is very dependent on the technique used. Posterior approaches are the most problematic (3–27%). Percutaneous approaches have generally very low rates of infection; however, it has been considerable in some studies and is believed to be secondary to soft tissue injury. Large series generally report infection rate at less than 5%.

#### Non-union

The overall incidence of this complication is unknown but appears to be very small. The risk of non-union increases with displacement and instability.

#### Function

There are no controlled trials to allow direct comparison of the outcomes of non-operative and operative treatment options. Much of the evolution has been based on comparison with historical studies and expert opinion. Many studies have attempted to correlate features related to pelvic fracture and outcome. The results of these studies are not conclusive. This has been attributed to significant confounding variables, in particular the measurement methods and associated injury.

In general there is acceptance that the outcome is worse with increased severity of pelvic injury. However, severe pelvic injury is more likely to be associated with a higher incidence of significant associated injuries and neurological deficit. In addition it can also make reduction harder. Pure SI joint injury appears to have worse outcome than fractures and fracture dislocations of the posterior ring, especially when associated with non-anatomical reduction. However, anatomical reduction of any pelvic ring injury pattern does not guarantee a good outcome. The opposite is also demonstrated with some displaced unstable injuries reporting relatively good outcomes. Correction of leg length discrepancy has been correlated with better outcome scores in some studies.

Outcome measurement varies amongst studies and the methods used influence the ability to identify good and bad outcome groups. Health survey questionnaires such as SF-36 and Sickness Impact Profile are useful measures of general health but are...
Many studies have inconsistently correlated outcome with classification systems that amalgamate very different osteoligamentous injuries into groups based on stability. Outcome based on injury types has demonstrated clear differences within these groups. APC injuries in general have worse outcome than lateral compression injuries however both are classified as rotationally unstable. In a large study comparing functional outcome rotationally unstable lateral compression patterns (LC II + III) had a good or excellent outcome in 92% compared with 74% in rotationally unstable APC injury (APC II); despite a difference in anatomical reduction 75% vs 94%. In the same study completely unstable fracture patterns had an anatomical reduction in 63% and a good or excellent outcome in 71%. It is also apparent that within the completely unstable fracture group there are different outcomes depending on the type of posterior injury.

A significant proportion of pelvic fractures are not associated with multisystem trauma and are satisfactorily managed non-operatively or with minor surgical intervention. As a result they will not need transfer to a specialist centre for treatment. Due to the relative rarity of the injury only the specialist centres are in a position to publish on the subject, resulting in a bias in the study population presented.

One of the most frequently used outcome measures is return to work. Although not directly comparable it does allow for the physical impact of the injury to be appreciated. Not all patients who return to work will return to the same job, however in most studies the majority do. Overall approximately 75% of pelvic fractures return to their original employment. In studies looking at rotationally unstable injuries, 85% return to work has been reported in contrast to 33–69% of completely unstable injuries. Difficulty in sitting has been reported as high as 60% in rotationally and completely unstable injuries.

Pelvic pain is a significant feature in the outcome of pelvic fractures. Low back pain is common in sacral and sacroiliac injury and the overall incidence has been reported at 17–90%.

In rotationally unstable injuries, pain of some degree is reported in 11–45%. In a study reviewing patients treated with external fixation they were functionally normal if the pelvis remained reduced but 80% required analgesia for posterior pain if reduction was not maintained. A German multicentre study identified persistent pain in 32% of rotationally unstable APC type injuries in contrast to 18% in those rotationally unstable fracture patterns that result from lateral compression.

In vertically unstable fracture patterns significant pain is reported in 30–90% and has been correlated with residual displacement. In these fractures the average patient has been reported as having an average visual analogue score (VAS) at rest of 2.8 and 4.1 when ambulating. This was noted to be higher in those patients with an unresolved lumbosacral injury or extremity injury.

The outcome of pelvic fractures is very dependent on the contribution of the frequently occurring significant associated injuries.

A significant proportion of severe pelvic injury have an associated neurological deficit. It is the presence of a neurological injury that has been a consistent determinant of poor outcome. In addition to neurological deficit the neurological injury is believed to contribute to pain. Nerve injuries have been reported in 5–17% of rotationally unstable (more common in APC type injuries) and 25–40% of completely unstable fractures. Nerve injuries seen in rotationally unstable fractures have been noted to be more likely to recover than in completely unstable injuries, 70 vs 29% respectively. In sacral fractures displaced more than 10mm, 87% were identified as having a sensory deficit, 45% motor dysfunction of the lower extremities, 52% voiding dysfunction, 36% bowel dysfunction, 39% altered sexual function, and 65% gait impairment. In this group only 33% returned to work.

In completely unstable pelvic fractures the frequency of long-term urinary dysfunction (frequency, incontinence, retention, urethral stricture and urgency) is 37%.

The psychological impact of being involved in an accident and sustaining serious injuries is becoming increasingly understood. Treatment of the physical problems in isolation may be inadequate in optimizing a patient’s outcome.

Sexual function is an important aspect of pelvic fracture outcome as a result of residual pain, urological, neurological, vascular, and psychological injury. Overall approximately 75% of pelvic fracture patients return to normal sexual function. Unstable pelvic injury patterns are associated with a 24–40% incidence of sexual dysfunction. Male sexual dysfunction has a reported incidence of 30% within the general pelvic fracture population. Although the cause may be multifactorial, a vascular rather than neurological cause is most frequently reported. An important relationship has been identified between mental and sexual health. Within the group returning to their original work without sexual dysfunction, the psychosomatic and affective status is near normal, unlike those with sexual dysfunction who demonstrate depressive affectation.

Summary

Pelvic fractures and the associated injuries represent complex problems with variable outcomes. Many of the factors that determine outcome are predetermined by the injury. It is therefore important to optimize those factors that are amenable to treatment.

Chapter: Fractures of the acetabulum: radiographic assessment and classification

Summary points

- This injury is relatively uncommon at 3 per 100,000 patients annually
- Understanding the complex anatomy of the innominate bone is key
- Assessment is based on interpretation of three basic plain radiographs supplemented by computed tomography
- Fractures are classified into five elementary and five associated types
- A systematic approach to the radiographic interpretation facilitates diagnosis and treatment.

Incidence and mechanism of injury

Acetabular fractures represent a serious injury with disruption of the articular surface of the hip joint. Fortunately, these injuries are relatively uncommon with an incidence of about three per 100,000 patients annually in the United Kingdom. In 1998, there were 12,000 fractures of the acetabulum reported in the United States of America. This compares with 323,000 fractures of the femoral neck that occurred in the same time period. The majority of patients sustaining fractures of the acetabulum are injured in a motor vehicle or motorcycle collision, as a pedestrian struck by a motor vehicle, or in a fall from a height. For more than a decade, the reported annual incidence in the United Kingdom has remained stable. However, over time, there has been a change in demographics, with an increase in acetabular fractures caused by simple falls and an increase in the proportion of women with acetabular fractures.

Bony anatomy

The classification and treatment of acetabular fractures is based on a thorough understanding of the anatomy of the innominate bone. The innominate bone is formed as a condensation of pubis, ischium, and ilium at the triradiate cartilage which fuse at the time of skeletal maturity. The articular surface of the acetabulum can be visualized as being supported between limbs of an inverted Y of bone. Letournel was the first to describe the surgical anatomy of the innominate bone, identifying these two limbs as the anterior column or iliopectineal segment and posterior column or ilioischial segment (Figure 12.48.1). The anterior column refers to the anterior half of the iliac wing that is contiguous with the pelvic brim to the superior pubic ramus, as well as the anterior half of the acetabular articular surface. The posterior column begins at the superior aspect of the greater sciatic notch, and is contiguous with the greater and lesser sciatic notches inferiorly and includes the ischial tuberosity. The posterior column also contains the cortical surface of bone posterior to the acetabulum, known as the ‘retroacetabular surface’. The coalescence of the pelvic brim and greater sciatic notch is referred to as the sciatic buttress and links the anterior and posterior columns (inverted Y of bone) to the axial skeleton (Figure 12.48.2).

Fig. 12.48.1
Illustration of the surgical divisions of the innominate bone into the anterior and posterior columns. Letournel described the acetabulum as contained between the arms of an inverted Y formed by these two columns.
Fig. 12.48.2
A) Anatomical regions of the internal aspect of the innominate bone are illustrated. The quadrilateral surface is bound by the pelvic brim anteriorly, the greater and lesser sciatic notches posteriorly, the obturator foramen inferiorly, and the sciatic buttress superiorly. The iliopectineal eminence lies directly over the anterior wall of the acetabulum. The nutrient foramen of the iliac wing is a consistent landmark found adjacent to the sacroiliac joint. B) The external aspect of the innominate bone is shown. The retroacetabular surface is outlined.

Radiography of acetabular fractures

Three radiographic projections of the pelvis are used to evaluate fractures of the acetabulum (Figure 12.48.3): the anteroposterior (AP) view of the pelvis, the obturator (or 45-degree internal, Judet) oblique view, and the iliac (or 45-degree external, Judet) oblique view. Interpretation of plain films is based on the understanding of normal radiographic landmarks of the acetabulum and disruption of these landmarks represents a fracture involving that portion of the bone. Computed tomography (CT) and three-dimensional reconstructions are helpful to further define fracture patterns and assess for associated injuries (Box 12.48.1). However, it does not replace the standard radiographic evaluation.

Fig. 12.48.3
A) Radiographic landmarks of the acetabulum on the anteroposterior view of the pelvis. 1, iliopectineal line; 2, ilioschial line; 3, teardrop; 4, roof; 5, anterior rim of the acetabulum; 6, posterior rim of the acetabulum. The iliopectineal line, the anterior rim, and teardrop are landmarks of the anterior column; the ilioschial line and posterior rim are landmarks of the posterior columns. (b) Obturator oblique view of the hemipelvis, obtained by turning the injured side 45° toward the X-ray beam. The obturator ring is seen en face, and the iliopectineal line is also present. 1, Area of the anterior column; 2, posterior rim of the acetabulum. Posterior wall fractures are best seen on this view. (c) Iliac oblique view, obtained by rotating the injured side away from the X-ray beam. The iliac wing is seen en face, and fracture lines extending into the iliac wing are often best seen on this view. 1, the greater sciatic notch is seen on this view, and represents the posterior column; 2, the anterior rim of the acetabulum is best seen on this view. Box 12.48.1 Investigations

- AP view of pelvis
- 45-degree iliac oblique view
- 45-degree obturator oblique view
- Axial two-dimensional CT scan ± three-dimensional reconstructions.
**Anteroposterior view**

On the AP view, there are six basic landmarks (Figure 12.48.3A and Box 12.48.2). The iliopectineal line is the major landmark of the anterior column. The inferior three-quarters of the iliopectineal line represents the pelvic brim. The superior quarter of this line is formed by the tangency of the x-ray beam to the superior quadrilateral surface and the greater sciatic notch. The ilioschial line is formed by the tangency of the x-ray beam to the posterior portion of the quadrilateral surface, and is considered a radiographic landmark of the posterior column. The radiographic U or teardrop consists of a medial and lateral limb and represents a radiographic finding and not a true anatomical structure. The lateral limb represents the middle third of the cotyloid fossa in the acetabulum, and the medial limb is formed by the obturator canal and the anteroinferior portion of the quadrilateral surface. Because the teardrop and the ilioschial line both result, in part, from the tangency of the x-ray beam to a portion of the quadrilateral surface, they are always superimposed on the AP pelvis view of the normal acetabulum. Dissociation of the teardrop and the ilioschial line indicates either rotation of the hemipelvis, or a fracture of the quadrilateral surface. The roof of the acetabulum is a radiographic landmark resulting from the tangency of the x-ray beam to a narrow portion of the subchondral bone of the superior acetabulum. Interruption of the radiographic line of the roof indicates a fracture involving the superior acetabulum. The anterior rim represents the lateral margin in the anterior wall of the acetabulum and is contiguous with the inferior margin of the superior pubic ramus. The anterior rim is typically medial to the posterior rim, and has a characteristic undulation in its mid-contour in the AP pelvis view. The posterior rim represents the lateral margin of the posterior wall of the acetabulum. Inferiorly, the posterior rim is contiguous with the thickened condensation of the posterior horn of the acetabulum.

**Box 12.48.2 AP x-ray—six basic landmarks**

- Iliopectineal line (anterior column)
- Ilioschial line (posterior column)
- Radiographic U or teardrop
- Roof of the acetabulum
- Rim of the anterior wall
- Rim of the posterior wall.

**Obturator oblique view**

The obturator oblique view (also known as the internal oblique view) is taken with the patient rotated so that the injured hemipelvis is rotated 45 degrees toward the x-ray beam (Figure 12.48.3B and Box 12.48.3). This view shows the obturator foramen in its largest dimension and profiles the anterior column. The iliopectineal line has the same relationship with the pelvic brim as on the AP view. The posterior rim of the acetabulum is best seen in the obturator oblique view. Comparison of the relationship of the femoral head with the posterior wall on the normal hip and the injured hip on the obturator oblique view will allow the surgeon to detect subtle amounts of posterior subluxation.

**Box 12.48.3 Obturator oblique x-ray—four landmarks**

- Obturator foramen
- Posterior rim of acetabulum
- Anterior column.

**Iliac oblique view**

The iliac oblique view (also known as the external oblique view) is taken with the patient rotated so that the injured hemipelvis is tilted at 45 degrees away from the x-ray beam (Figure 12.48.3C and Box 12.48.4). This view shows the iliac wing in its largest dimension, and profiles the greater and lesser sciatic notches, as well as the anterior rim of the acetabulum. Involvement of the posterior column is often best seen on this view. Fractures of the anterior column traversing the iliac wing can also be detected.

**Box 12.48.4 Iliac oblique x-ray—three landmarks**

- Iliac wing (fractures of anterior column)
- Anterior rim of acetabulum
- Posterior column.

**Computed tomography scan**

Two-dimensional (axial) and three-dimensional CT scans are used as an adjunct to the analysis of the AP and oblique plain
radiographic projections. After studying the plain films, the surgeon should use the two-dimensional CT to answer specific questions about the fracture that remain unanswered (Box 12.48.5). In addition, two-dimensional CT has been shown to be superior to plain radiographs in the detection of fracture step and fracture gap deformities. In order to obtain reliable and useful information, the CT scan should consist of contiguous sections of no more than 3mm in thickness. Although the two-dimensional CT has also been advocated as a means to determine hip joint stability, this has proven unreliable. Furthermore, CT analysis may overestimate the extent of fracture comminution.

**Box 12.48.5 Aspects of injury associated with acetabular fractures which can be recognized using axial CT**

- Identification and orientation of additional fracture lines
- Injuries to the posterior pelvic ring
- Intra-articular osteochondral fragments
- Fractures of the femoral head
- Marginal impaction of the articular surface
- Size and location of anterior and posterior wall fractures
- Rotation of the fracture fragments
- Fractures of the quadrilateral plate not seen on radiographs
- Involvement of the superior acetabular articular surface.

Three-dimensional CT scan technology has improved to the point that it is helpful in further defining the fracture pattern and thereby assisting in preoperative planning. However, it does not provide the diagnostic detail of the two-dimensional CT scan.

**Fracture classification**

The basic acetabular fracture classification developed by Judet and Letournel has been incorporated into the alphanumeric comprehensive fracture classification systems of the Orthopaedic Trauma Association and AO. Therefore, the ‘Letournel’ acetabular fracture classification continues to remain the international language of the majority of surgeons treating these complex injuries. The classification is based on the anatomy of the fracture pattern and has ten distinct categories, which are divided into five elementary types and five associated types (Figure 12.48.5 and Box 12.48.6). Variants of these ten basic types are not uncommon. However, they can usually be easily integrated into the system. This system is important not only for its ability to describe the fracture, but it also serves as a guide for subsequent operative treatment. High rates of interobserver and intraobserver reliability have been reported using this classification system.

**Fig. 12.48.5**

Letournel classification of acetabular fractures is based on anatomic description of fracture patterns. There are 10 fracture types, divided into five elementary patterns and five associated patterns. The elementary patterns are: A, posterior wall; B, posterior column; C, anterior wall; D, anterior column; E, transverse. The associated patterns are as follows: F, posterior column and posterior wall; G, transverse and posterior wall; H, T-shaped; I, anterior column (or wall) with associated posterior hemitransverse; J, both-column. Reproduced with permission from Orthopaedic Knowledge Update 2. Rosemont, IL, American Academy of Orthopaedic Surgeons, 1987.

**Box 12.48.6 Classification of acetabular fractures**

- Elementary fracture patterns:
  - Posterior wall
  - Posterior column
  - Anterior wall
  - Anterior column
- Transverse

- Associated fracture patterns:
  - Posterior column and posterior wall
  - Transverse and posterior wall
  - T-shaped
  - Anterior column (or wall) and posterior hemitransverse
  - Both-column.

### Elementary fracture patterns

#### Posterior wall fractures

Fractures of the posterior wall are the most common type of acetabular fractures. The posterior wall fracture involves disruption of the posterior rim of the acetabulum, along with a portion of the articular surface and retroacetabular surface. Fractures can vary in size from a very small portion of articular surface to nearly the entire posterior wall, and can vary in location from the posteroinferior to the posterosuperior aspect of the acetabular articular surface. On the AP and obturator oblique x-rays, posterior wall fractures disrupt the posterior rim, but no other radiographic landmarks (Figure 12.48.6). Impaction of the articular surface (marginal impaction) (Figure 12.48.4) is a common associated finding. The typical posterior wall fracture does not disrupt the greater and lesser sciatic notches or extend into the quadrilateral surface. Extended posterior wall fractures represent a more severe injury that involve a disruption of the greater or lesser sciatic notches, and a portion of the quadrilateral surface. These fractures do not extend into the obturator foramen.

![Click to view larger](#)

*Fig. 12.48.4*  
Axial CT image through the acetabulum. The right acetabular posterior wall is fractured (black arrows). There is an intra-articular loose body between the femoral head and acetabulum (white arrow). The asymmetry of the contour of the posterior wall from side to side is secondary to marginal impaction (white arrowhead), which occurs when a segment of the articular surface and underlying cancellous bone adjacent to a major fracture line is impacted or depressed away from the normal contour of the joint. (Copyright Dr. Berton R. Moed.)
Posterior column fractures

Posterior column fractures (Figure 12.48.7) disrupt the posterior or ischial portion of the acetabulum and are best seen on the iliac oblique view. The majority of the retroacetabular surface is displaced with the posterior column. A vertical or oblique fracture line starting near the apex of the greater sciatic notch and crossing in the acetabular fossa, separates the anterior and posterior columns, and commonly enters the obturator foramen. There is usually an associated fracture of the inferior pubic ramus. The femoral head usually follows the posterior column posteriorly and medially. The ilioischial line is typically displaced relative to the teardrop. However, when a large portion of the quadrilateral surface remains intact with the posterior column, the teardrop will displace with the ilioischial line.

Fig. 12.48.7
Posterior column fracture: A) anteroposterior; B) obturator oblique; C) iliac oblique views and selected CT section. The anteroposterior view shows disruption of the ilioischial line displaced medial to the teardrop (arrow) and the fracture through the inferior pubic ramus (arrowhead). The obturator oblique view shows the intact iliopectineal line (arrow) and the fracture through the inferior pubic ramus (arrowhead). On the iliac oblique view, the fracture propagates through the greater sciatic notch. The CT shows the separation between the anterior and posterior columns (arrow). (Courtesy of Mr. Martin D. Bircher.)

Anterior wall fractures

Anterior wall fractures disrupt the central portion of the anterior column (Figure 12.48.5C) and are rare fractures (1–2%). The inferior pubic ramus is typically intact. The iliopectineal line commonly has displacement in its mid-portion on the AP and obturator oblique views and the ilioischial line is intact. An anterior wall fracture variant has been described (Figure 12.48.8), which does not involve the pelvic brim and is a morphological equivalent to the posterior wall fracture.

Fig. 12.48.8
Plastic bone model showing external aspect of the innominate bone. The anterior wall fracture variant drawn on the external surface of the innominate bone. (Copyright Dr. Berton R. Moed.)

Anterior column fractures

Anterior column fractures can occur at a variety of levels. The fracture is named based on where it exits the bone anteriorly. High
fractures exit the iliac crest, intermediate fractures exit at the anterior superior iliac spine (ASIS), low fractures exit below the anterior inferior iliac spine (AIIS), and very low fractures exit at the iliopectineal eminence. The fracture typically involves disruption of the superior acetabular articular surface in the coronal plane. The iliopectineal line and anterior rim are typically displaced. Displacement of the superior articular surface is often best seen on the obturator oblique view. Inferiorly, the fracture disrupts the obturator ring through the ischiopubic ramus. Many variants have been described (Figure 12.48.9).

Transverse fractures

Transverse fractures divide the innominate bone into two portions, with a horizontally displaced fracture line, an intact superior acetabular fragment, and an inferior ischiopubic segment. The fracture begins at the pelvic brim, superomedially, and extends obliquely laterally and distally. The fracture line can cross the acetabulum at various levels and have been subdivided into three groups: transtectal fractures—the fracture line crosses the superior acetabular articular surface; juxtatectal fractures—the fracture line crosses at the junction of the superior acetabular articular surface and superior cotyloid fossa; and infratectal fractures—the fracture line crosses through the cotyloid fossa. Disruption of the vertical landmarks on the AP view (i.e. iliopectineal line, ilioischial line, anterior, and posterior rims) are noted. On CT scan, the fracture line is oriented in an AP direction in the axial section (see Figure 12.48.10D).

Associated patterns
Posterior column and posterior wall fractures

The association of a posterior column and posterior wall fracture represents a typical posterior column fracture, complicated by injury to the posterior wall. The femoral head usually dislocates with the wall component. Radiographic signs of a posterior column fracture with a dissociation of the ilioschial line and teardrop are commonly noted. Posterior wall fractures will be best seen on the obturator oblique view.

Transverse and posterior wall fractures

Associated transverse and posterior wall fractures are an extremely common type of acetabular fracture, approximately 20% of all acetabular fractures. The femoral head is often dislocated. This fracture combines a normal transverse configuration with a posterior wall fracture component. When the posterior wall fragment is minimally displaced, it may be missed on the AP pelvis, but is commonly seen on the obturator oblique view, as well as the CT.

T-shaped fractures

T-shaped fractures are similar to transverse fractures with the addition of a vertical fracture in the ischiopubic segment along the quadrilateral surface and acetabular fossa, separating the anterior and posterior columns inferiorly (Figure 12.48.10). This inferior fracture is known as the stem of the T. The stem will typically extend through the obturator foramen, exiting through the ischiopubic ramus; however, it may also extend posteriorly (exiting through the ischium) or anteriorly (exiting near the pubic body). Medial or posterior subluxation of the femoral head can occur.

Anterior column and posterior hemitransverse fractures

Anterior column with associated posterior hemitransverse fracture combines an anterior wall or anterior column fracture with a transverse component posteriorly. The posterior component of this fracture pattern is identical to the posterior half of a transverse fracture. The distinction between the associated anterior column and posterior hemitransverse and the T-shape patterns is often subtle. The anterior injury is typically at a higher level and more displaced than the posterior hemitransverse component. Anterior subluxation of the femoral head is typical with an anterior column and posterior hemitransverse injury.

Both-column fractures

Both-column fractures by definition have the anterior and posterior columns separated from each other, and all articular segments of the acetabulum are detached from the intact portion of the posterior ilium (Figure 12.48.11). The both-column fracture is unique, in that it represents an acetabulum completely disconnected from the axial skeleton. If the femoral head medializes, the articular fragments can rotate around the head because the labrum is usually intact. This is called ‘secondary congruence’ and is unique to both column fractures. Both-column fractures are associated with the ‘spur’ sign. This represents the fracture edge of the intact posterior ilium that is seen prominently on the obturator oblique view. This spur sign is pathognomonic of a both-column fracture (Figure 12.48.11B). The surgeon should recognize that transverse fractures, transverse and posterior wall fractures, T-shaped fractures, and anterior column and posterior hemitransverse fractures all involve the anterior and posterior columns of the acetabulum, but are not ‘both-column’ fractures. In these four fracture types, a portion of the articular surface remains intact with the ilium and the axial skeleton.

Systematic approach to interpretation

The acetabulum is a complex three-dimensional structure and effort is required to develop the required interpretive skills. The majority of fractures can be classified from the information gleaned from high-quality plain radiographs. An organized approach to
the examination of the three radiographs (AP and obliques) and the CT scan of a patient with an acetabular fracture must be used. One method is as follows.

First, the lines on the AP radiograph (Figure 12.48.3A) should be carefully analysed in turn. Is the iliopectineal line disrupted? If so, the fracture possibilities include the anterior wall, anterior column, transverse types, T-shaped, anterior column and posterior hemitransverse, and both-column. If the ilioischial line is disrupted, possibilities include the posterior column types, transverse types, T-shaped, anterior column and posterior hemitransverse, and both-column. With both lines disrupted, the possibilities are reduced to transverse types, T-shaped, anterior column and posterior hemitransverse, and both-column. Is the line along the posterior rim disrupted? If so, this will add the possibility of a posterior wall fracture. Is the ilioischial line displaced from its normal relationship to the teardrop? If so, this would indicate, in general, that the two columns are separated from each other.

Next the obturator oblique is examined. This view will refine the diagnosis made from the AP view. A suspected posterior wall component will become obvious, as well as disruption involving the anterior wall or column. Is the obturator ring fractured? If so, this, again, would suggest that the two columns are separated from each other. The presence of a spur sign (Figure 12.48.11B) is pathognomonic for a both-column fracture. The iliac oblique is viewed next. Injury to the posterior column is further defined, as well as the presence and location of fractures involving the iliac wing (for example, anterior column, anterior column and posterior hemitransverse, and both-column fractures).

Finally, the CT scan is studied to reveal the additional information described previously (Box 12.48.5). After this analysis, the plain films should be revisited to refine the diagnosis for fracture subtypes (for example, the level of transverse fracture or the path of the stem of the T-shaped fracture). If the diagnosis continues to be unclear, the three-dimensional CT scan can prove helpful. However, as noted previously, the three-dimensional CT scan has its limitations.

In some clinical situations, high-quality plain radiographs, especially the Judet oblique views, may be difficult to obtain. Investigators have reported on the advantages of equivalents to the plain oblique radiographs, which are reconstructed from CT scan data using three-dimensional CT modelling software. However, the use of this approach and an overall increased role for the three-dimensional CT scan, awaits further study, as well as technological improvements.

### Summary

Acetabular fracture patterns can be complex; however, classification can be achieved with the use of appropriate imaging and a systematic approach. Classification is not only important for communication but is essential in allowing the surgeon to understand the fracture pattern and select the most appropriate surgical strategy.

### Further reading

Summary points

- Acetabular fracture patients often have associated injuries
- Restoration of hip joint congruity and stability are the treatment goals
- Stable concentrically reduced fractures can be considered for non-operative management
- Operative treatment is indicated for fractures with hip joint instability or incongruity
- Choosing the proper surgical approach is one of the most important treatment aspects
- Although the surgery is demanding, an experienced surgeon can obtain excellent results.

Introduction

Restoration of hip joint congruity and stability are the goals of acetabular fracture treatment. The achievement of these goals should minimize pain, prevent post-traumatic osteoarthritis, and thereby improve long-term functional outcome. Although certain fracture patterns may not require surgery to have a satisfactory outcome, in general, a patient with a displaced fracture in the superior weight-bearing area of the acetabulum should be managed with open reduction and internal fixation. However, the surgery is complex and demanding, even for the experienced surgeon, and has the potential for many serious complications. Therefore, many factors, including the patient’s age, general medical condition, and associated injuries, must be considered prior to making definitive management decisions.

Patients with severe associated injuries should be treated non-operatively until their general condition improves. Continued poor general medical status and a long delay (>3 weeks) from injury to possible operative intervention may dictate a non-operative management course. Elderly, debilitated patients and others with pre-existing osteopenia require special consideration since the ability to achieve and maintain an anatomical reduction may be more difficult due to poor bone stock and extensive comminution. Furthermore, these patients often have sustained low-energy trauma resulting in a fracture pattern more amenable to non-operative care. Total hip arthroplasty may be a reasonable option either acutely or as a delayed reconstruction.

Initial management (Box 12.49.1)

In most cases, the patient with a fracture of the acetabulum has sustained high-energy trauma. Therefore, these patients often will have an associated injury that must be identified during the initial work-up. Consequently, the initial evaluation, even in those patients with an apparent isolated injury, should be part of a well-organized overall approach. Associated injuries can be life- or limb-threatening. In contradistinction to the unstable pelvic ring injury, a closed fracture of the acetabulum, occurring alone or in combination with other extremity fractures, should not be considered as the primary cause of hypotensive shock. An alternative source of haemorrhage should always be sought. However, laceration of the superior gluteal artery with severe bleeding can be caused by fractures of the acetabulum having wide posterior column displacement. One must be alert to this possibility, which is treatable by therapeutic embolization.

A detailed physical examination is a necessity. The soft tissues should be carefully evaluated, as soft-tissue injury has important implications for subsequent surgery. Acetabular fracture surgery through a compromised soft-tissue envelope is ill advised due to the increased risk of infection. Closed de-gloving soft-tissue injuries over the trochanteric region associated with underlying haematoma formation and fat necrosis (the Morel-Lavallé lesion) or open wounds may require debridement followed by delayed wound closure. More recently, a percutaneous method has been reported in a small number of patients, using a plastic brush to debride the injured fatty tissue, which is then washed from the wound with pulsed lavage. A medium closed-suction drain is placed within the lesion and removed when drainage is less than 30mL over 24h. Fracture fixation is deferred until at least 24h after drain removal. The prevalence of post-traumatic sciatic nerve injury has been reported as being as high as 29%. Other peripheral nerves, such as the femoral nerve and obturator nerve, may also be injured. A complete and clearly documented neurological examination is extremely important both for patient prognosis and for medicolegal concerns.

Box 12.49.1 Initial management

- Assess and treat according to ATLS® protocols
- Evaluate soft tissue, e.g. Morel-Lavallé lesion
- Evaluate neurology
- Reduce hip dislocation ± dynamic assessment of stability
- Skeletal traction
- Diagnostic imaging (see Chapter 12.48)
Initial acetabular fracture management depends on the specific fracture pattern, the amount of fracture displacement, and the relative stability and congruency of the hip joint. The initial anteroposterior (AP) radiograph of the pelvis (which is often an adjunct to the ATLs primary survey) can provide substantial diagnostic information and indicate the need for emergency treatment. This radiograph must be supplemented by further studies (oblique plain films and computed tomography (CT)—see Chapter 12.48) in order to define the injury completely.

Dislocation of the femoral head, which can be diagnosed on the initial AP radiograph, requires prompt reduction as the rate of osteonecrosis increases significantly if reduction is not performed within 12h of the injury. The reduction manoeuvre can often be performed in the emergency room setting. However, adequate sedation and pain medication are necessary. Subsequent failed closed reduction, pre-existing contraindications to conscious sedation, or doctor preference constitute indications for closed reduction using general anaesthesia. Immediately following reduction, confirmatory radiographs should be obtained. There is no need to stress an obviously unstable hip and redislocation may be injurious. Only when the fracture pattern suggests that the hip joint should be stable or stability is equivocal (such as with a small posterior wall fracture) should the hip be taken through a full range of motion to evaluate postreduction stability. As a diagnostic procedure, this examination is best performed using fluoroscopic visualization of the hip joint with the patient under general anaesthesia.

Patients with an acetabular fracture may not require skeletal traction. However, there are notable situations in which skeletal traction (preferably using a distal femoral, rather than a proximal tibial, traction pin) is either mandatory or desirable. Unstable fracture–dislocations require skeletal traction following reduction to prevent recurrent dislocation. When hip stability is in doubt, it is also prudent to use traction, pending further evaluation. Preoperative skeletal traction is also important to prevent further femoral head articular surface damage from abrasion by the raw acetabular bony fracture surfaces and may occasionally improve fracture position (Figure 12.49.1). Skin traction is ineffective and should not be used. Skeletal traction using a trochanteric pin is contraindicated due to its associated high infection risk and ineffectiveness in fracture reduction. In general, fractures with minimal or no displacement, both-column fractures in which the hip joint remains congruent and in acceptable position (so-called secondary congruence), and other displaced fractures not meeting operative criteria initially require only bed rest with symptomatic treatment. However, these patients, as well as those with fractures meeting operative criteria who do not require skeletal traction for fracture management, may benefit from skeletal traction for pain relief.

Operative treatment of acetabular fractures is not an emergency and is generally delayed 3–5 days to allow for stabilization of the patient’s general status and for preoperative planning. However, the time to surgery has been shown to be a significant predictor of radiological and clinical outcome. In one study, a good-to-excellent clinical outcome was more likely when surgery was performed within 15 days for elementary fractures and 10 days for associated types. The indications for emergency fracture fixation are uncommon (see later).

Non-operative management

In general, all stable concentrically reduced acetabular fractures not involving the superior acetabular dome can be considered for non-operative management. This group of fractures includes non-displaced and minimally displaced fractures, fractures in which the...
intact part of the acetabulum is large enough to maintain stability and congruity, and those with secondary congruence (Box 12.49.3). Non-operative management may also be selected for patients with severe osteoporosis or severe underlying medical problems that preclude surgical intervention. This is a relatively small group, consisting mainly of elderly patients.

**Box 12.49.2 Radiological criterion for non-operative treatment**

- Displacement <2mm
- Stability
  - Roof arc angles
    - medial 45 degrees
    - anterior 25 degrees
    - posterior 70 degrees
  - Dynamic fluoroscopy.

**Box 12.49.3 Fractures amenable to non-operative treatment**

- Stable non-displaced and minimally displaced fractures
- Selected displaced fractures:
  - Remaining intact acetabulum maintains stability and congruency
    - low anterior column fractures
    - low transverse fractures
    - low T-shaped fractures
  - Both-column fractures with secondary congruence
  - Wall fracture not compromising hip stability.

The condition of the superior dome of the acetabulum is a significant prognostic indicator of clinical outcome. The superior dome of the acetabulum is described as the superior third of the weight-bearing area of the acetabulum. Roof arc measurements can be used to decide whether or not an acetabular fracture has violated the weight bearing dome. This measurement has been used to determine if the remaining intact acetabulum is sufficient to maintain a stable and congruous relationship with the femoral head. In this way, operative verses non-operative treatment can be selected. The roof arc is measured on all three radiographic views with the leg out of traction. The medial roof arc is measured on the AP view. The anterior roof arc is measured on the obturator oblique, and the posterior roof arc is measured on the iliac oblique. To obtain these measurements, the first line is a vertical line through the centre of the femoral head and the second line is drawn from the centre of the femoral head to the fracture location at the articular surface (Figure 12.49.2). Roof arc measurements are not applicable to both-column fractures or those with a fracture of the posterior wall. The previous recommendations were that roof arc measurements greater than 45 degrees on the AP (medial roof arc), iliac oblique (posterior roof arc), and obturator oblique radiographs (anterior roof arc) indicate preservation of the weight-bearing dome, and these patients should be considered for non-operative management. More recently, however, biomechanical analysis has produced different criteria. Non-operative fracture management is considered with a medial roof arc angle of greater than 45 degrees, an anterior roof arc angle of greater than 25 degrees, and a posterior roof arc angle of greater than 70 degrees (Figure 12.49.3).

Fig. 12.49.2
A) Anteroposterior; B) internal oblique; and C) external oblique radiographs of a transverse fracture of the acetabulum of a 35-year-old man treated in 1992 showing roof arcs all approximately 50 degrees in measurement, indicative of a stable hip joint by the initial recommendations. (Copyright Dr. Berton R. Moed.)
CT cuts of the superior 10mm of the acetabular articular surface are equivalent to the weight-bearing dome region, and can also be useful in determining if acetabular fracture lines involve this region. Although controversy exists regarding the exact amount of displacement that is considered acceptable when the superior dome of the acetabulum is involved, most authors recommend surgical intervention if displacement exceeds 2mm.

Displaced low anterior column, low transverse and low T-shaped acetabular fractures are amenable to non-operative treatment, provided the fracture position is stable and the joint remains congruent.

Displaced both-column fractures of the acetabulum may be considered for non-operative management in the presence of secondary congruence (see Chapter 12.48, Figure 12.48.11), defined as congruency between the femoral head and the displaced acetabular articular fragments without skeletal traction being applied. Parallelism between the femoral head and acetabular articular surface must be maintained in all three radiographic views, especially in a young patient. In addition, articular fragment displacement and medial joint displacement should not be so excessive as to limit motion. However, it must be recognized that fractures with secondary congruence do not have as good a prognosis as those reduced in anatomical position.

Fractures involving the acetabular walls should be treated non-operatively only if the hip joint remains completely stable. Recurrent dislocation and subluxation have disastrous consequences. Although hip instability is much more common with fractures of the posterior wall, anterior wall fractures are also potentially unstable. CT studies of posterior wall fractures indicate that those involving greater than 40–50% are usually unstable, whereas fractures less than 20–25% are usually stable. However, there is evidence that these radiographic measurements are not reliable. When in doubt, it is safest to assume that all of these fractures are unstable until proven otherwise. Therefore, clinical evaluation of stability is mandatory if non-operative treatment is being considered. As noted previously, this examination is best performed using fluoroscopic visualization of the hip joint with the patient under general anaesthesia. With this method, the patient is placed supine with the hip in neutral rotation and full extension. The hip is then gradually flexed past 90 degrees while progressive manual force is applied through the hip along the longitudinal axis of the femur; simultaneously, fluoroscopic imaging of the hip is performed, first using the AP projection and then using the obturator oblique projection. If the hip appears stable (remains congruent) on this assessment, the exam is repeated with the addition of slight adduction and internal rotation (approximately 20 degrees). Frank redislocation is neither required nor clinically desirable. Therefore, posterior subluxation demonstrated in either view (as evidenced by a widening medial clear space or loss of joint parallelism) is indicative of dynamic hip instability. This technique has been proven to predict long-term stability and outcome. Acetabular wall fracture presenting in the absence of known hip dislocation is no guarantee of hip stability (Figure 12.49.4).
Fluoroscopic internal oblique views of a fracture of the posterior wall of the acetabulum without history of hip dislocation and involving less than 20% of the articular surface and presumed stable. A) The hip is in neutral position and the joint is congruent. B) The femoral head is subluxed posteriorly with 70 degrees of hip flexion indicating occult instability.

It seems obvious that all non-displaced and minimally displaced acetabular fractures should be considered for non-operative management. However, there have been advocates for percutaneous fracture fixation in this group of patients. The concern centres on the questionable stability of these fractures with the contention that a certain percentage will displace. Therefore early percutaneous fixation would avoid a subsequent more extensive open procedure or prevent the disaster of early traumatic arthritis in those (for whatever reason) not having the benefit of further treatment. However, only a very small number (less than 7%) of these non-displaced and minimally displaced fractures are potentially unstable and will significantly displace without traction. Rather than unnecessarily operating on a large number of fractures to prevent problems in these few or subject all of these patients to prolonged bed rest in traction, it makes more sense to try to identify those at risk for fracture displacement. Dynamic fluoroscopic stress examination with the patient under general anaesthesia, as noted earlier, is one proposed method of identifying these fractures at risk. However, the exact technique for performing this examination is ill defined for fractures other than the posterior wall. Another method is to closely observe all patients presenting with non-operative parameters via weekly radiographic follow-up, being prepared to shift immediately to operative management (percutaneous or otherwise) should joint instability or incongruency be detected.

**Technique**

The non-operative management of patients with acetabular fractures mainly consists of bed rest with joint mobilization and eventual progression to full weight-bearing activity. Bed rest is necessary in the acute injury phase only for symptomatic relief. Mobilization of the patient and the hip joint should follow as soon as symptoms allow. Patients should begin with touch-down partial weight bearing of the affected extremity (<10kg). AP and oblique radiographs should be obtained at frequent intervals (weekly for the first 4 weeks) to confirm maintenance of satisfactory position. When there is adequate fracture healing, usually by 6–12 weeks, the patient should gradually progress to full weight bearing. Joint mobilization should be continued throughout the rehabilitation period. The use of formal physiotherapy or continuous passive motion modalities should be tailored to the individual.

Prolonged traction treatment should be reserved for those patients with operative indications related to fracture displacement, but having medical contraindications. In these cases, traction should be maintained until fracture healing is sufficient to allow progressive weight-bearing ambulation and may range from 4–12 weeks.

**Results**

Good or excellent results can be achieved when congruency and stability are maintained with non-displaced fractures and some displaced fractures not involving the superior dome. Displaced fractures of the superior acetabular dome and posterior acetabular fractures are generally associated with poor clinical results. Delayed reduction of the hip dislocation, injury to the femoral head, and continued instability are all factors contributing to a poor outcome in patients with acetabular fractures.

### Operative management

**Indications (Box 12.49.4)**

Operative treatment is indicated for all acetabular fractures that result in hip joint instability and/or incongruity, no matter what the classification type. This statement applies to displaced fractures as well as to those with occult findings. Posterior and anterior wall fractures with instability of the hip joint require operative fixation. In addition, fragments of bone or soft tissue incarcerated within the hip joint may result in joint incongruity. Open reduction and removal of the loose body or obstructive tissue is indicated to prevent early onset of traumatic arthritis. Internal fixation should be performed in this setting as dictated by hip joint stability parameters.

Fracture displacement in the weight-bearing dome results in joint incongruity and constitutes one of the main indications for open reduction and internal fixation. As described previously, plain radiographs and CT can be effectively used to determine whether an acetabular fracture violates the weight-bearing dome. For the both-column fracture, loss of parallelism between the femoral head and the acetabular articular surface noted on any of the three radiographic views is an indication for operative management.

**Technique**

Acetabular fractures are difficult to define anatomically and radiographically, and especially challenging to treat surgically. However, these articular fractures should be treated according to standard orthopaedic principles: the objectives being stable, anatomical fracture fixation combined with early joint motion.

**Timing of surgery**

In general, the surgical treatment of an acetabular fracture is not an emergency. A delay of 3–5 days is commonly employed to allow for evaluation of any underlying medical problems or associated injuries and for preoperative planning. Much of the intraoperative manoeuvring for acetabular fracture reduction is performed indirectly, without direct exposure or complete visualization of the fracture fragments. These techniques rely on the presence of relatively mobile fracture fragments. Ten days following injury, early fracture healing begins to limit this type of fracture mobilization. Two weeks following injury, healing has often progressed to the point that this fracture mobility has been lost and a more extensive surgical approach is required for certain fracture types, such as the transverse, T-shaped, anterior column with posterior hemitransverse, and both-column patterns. After 3 weeks, callus formation is extensive to the point that the fracture is no longer considered to be an acute injury. It has been shown...
that a good-to-excellent clinical outcome is more likely when surgery was performed within 10–15 days. This compromised outcome is probably related to many factors beyond the more extensive surgical exposure with its attendant higher complication rate, such as acetabular cartilage damage and femoral head erosion. Therefore prolonged delay in operative treatment should be avoided if possible.

Indications for emergency open reduction and internal fixation are uncommon (Box 12.49.5). Treatment of open fractures of the acetabulum should follow the standard principles of open fracture management, which include emergency irrigation, debridement, and fracture stabilization. Fracture stabilization options include acute open reduction and internal fixation or traction followed by delayed open reduction and internal fixation. When an acetabular fracture is directly related to a vascular injury and fixation is an important adjunct to the vessel repair (i.e. femoral artery laceration with anterior column fracture), concomitant open reduction and internal fixation is indicated.

**Box 12.49.5 Timing of acetabular fracture surgery**

- **Emergency:**
  - Recurrent dislocation despite traction
  - Irreducible hip dislocation
  - Progressive sciatic nerve deficit following closed reduction
  - Associated vascular injury requiring repair
  - Open fractures
  - Ipsilateral femoral neck fracture
- 3–5 days after planning is ideal
- Results deteriorate after 10 days to 2 weeks.

**Planning and facilities**

Plain radiographs and CT imaging should allow the surgeon to classify the fracture type and to achieve a precise understanding of the ‘personality’ of the fracture. The three-dimensional CT reconstruction may obscure some fracture lines. However, this study can be very helpful in visualizing the overall fracture pattern in the mind’s eye (Figure 12.49.5). Drawing the fracture on paper or on a whole bone specimen is also very instructive. In this way the appropriate surgical approach, reduction technique, and hardware configuration can be planned with confidence that the required anatomical reduction and stable fixation will be accomplished.

**Box 12.49.4 Operative indications**

Intraoperative traction is very important in obtaining fracture reduction. Therefore, purpose-specific traction tables, such as the Judet fracture table or the Jackson table, are recommended. The operating table should be radiolucent. Intraoperative C-arm fluoroscopy can then be used to assess fracture reduction and hardware location. Therefore fluoroscopy equipment and trained radiology personnel are needed. An extensive array of instruments and implants is also required (Figure 12.49.6). An oscillating drill is helpful for placing screws deep within the wound.

Fig. 12.49.6
Example of some of the instruments often needed for fracture reduction (Synthes, Philadelphia, PA).

Reduction techniques and aids

Anatomical reduction of the intra-articular fracture fragments is the objective of acetabular fracture surgery. While correction of fracture displacement is very important, failure to appreciate and correct malrotation (which is considerable in many of the fracture types) is probably the most common cause of fracture malreduction. Developing an understanding of the deformity (gleaned from the preoperative imaging studies) is critically important. This will facilitate planning of intraoperative reduction manoeuvres. Various tools and techniques developed specifically for acetabular fracture reduction are essential. Long pointed reduction clamps, ball spike pushers, and Farabeuf clamps are extremely helpful in obtaining satisfactory reduction (Figure 12.49.7). Intraoperative traction, to unload the fracture fragments from the considerable deforming forces across the hip, is instrumental in assisting fracture reduction. Traction may be applied manually by a surgical assistant, either pulling on the leg or on a traction pin placed in the greater trochanter or distal femur. However, traction by this means is often difficult to maintain effectively. As noted earlier, operating room tables with traction capability are preferable. On board traction using a Universal Distractor is one possible alternative. A Schanz screw with T-handle attachment is helpful for traction and for direct fracture manipulation. K-wires and cerclage wires can be used to secure provisional fixation, and the reduction should be carefully evaluated using fluoroscopy or plain radiographs prior to permanent hardware placement. Fluoroscopy or intraoperative radiographs should be used throughout the procedure to confirm maintenance of reduction and appropriate placement of hardware (Figures 12.49.8 and 12.49.9).

Fig. 12.49.7
Intraoperative fluoroscopic views of a transverse type fracture before (top) and after (bottom) reduction using a pointed reduction clamp. The clamp has been placed through the greater sciatic notch, correcting the displacement and malrotation. (Reproduced from Moed, B.R. (2006). Acetabular fractures: the Kocher-Langenbeck approach. In Master techniques in orthopaedic surgery: fractures (ed. D.A. Wiss), pp. 685–709, Lippincott Williams & Wilkins, Philadelphia, PA.)
Implants

After an anatomical reduction has been obtained, stable fracture fixation is best accomplished using interfragmentary screws augmented by plates. Cortical screws of 3.5mm and 4.5mm diameter are ideal for this purpose and should be available in lengths up to 110mm. Longer or smaller diameter (2.7mm or 2.0mm) screws may be required depending on the fracture configuration or comminution (Figure 12.49.8). These sizes may not be readily available in standard instrument sets. Therefore, preoperative planning is invaluable in these instances. Reconstruction-type plates of 3.5mm (Synthes or Stryker), which can be contoured to the curved, irregular surface of the pelvis and acetabulum, are appropriate for stable fracture fixation (Figure 12.49.9). Implant sites should be carefully selected to obtain satisfactory bony purchase while avoiding neurovascular injury and intra-articular hardware placement. Experience dictates the quantity of hardware required to achieve a stable fixation construct.

Surgical approach (Box 12.49.6)

Selection of the appropriate surgical approach is one of the most important aspects of the preoperative planning for acetabular fracture surgery. The main determinants in the decision-making process are the fracture type, the elapsed time from injury to operative intervention, and the magnitude and location of maximal fracture displacement. The mainstay surgical approaches to the acetabulum are the Kocher–Langenbeck, iliinguinal, iliofemoral and the extended iliofemoral. The first three provide direct access to only one column of the acetabulum (posterior for the Kocher–Langenbeck; anterior for the iliinguinal and iliofemoral) and rely on indirect manipulation for reduction of any fracture lines that traverse the opposite column. The extended iliofemoral approach affords the opportunity for almost complete direct access to all aspects of the acetabulum.

Variations of the Kocher–Langenbeck include the addition of an osteotomy of the greater trochanteric or moving the proximal limb of the incision slightly more anterior (modified Gibson approach). These variations increase somewhat the anterior extent of the surgical exposure (see later). The modified Stoppa surgical approach, an extension of the standard Pfannenstiel incision, is an anterior intrapelvic approach and can be considered as a variation of the iliinguinal approach. This approach may provide improved...
visualization of the quadrilateral plate, while avoiding dissection of the femoral nerve and vessels. However, a secondary posterior incision (Kocher–Langenbeck) or one paralleling the iliac crest is often required. In addition, if the surgeon shifts his/her position to the opposite side of the operating room table from the ilioinguinal incision, all of the potential advantages of the modified Stoppa approach can be attained.

Modifications of the extended iliofemoral approach have been developed by others, such as the triradiate approach and the T-shaped variant. Each of these extended approaches has its distinguishing aspects. However, they are all variations on the same theme. The price to be paid for the greater surgical access is a greater risk of surgical complications.

As common sense would dictate, posterior fracture types require a posterior approach and anterior fracture types require an anterior approach. Fractures involving both columns demand some decision-making. In general, acute fractures without displacement through the weight-bearing dome can be reduced through a single surgical approach to that column of the acetabulum having the greatest fracture displacement, as long as the fracture lines traversing the opposite column can be accessed and manipulated by indirect reduction manoeuvres. Fracture mobility is gradually lost over time. Therefore, an extended approach (with its attendant higher complication rate) may be needed for delayed surgery of fractures that were otherwise amenable to a less extensive surgical exposure (see earlier). Other indications for the extended approaches include transverse and T-shaped fractures with displacement through the anatomical roof (weight-bearing area) of the acetabulum (i.e. transtectal fractures), T-shaped fractures having wide displacement of the vertical limb, and both-column fractures with sacroiliac joint involvement or segmental fracturing of the posterior column.

The full extent of an anterior approach is obtainable only with the patient in the supine position. Similarly, the posterior Kocher–Langenbeck approach is fully utilized with the patient prone. A simultaneous anterior and posterior surgical approach with the patient in the lateral position limits the access from either. Lateral patient positioning for other than posterior wall fracture fixation creates a tendency to use a more extensive surgical approach (i.e. extending a Kocher–Langenbeck to a triradiate or using simultaneous anterior and posterior incisions) when, with proper positioning and planning, less may have sufficed (Figure 12.49.10).

**Box 12.49.6 Surgical approaches**

- **Combined anterior and posterior**

Fig. 12.49.10

A 30-year-old woman struck a tree while skiing, sustaining a both-column fracture. Evaluation of (A) the plain radiographs and (B) the CT scan revealed a posterior superior wall fragment in a fracture otherwise readily amenable to the ilioinguinal surgical approach. The addition of a second surgical approach might be considered. However, in this case the wall fragment was
addressed through (C) the ilioinguinal approach by placing one tine of the reduction forceps along the external surface of the ilium accessed via limited elevation of the muscles along the iliac crest. (D) Postoperative radiographs and CT scan demonstrated an anatomical reduction.

Kocher–Langenbeck approach

The Kocher–Langenbeck approach is ideal for posterior wall fractures and posterior column fractures with or without an associated posterior wall fracture. Transverse and T-type fractures without displacement in the anatomical roof, treated within 15 days of injury, are also amenable to this surgical approach. In addition, for T-shaped fractures, the major displacement should be posterior, with only minor displacement occurring anteriorly at the pelvic brim.

The patient can be placed in the lateral or prone position. However, as noted previously, the prone position is preferred for the more complex fracture types. The knee must remain flexed throughout the procedure to reduce the risk of injury to the sciatic nerve. The incision begins approximately 6cm lateral to the posterior superior iliac spine, courses distally in a curvilinear fashion over the greater trochanter and extends in a mid-lateral position to the midpoint of the thigh. The fascia lata is sharply incised and the gluteus maximus muscle is bluntly divided toward the posterior superior iliac spine. The innervation of the gluteus maximus muscle comes from the inferior gluteal nerve, which runs from posterior to anterior in the muscle. Therefore the splitting of this muscle should stop as soon as the first nerve trunk is met, approximately at the midpoint between the greater trochanter and the posterior superior iliac spine. Next, the insertion of the gluteus maximus muscle into the femur is released. This allows posteromedial retraction of the muscle without excessive stretch on the inferior gluteal nerve. The sciatic nerve is then located along the posterior surface of the quadratus femoris muscle and traced proximally to the piriformis muscle. The short external rotators and piriformis tendon are divided and tagged with sutures to assist with retraction. These tendons should be incised approximately 1.5cm from their trochanteric insertion to avoid injury to the blood supply of the femoral head. Gentle retraction of the short external rotators allows visualization of the posterior column and retroacetabular space but provides only limited protection of the sciatic nerve.

The Kocher–Langenbeck approach provides direct visualization of the entire lateral aspect of the posterior column of the acetabulum (Figure 12.49.11). Visualization may be extended anterosuperiorly by dividing a portion of the gluteus medius insertion or performing a transtrochanteric osteotomy (Figure 12.49.12). Indirect access to the quadrilateral surface can be attained by the palpating finger or the use of special instruments placed through the greater sciatic notch. A posterior capsulotomy allows limited access to the posterior aspect of the joint surface. This access is increased in the presence of a fractured posterior wall. This approach has a relatively high risk for sciatic nerve injury and an intermediate risk for heterotopic ossification.
Modifications of the Kocher–Langenbeck approach

The modified Gibson approach differs from the Kocher–Langenbeck approach in its proximal dissection such that the interval between the gluteus maximus and tensor fasciae latae muscles is divided rather than splitting of the gluteus maximus muscle (Figure 12.49.13). In this way, the neurovascular supply to the anterior portion of the gluteus maximus muscle is not at risk. In addition, anterosuperior visualization and access are extended (Figure 12.49.12). Having a straight, rather than angled skin incision, may make the modified Gibson more cosmetically appealing, especially in obese female patients. Either the Kocher–Langenbeck or modified Gibson approaches can be combined with a trigastric trochanteric osteotomy, maintaining the gluteus medius, vastas lateralis and gluteus minimus muscle attachments to the mobile trochanteric fragment. In this way, intraoperative dislocation of the femoral head for inspection of the joint is facilitated.

Ilioinguinal approach

The ilioinguinal approach is indicated for fractures involving the anterior wall and anterior column. Transverse and T-type fractures in which the major displacement is anterior with minimal posterior displacement and both-column fractures having a non-comminuted posterior column fragment can also be managed using this approach. Again, these complex fracture types must not have displacement in the anatomical roof and must be treated within 15 days of injury.

The patient is placed supine on the operating room table. The incision extends from just posterior to the gluteus medius tubercle, paralleling the iliac crest to the anterior superior iliac spine and then coursing medially to the midline ending two finger-breaths above the pubic symphysis. The iliacus muscle is elevated from the internal iliac fossa. The aponeurosis of the external oblique muscle (along with the anterior aspect of the sheath of the rectus abdominis) is then incised from the anterior superior iliac spine to the midline, passing at least 1cm superior to the superficial inguinal ring. The aponeurosis is reflected distally revealing the spermatic cord in the male and the round ligament in the female. This structure is bluntly isolated along with the ilioinguinal nerve and retracted using a rubber sling. The now exposed inguinal ligament is split through its entire length revealing the laterally placed lacuna musculorum contents (lateral femoral cutaneous nerve, the iliopsoas muscle mass and femoral nerve) and the medially placed lacuna vasorum containing the external iliac vessels and lymphatics. The iliopectineal fascia, which separates these lacunae, must be incised to allow access to the quadrilateral plate and true pelvis. Separate rubber slings are placed around the lacuna musculorum contents and the external iliac vessels. In this way medial, middle and lateral surgical access ‘windows’ are created.

The internal iliac fossa, anterior aspect of the sacroiliac joint, and lateral portion of the anterior column can be visualized by retracting the iliopsoas medially. The quadrilateral plate can be accessed by retracting the iliopsoas laterally and the external iliac sheath medially. The superior pubic ramus is visualized by retracting the external iliac sheath laterally and spermatic cord medially. Lateral retraction of the spermatic cord (aided by release of the insertion of the rectus abdominis muscle) allows visualization of the symphysis pubis and access to the retropubic space. Prior to retraction of the vessels, care must be taken to look for an anomalous origin of the obturator artery, known as the corona mortis or other anastomoses between the obturator and the external iliac systems (Figure 12.49.14).
Iliac systems (Figure 12.49.14). Illustration of the commonly occurring small calibre anastomoses between the obturator and external iliac systems (A). Illustration of the true ‘corona mortis’, aberrant origin of the obturator artery from the external iliac system (B). (Reproduced from Grant, J.C.B. (1972). Grant’s atlas of anatomy (6th edn). Williams & Wilkins, Baltimore, MD.)

The ilioinguinal approach allows direct access to the entire pelvic brim and the internal iliac fossa (Figure 12.49.15). Indirect access to the quadrilateral surface can be attained by the palpating finger or the use of special instruments. This approach has the lowest rate of heterotopic ossification. The lateral femoral cutaneous nerve, the femoral nerve, the external iliac vessels, and the inguinal canal contents are all at risk for injury.

Fig. 12.49.15 Access provided by the ilioinguinal approach. Dots delineate the available area of direct visualization. Horizontal lines delineate the area of indirect access. Vertical lines delineate the area of visualization and access extended by release of the tensor fasciae latae muscle. (Copyright Dr. Berton R. Moed.)

Iliofemoral approach

The iliofemoral approach has limited application. It is the approach of choice for anterior wall fracture variants (see Chapter 12.48, Figure 12.48.8). Although the ilioinguinal is usually the better choice, the iliofemoral approach may be used for high anterior column fractures.

The patient is placed supine on the operating room table. The incision extends from just posterior to the gluteus medius tubercle, paralleling the iliac crest to the anterior superior iliac spine and then coursing distally for approximately 15cm along the lateral aspect of the sartorius muscle. The iliopsoas muscle is elevated off the inner aspect of the iliac crest. The sartorius origin and inguinal ligament are released from the anterior superior iliac spine. The interval between the sartorius and the tensor fascia lata is developed to allow exposure of the anterior hip joint capsule, the anteroinferior iliac spine, and the anterior column as far medial as the iliopectineal eminence.

This approach is fairly simple and low risk. However, access to the anterior column is quite limited. The lateral femoral cutaneous nerve or some portion thereof is usually injured with this approach.

Extended iliofemoral approach

The extended iliofemoral approach is indicated for selected complex acetabular fracture types and for surgery delayed more than 2 weeks following injury (see earlier section on timing of surgery). These include high transverse and T-type fractures involving the acetabular roof (i.e. transtectal fractures) and both-column fractures having a comminuted posterior column component, a displaced fracture through the sacroiliac joint or wide separation of the anterior and posterior columns at the acetabular rim.

The patient is placed in the lateral position and the knee maintained in a flexed position to relax the sciatic nerve. An inverted J incision is used, extending from the posterior superior iliac spine along the iliac crest to the anterior superior iliac spine and then continued distally to the midpoint of the thigh angling toward a point 2cm lateral to the lateral aspect of the patella. The gluteal and tensor fascia lata muscles are elevated from the external surface of the ilium and are hinged on the superior gluteal neurovascular bundle. The hip abductors and the short external rotators are released from their insertion into the greater trochanter to complete the exposure of almost the entire external surface of the bone. Release of the reflected head of the rectus femoris combined with a
The exposure of almost the entire external surface of the bone. Release of the reflected head of the rectus femoris combined with a circumferential capsulotomy at the acetabular rim provides direct visualization of the hip joint. The exposure can be extended medially by release of the sartorius and rectus femoris origins and elevation of the iliococcygeus from the internal iliac fossa. However, this additional muscle stripping creates added risk of iliac wing and acetabular dome devascularization and increased risk of infection.

The extended iliofemoral approach allows exposure of the entire outer surface of the ilium, posterior column, posterior wall, and anterior column to the level of the iliopectineal eminence (Figure 12.49.16). The articular surface is exposed following capsulotomy, and access to the iliac fossa is also possible, as noted earlier. This approach has a high rate of heterotopic bone formation. The risk of infection is significant, over 8% in one series. There is also a risk of injury to the sciatic nerve and the superior gluteal neurovascular bundle. At one time it was postulated that severe abductor muscle necrosis would result from injury to the superior gluteal artery. However, extensive clinical experience and animal studies indicate that this is not a clinically significant problem.

Triradiate approach

The triradiate approach has indications similar to those for the extended iliofemoral. However, the exposure is more limited, lacking complete visualization of the iliac crest. The skin incision is Y-shaped, with the posterior limb being nearly identical to the Kocher–Langenbeck incision. The anterior limb of the incision extends from the greater trochanter to the anterior superior iliac spine. The skin incision is deepened through the fascia. Posteriorly, the approach is as for the Kocher–Langenbeck. A trochanteric osteotomy is performed to release the abductor insertion, and the glutei and tensor muscles are elevated from the external surface of the ilium. The triradiate approach can be performed when the surgeon cannot address the fracture through an initial Kocher–Langenbeck approach.

Combined anterior and posterior approaches

Combined anterior and posterior approaches were originally used in sequential fashion when one approach was planned, but proved inadequate for fracture fixation. One example of this is the inability to reduce or fix the posterior column of a both-column fracture initially approached using the iliogingual. Use of simultaneous anterior (iliofemoral or iliogingual) and posterior (Kocher–Langenbeck) approaches has been advocated for complex fracture patterns. The patient is first positioned supine and then turned 45 degrees toward the side opposite the fracture and secured in this position. The initial incision is used to approach the column with the greatest displacement.

Postsurgical care

Patients should receive prophylactic intravenous antibiotics, administered preoperatively and continued at least 24h postoperatively. Prophylaxis for thromboembolic disease (mechanical or chemical) should be routinely used during the perioperative period and continued up to 12 weeks postoperatively, until the patient regains mobility. Heterotopic ossification is associated with all approaches that involve stripping of muscle from the external surface of the ilium and is a particular risk of extended surgical approaches. Therefore, prophylaxis should be considered in these cases.

AP and oblique postoperative radiographs should be obtained, and repeat radiographs should be evaluated at routine 4- to 6-week intervals during the early postoperative period to check maintenance of reduction and fracture healing. A postoperative CT scan should be considered if there is concern for intra-articular hardware or inadequate reduction.

Postoperatively, the patient is mobilized as quickly as the associated injuries will allow. Sitting up on the first postoperative day, is followed by formal physical therapy for muscle strengthening and active range of motion exercises on subsequent postoperative days. Total hip arthroplasty precautions should not be needed, as internal fixation has rendered the hip joint stable. Partial toe-touch weight bearing of 10–15kg with crutches or a walker is required for 10–12 weeks. However, progression to full weight bearing must be tailored to the individual. Physical therapy should continue until muscle strength and range of motion are regained or a plateau is reached.

Results
Clinical outcome and the subsequent development of post-traumatic osteoarthritis strongly correlate with the adequacy of fracture reduction. Early studies considered residual displacement of up to 2–3mm as ‘satisfactory’ and demonstrated good, very good, or excellent results in approximately three-quarters of the study group.

A more recent study used less than 2mm of residual displacement as an anatomical reduction and at an average follow-up of 10.9 years demonstrated 81% good or excellent clinical result, whereas only 64% of patients with non-anatomical reduction achieved a good or excellent clinical result. The rate of anatomical reduction was found to decrease with increased fracture complexity, patient age, and time delay to fracture fixation. Many studies have demonstrated the detrimental effect of delay to surgery. This affects the ability to achieve anatomical reduction and clinical outcome. It has been demonstrated that anatomical reduction is more likely if performed within 15 days for elemental and 5 days for associated fracture patterns.

Certain fracture patterns appear to have better outcomes after surgical treatment than others. Both-column fractures are complex injuries and technically demanding. However, they have a generally better outcome than many fracture types, despite a higher rate of non-anatomical reduction. Despite anatomical reduction in only 57% of cases, good to excellent result were achieved in 77% of one study group. Posterior wall fractures present as a straightforward treatment problem with excellent anatomical reduction rates reported as high as 100%. However, despite the anatomical reduction obtained, clinical failure rates as high as 32% have been reported. Other studies have reported better results and this disparity has been shown to be in large part, to the inadequacy of radiographs in assessing the quality of the postoperative posterior wall reduction.

Complications

The common major early complications consist of infection, iatrogenic nerve injury, intra-articular screw placement, and thromboembolism. Late complications include heterotopic ossification, post-traumatic arthritis, and osteonecrosis of the femoral head.

Infection

The rate of infection is approximately 5% in most series of acetabular fractures treated operatively. The risk of infection is increased in patients with open fractures and local soft tissue injuries such as Morel-Lavallé lesions. Gastrointestinal or urological injuries are also associated with increased infection rates. Appropriate antibiotics, less extensive surgical approaches, and aggressive debridement of open wounds can help to decrease the rate of infection. The adverse affect of a deep postoperative intra-articular wound infection cannot be minimized. Complete joint destruction can be expected in 50% of these cases.

Iatrogenic nerve injury

Although the superior gluteal, obturator, or femoral nerves (among others) may be injured during acetabular surgery, the prevalence of these injuries is low. However, iatrogenic damage to the sciatic nerve is one of the major complications encountered in acetabular fracture management. These injuries are most commonly associated with the posterior and extended surgical approaches which involve direct exposure and retraction of the sciatic nerve. However, injury at the time of indirect reduction of posterior column displacement through an anterior surgical approach can also occur.

Iatrogenic nerve injury rates have been reported ranging from 2–9%. Intraoperative sciatic nerve monitoring has been advocated by some authors as a method to decrease the incidence of sciatic nerve injury. However, the rate of nerve injury appears to decrease as surgeon experience increases. A 2% incidence has been reported without nerve monitoring when performed by experienced surgeons in a large centre. At present, there is no clear data indicating that intraoperative somatosensory evoked potential nerve monitoring actually reduces the overall rate of iatrogenic sciatic nerve injury. Spontaneous motor potential monitoring is another option and preliminary results indicate that this method may prove to be more effective. At present, there is no substitute for attention to detail in the operating room with careful patient positioning and good surgical technique.

Intra-articular hardware

Although specific rates are not available, intra-articular placement of screws is a documented and often destructive complication of acetabular fracture surgery. Intraoperative fluoroscopy is the best method of preventing this complication and avoiding post-traumatic arthritis.

Thromboembolism

Post-traumatic and postoperative thromboembolism is a significant problem in acetabular fracture patients. Proximal deep vein thrombosis has been identified using magnetic resonance venography in 34% of acetabular fracture patients. Therefore, some form of mechanical or chemical prophylaxis is recommended to decrease the risk of thromboembolic complications. One study indicated that early (at the time of hospital admission) mechanical prophylaxis with foot pumps and the addition of enoxaparin on a delayed basis (5 days after admission) is a very successful strategy for prophylaxis against venous thromboembolic disease following serious musculoskeletal injury. For any patient who was required to return to the operating room, the enoxaparin was discontinued on the night prior to surgery and was resumed within 12h of surgery. Despite the use of prophylactic treatment, the prevalence of post-traumatic and postoperative thromboembolism approximates 11% and the value of screening, using Doppler ultrasound or magnetic resonance venography remains controversial. The placement of prophylactic vena caval filters is controversial but may be indicated in selected high-risk patients.

Currently, no prophylactic treatment consensus exists. Our approach consists of mechanical sequential compressive devices applied on hospital admission to both lower extremities, low-molecular-weight heparin for chemical prophylaxis as soon as the patient is haemodynamically stable and screening using duplex colour Doppler ultrasound. For patients who require operative intervention, the low-molecular-weight heparin is discontinued on the night prior to surgery and resumed within 36h after surgery.
After discharge from the hospital, the patients are maintained on chemical prophylaxis until they have regained mobility, usually 6–12 weeks postoperatively. Venous caval filters are reserved for those high-risk patients having contraindications to chemical prophylaxis.

**Heterotopic ossification**

Heterotopic ossification has been reported as occurring in as many as 90% of patients after acetabular fracture surgery (range 18–90%) with severe involvement as high as 50% in some patient groups. The terminology ‘severe heterotopic ossification’ is often used to describe the amount of heterotopic ossification necessary to impair function. Greater than 20% loss of total hip motion is thought to be the best clinical definition for severe heterotopic ossification. Many reports have used the Brooker classification (Table 12.49.1), which relies solely on the AP radiographic view of the hip, for this determination. However, this radiographic method does not consistently correlate with hip joint motion and generally overestimates the clinical severity of heterotopic ossification. A radiographic classification that would accurately correlate with significant limitation of hip motion should be useful in evaluating the independent effect of heterotopic ossification on functional outcome in patients after acetabular fracture surgery. Adding the standard Judet oblique views (which would routinely be obtained in the course of the patient’s postoperative evaluation) to the AP view and reading them in a logical specified sequence appears to give a more reliable indication of the restriction of motion that can be attributed to heterotopic ossification. Using this modified system, class 0, I, and II typically demonstrate unimpaired range of motion.

The most notable risk factor for heterotopic ossification is stripping of the gluteal muscles from the external surface of the ilium. In a recent series, in which significant heterotopic bone formation was defined as motion limited by greater than 20% and patients were not given prophylactic treatment, the following prevalence figures were reported: Kocher–Langenbeck 8%; extended iliofemoral 20%; ilioinguinal, 2%.

It appears that the rate of heterotopic ossification can be significantly reduced with the use of indomethacin and radiation therapy. A recent prospective randomized study comparing indomethacin and radiation therapy demonstrated both to be safe and effective prophylactic agents. Non-compliance was the problem with indomethacin; radiation was strikingly more expensive. Use of a combination of irradiation and indomethacin essentially eliminated postoperative heterotopic ossification in one series as no progression of heterotopic ossification was noted, even when early ossification was seen on preoperative radiographs.

Heterotopic ossification is a significant potential postoperative complication of acetabular fracture surgery and prophylactic therapy is desirable. However, one must weigh the risk of prophylaxis and its potential for failure against the actual risk of occurrence in each particular clinical situation. A recent study in acetabular fracture patients has shown that the use of indomethacin increases the risk of long-bone non-union. Although genetic alterations in offspring may also be at issue, the possibility of induced malignant disease is the main concern with low-dose radiation therapy. However, for the radiation dosage and methods used for the prophylaxis of heterotopic ossification about the hip, the likelihood of induced malignancy is very low. Based on a review of the current evidence available in the literature, recommendations have been made regarding the use of heterotopic ossification prophylactic treatment (Box 12.49.7). Indomethacin is inexpensive, simple, safe, and probably works. As with other non-steroidal anti-inflammatory drugs, gastric and duodenal mucosal lesions may occur. In addition, gastrointestinal prophylaxis (such as misoprostol) should be considered to decrease the risk of these drug-induced lesions. However, the use of this drug, or that of any other gastrointestinal mucosal protective agent, in acetabular fracture patients receiving indomethacin for heterotopic ossification prophylaxis has not been studied. Irradiation should be considered in high-risk cases (e.g. head injured) and for adult patients (women beyond child-bearing age) requiring an extended surgical approach.

### Box 12.49.7 Recommendations for heterotopic ossification prophylaxis

- Prophylaxis after acetabular fracture fixation using the ilioinguinal surgical approach or similar surgical approaches is not recommended
- Prophylaxis after acetabular fracture fixation using the extended iliobrosal surgical approach or similar surgical approaches is recommended
- Despite conflicting evidence, prophylaxis with indomethacin after acetabular fracture fixation through the Kocher–Langenbeck surgical approach or similar posterolateral surgical approaches is recommended
- Prophylaxis with irradiation after acetabular fracture fixation through the Kocher–Langenbeck surgical approach or similar posterolateral surgical approaches is not recommended.
Post-traumatic arthritis and osteonecrosis of the femoral head

Post-traumatic arthritis is a well-documented complication of patients sustaining a fracture of the acetabulum. The quality of the fracture reduction appears to be the main determinant for clinical outcome and for the risk of late traumatic arthritis. Damage to the femoral head at the time of initial injury is another important factor. Osteonecrosis of the femoral head is known to result from acetabular fracture associated with hip dislocation and can also result in post-traumatic arthritis. However, post-traumatic arthritis is more commonly due to wear of the femoral head against a malreduced fracture and often may be incorrectly attributed to osteonecrosis. Total hip arthroplasty or arthrodesis is indicated for patients with post-traumatic arthritis and disabling pain.

Special circumstances

Elderly patients

Displaced acetabular fractures in elderly patients may be effectively treated with open reduction and internal fixation. Good or excellent results at 2-year minimum follow-up have been reported, in 16 of 17 elderly (over 60 years old) patients treated surgically. However, elderly patients often have low-energy fracture patterns (anterior column or both-column) that have a relatively good prognosis with conservative treatment. The decision to perform open reduction and internal fixation should be based on the fracture pattern, the medical status of the patient, and the degree of osteoporosis. Extended surgical approaches are to be avoided. The alternative is non-operative treatment followed by total hip arthroplasty, as the symptoms dictate, with the knowledge that the prognosis for conservative treatment is poor. Unfortunately, studies indicate that, overall, the late outcome of total hip arthroplasty after acetabular fracture is inferior to that of arthroplasty performed because of degenerative arthritis. Therefore, open reduction and internal fixation combined with primary total hip arthroplasty, as a single operative procedure, has been advocated for a highly selected group of especially severe acetabular fractures, particularly those in elderly patients.

Associated femoral shaft fractures

Fractures of the ipsilateral femoral shaft are common, and should be acutely fixed. Acute fixation of both the femoral and acetabular fracture may be undertaken, but this is often not desirable or logistically possible. If the two procedures are staged, the antegrade operative approach for femoral nailing may compromise a subsequent acetabular approach. Therefore, retrograde nailing of the femoral fracture should be considered.

Total hip arthroplasty after failed acetabular fracture surgery

As noted earlier, the results of total hip arthroplasty after failed acetabular fracture surgery are inferior to those of primary total hip arthroplasty for degenerative hip disease. There is a significantly higher rate of acetabular loosening (33%) and revision (14%) compared with patients who did not previously sustain an acetabular fracture. Factors contributing to these poorer results include the young age of the patients, the predominance of males, and the residual cessaosene deficiencies. The surgery itself is also technically more demanding. Therefore the performance of acetabular fracture surgery should not be approached as a satisfactory staging procedure prior to a definitive total joint replacement.

Summary

Since the initial publications of Judet and Letournel in the early 1960s significant strides have been made in the treatment of acetabular fractures. There is no doubt that excellent results can be obtained by experienced surgeons and the expansion of educational activities specific to acetabular fracture care has increased the number of experienced surgeons. However, acetabular fracture fixation remains extensive surgery with a significant potential complication rate. Not all patients achieve a good or excellent result, related mainly to residual fracture displacement, infection, nerve injury, thromboembolic disease and heterotopic ossification. Efforts continue toward the refinement in operative techniques and improved prophylactic measures. However, the results of Letournel and Judet (1993) remain as the ‘gold standard’. It is yet to be determined whether the advent of intraoperative, fluoroscopically-based three-dimensional image navigation systems, along with improved instrumentation for fracture reduction and fixation through limited-incisions, can better these results.

Further reading

Dislocations of the hip and femoral head fractures

Summary points

- Most injuries are high violence, so look for associated injuries
- Immediate closed reduction usually best under general anaesthetic
- Do not proceed to open reduction without appropriate imaging studies
- Surgical approach depends on injury pattern
- Some long term complications can be minimized/avoided by appropriate early treatment (e.g. avascular necrosis).

Background

Hip dislocations are commonly associated with other local and regional fractures and injuries resulting in a high risk of chronic disability and early or accelerated degenerative joint disease.

Importance

Avascular necrosis of the femoral head is a common complication of hip dislocation and a knowledge of the blood supply to the femoral head is therefore essential.

The main source of intraosseous blood supply of the weight-bearing portion of the femoral head is the deep branch of the medial femoral circumflex artery (MFCA) which gives rise to several ‘terminal’ superior retinaculum vessels. The deep branch of the MCFA passes between the psoas tendon laterally and pectineus medially, and runs laterally on the inferior border of obturator externus, which it crosses posteriorly, coming to lie between quadratus femoris and the inferior gemellus. It courses anterior to the inferior and superior gemellus muscles and the interposed obturator internus tendon (i.e. deep to these structures as seen from a posterior surgical approach) and enters the hip capsule just above the superior gemellus muscle, and distal to the piriformis tendon. The terminal retinacular vessels course towards the femoral head, bound to the femoral neck by the reflected fibres of the hip capsule.

The inferior gluteal artery may often anastomose with the MFCA through a branch that runs along the piriformis tendon, but the lateral femoral circumflex artery provides little contribution to the vascularity of the femoral head. A portion of the femoral head around the attachment of the ligamentum teres to the fovea is supplied by the medial epiphyseal branch of the acetabular branch of the obturator artery in the young.

Underlying causes

The underlying cause of dislocations and fracture–dislocations of the hip is high-energy force dissipation. The relationship of the pelvis to the vector of force through the femur will determine whether an anterior dislocation, posterior dislocation, or fracture–dislocation will occur.

Clinical features (Box 12.50.1)

History

Most patients presenting with dislocations and fracture–dislocations of the hip have a history of severe trauma with a high force dissipation, such as:

- Industrial accidents
- Falls from a height
- Road traffic collisions.

Because of high force dissipation, victims in motor vehicle collisions may suffer multiple injuries and other occupants of the same vehicle may suffer the same fate.

An accurate history is invaluable and must be sought from the ambulance officers or those delivering the patient to hospital:

- Patients with head injuries may be unable to provide a reliable history
- Patients with multiple injuries may have difficulty localizing their pain, especially after treatment with narcotic analgesics
- Regional injuries to the legs, pelvis, abdomen, and spine may obscure a hip dislocations

Physical examination
The high force dissipation involved in hip dislocation requires that medical staff should follow the principles of the early management of these injuries recommended by the Advanced Trauma Life Support method. Patients should undergo a thorough secondary examination initially to look for injuries to other organ systems and should be reviewed clinically over the next few days to exclude missed diagnoses.

Patients with a hip dislocation commonly present with:

- Pain
- Classical deformity
- Restricted and painful hip movement.

The positional deformity of a posterior hip dislocation is one of flexion, adduction, and internal rotation. In the presence of an anterior dislocation, the hip typically assumes a position of external rotation abduction and some extension. When ipsilateral fractures of the femoral shaft or neck occur, however, the leg may assume a near-normal position and the diagnosis of hip dislocation may be missed.

Knowledge of the mechanism of injury should alert medical staff to possible associated injuries for which a careful search must be made. Opposing forces of an impact to the knee at one end of the leg and the momentum of the body at the other can result in injury anywhere between those two points. Abrasions and lacerations over the patella or proximal anterior tibia may indicate the site of force application. Injuries about the knee include proximal tibial fractures, patellar fractures, osteochondral fractures of the patellar and distal femoral articular surfaces, and distal femoral fractures. Patellar and knee ligament injuries may lead to instability of the knee which must be carefully assessed. The pelvis and spine must be examined thoroughly to exclude pelvic fractures, pelvic ring disruption, and spinal injuries.

A detailed assessment must be made for neurological injuries and if these are present they must be documented before and after reduction of the hip. Sciatic nerve injuries, particularly of the peroneal component, occur commonly in hip dislocations. Injuries to the lumbosacral trunk may accompany disruptions of the pelvic ring and spinal nerve root injuries may be present in patients with vertebral fractures.

### Investigations

#### Imaging

**Plain films**

All patients subject to severe trauma should have radiographs of the cervical spine and chest, and an anteroposterior view of the pelvis, as recommended in the Advanced Trauma Life Support method.

**Box 12.50.1 General features of hip dislocations**

- Hip dislocations often associated with local and regional fractures
- Leg position with a posterior hip dislocation—flexion, adduction, and internal rotation
- Leg position with an anterior dislocation—external rotation abduction and extension
- Sciatic nerve injuries, particularly the peroneal component
- Medial femoral circumflex artery—main branch to the femoral head
- Risk of avascular necrosis.

The anteroposterior radiograph of the pelvis must be scrutinized systematically for evidence of hip dislocation. Check for:

- Any difference in size of the femoral heads (femoral head measurably larger in anterior dislocation; smaller in posterior dislocation)
- Symmetry of the hip joint space (asymmetrical with dislocation/subluxation or when fragments of bone, cartilage or soft tissues incarcerated in the joint)
- Integrity of Shenton’s line (Shenton’s line broken with dislocation/subluxation)
- Position of femoral shaft (adduction, internal rotation and flexion with posterior dislocation; abduction, external rotation and extension with anterior dislocation)
- Note: the lesser trochanter lies posterolaterally on the femur. It normally presents a small image that becomes more prominent with external rotation of the femur
- Associated fractures of the acetabulum (the presence, size and location of acetabular fractures determines the classification and treatment of hip dislocation)
- Associated fractures of the femoral head (large impaction fractures limit the stable range of hip rotation and influence prognosis. Undisplaced fractures must be recognized prior to attempting closed reduction of the hip. Displaced fractures may lead to an irreducible hip dislocation).
A series of pelvic radiographs, as described by Letournel and Judet, should be obtained when a hip dislocations is recognized, to improve the accuracy of diagnosis of associated fractures and the presence of incarcerated fragments in the hip joint. These additional views include an anteroposterior view of the hemipelvis and two 45-degree oblique views (Judent views), all centred on the femoral head. The pelvic series of radiographs allows an assessment to be made of the anterior and posterior walls and columns of the acetabulum. The three radiographs provide a profile of the anterior, middle, and posterior portion of the hip joint, which can be used to assess the integrity of the femoral head and acetabular surfaces. The three views can also be used to diagnose incarcerated fragments in the hip joint, as shown by incongruity of the joint, but only when the fragments are larger than 2mm. The Judent views are commonly omitted because of pain. Appropriate analgesia, however, is an integral part of resuscitation and the assistance of an anaesthetist may be sought when analgesia is inadequate. If the patient still cannot be positioned correctly for the Judent views, despite these measures, then the views should be taken under anaesthesia before a reduction is performed.

Repeat radiographs must be obtained immediately after reduction to determine the following:

- Adequacy of reduction
- The presence or absence of fragments of bone, cartilage, or soft tissue incarcerated in the joint space
- The number, size, location, and adequacy of reduction of fracture fragments of the femoral head and acetabulum
- The presence of associated fractures of the acetabulum and the femoral head and neck that may have been caused by the reduction or missed by the pre-reduction radiographs.

It is imperative for the plain radiographs to be interpreted precisely to diagnose all associated fractures and any incarcerated fragments in the hip joint. This information is essential for an accurate classification of the hip dislocation, and hence the choice of appropriate treatment and operative approach when surgery is indicated.

**Computed tomography**

The benefits of computed tomography (CT) compared with plain radiography include

- Greater resolution than plain radiography
- Visualization of the anteroposterior relationship of structures
- Visualization of the integrity of the articular surfaces of the femoral head and acetabulum in multiple axial slices
- Improved assessment of congruence
- Increased accuracy of diagnosis of impaction fractures of the femoral head or acetabulum (Figure 12.50.1).

![Axial CT scan of a posterior hip dislocation demonstrates multiple intra-articular bony fragments, an impaction fracture of the femoral head, and a displaced fracture of the left posterior acetabular wall.](Click to view larger)

The additional information provided by CT therefore improves the assessment of the size and displacement of fractures of the femoral head and the acetabular wall and hence the stability of the hip joint. Measurement of the percentage of remaining posterior acetabulum on axial CT scans after posterior dislocation of the hip provides a useful determinant of the stability of the joint (Figure 12.50.2). The incidence of instability is high when the remaining posterior articular surface is less than 34%. Hips with greater than 55% of the remaining posterior acetabulum will be stable.
Routine CT scanning has been recommended after successful closed reduction of hip dislocations and prior to planned open reduction, when closed reduction is unsuccessful. However, CT scanning may not be necessary after concentric reduction of simple (type I) posterior hip dislocations assessed on plain radiography. Nevertheless, the usefulness of CT scanning remains undisputed following dislocations of the hip associated with fractures or in the presence of an irreducible hip dislocation.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) offers improved imaging of soft tissues compared with CT scanning. MRI scanning may be useful in the following:

- Detection of fragments of cartilage or labrum incarcerated in the articular space after a hip dislocation
- Assessment of integrity of the articular surfaces and the labrum
- Evaluation of the blood supply of the femoral head.

From a practical perspective, MRI has limited usefulness in the initial evaluation of the multiply injured patient, because the procedure severely restricts access to the patient. MRI, however, may become a useful option after the patient is clinically stable.

Classification in relation to pathogenesis and treatment

Hip dislocations are classified as posterior or anterior, according to the position of the femoral head. The previously recognized term of 'central' dislocation has been superseded by a more comprehensive classification of acetabular fractures (AO Comprehensive Classification of Fractures of the Pelvis and Acetabulum). This subset of dislocations is discussed separately under acetabular fractures.

Thompson and Epstein subclassified posterior dislocations of the hip into five types. More recently described an improved subclassification of posterior hip dislocations that combined clinical and radiological findings, thereby providing a basic indication of treatment (Table 12.50.1).

Table 12.50.1 Levin classification of anterior and posterior hip dislocations

The clinical findings included:

- Irreducibility
- Assessment of stability after reduction of the hip.

Radiological findings included:

- Joint incongruity
- Incarceration of fragments of bone, cartilage, or soft tissue between the articular surfaces
- Associated fractures of the femoral head and acetabulum, based on findings on CT, MRI, and plain radiographs

Epstein subclassified anterior hip dislocations (Figure 12.50.3) into five types, but the subclassification took no consideration of the postreduction radiological findings and provided no benefit in determining the choice of treatment, outcome or prognosis. Consequently, a preferred subclassification is that of which follows the same pattern used for posterior dislocations (see Table 12.50.1).
Fig. 12.50.3
Type 1 anterior dislocation, with classic position of abduction and external rotation. The dislocated femoral head is radiographically larger.

Discussion on treatment

Early diagnosis and treatment is essential for the patient with a hip dislocation. Avascular necrosis of the femoral head correlates strongly with the duration of an unreduced hip dislocation. Prompt reduction of a dislocated hip is therefore mandatory. Epstein reported markedly improved long-term results with immediate open reduction compared with closed treatment. However, those improved results may have resulted from a visual clearance of loose bodies, from the hip joint, which could not be radiologically demonstrated at that time. The advent of CT scanning for postproduction assessment after hip reduction nullifies the advantage of visual assessment of loose bodies during open reduction. Most authors now favour an immediate attempt at closed reduction.

Ideally, a closed reduction should be performed under general anaesthesia if an anaesthetist is readily available. The reduction can be performed under intravenous analgesia and sedation just as easily in a well-equipped emergency department as in an operating room. Patients already intubated for the treatment of closed head injuries can have an immediate closed reduction of the hip. Patients undergoing a general anaesthetic for treatment of multiple injuries should have a closed reduction of the hip performed first.

If it is not possible for a patient to undergo an immediate general anaesthetic, then a closed reduction can be attempted in the emergency department. Only one attempt at closed reduction should be made, and only once the patient is adequately sedated. Forceful attempts at closed reduction should be avoided when the patient is inadequately sedated as further damage to articular cartilage can result. If the attempt at closed reduction is unsuccessful, the patient should undergo a closed reduction in the operating room under general anaesthesia and complete muscle paralysis. If a closed reduction is still unsuccessful, an immediate open reduction must be performed.

Before progressing to open reduction, the full pelvic series of radiographs must be available. Irreducible hip dislocations may be associated with the following:

- Fractures of the acetabulum or femoral head
- Buttonholing of the femoral head through the capsule
- Displacement of the piriformis muscle across the acetabulum
- Intra-articular loose bodies.

An accurate diagnosis of associated pathology is essential for preoperative planning of surgical approaches. For example:

- Fractures of the posterior acetabular wall should be approached through a posterior exposure of the hip joint
- Anterior wall fractures will require an anterior exposure
- Fractures of the femoral head are best approached through a surgical dislocation of the hip
- Intra-articular loose bodies may not be recognized in plain radiography and should be evaluated by CT scanning, but surgery should not be delayed if the CT scan cannot be performed immediately.

Methods of closed reduction

Standard principles of reduction of a dislocated joint should be followed:

- Apply traction in line with the deformity
- Then gently increase the deformity while maintaining traction
Gentle rotatory movements of the hip may aid reduction. Avoid forceful manipulative techniques (may cause increased risk of damage to the articular surface of the femoral head, a iatrogenic fracture of the femoral neck, or displacement of an unrecognized fracture).

Successful reduction is usually evidenced by an audible or palpable 'clunk', return of a leg to a normal position, and immediate relief of pain when the patient is awake.

Stimson described a gravity reduction technique in which the affected leg is left hanging off the end of the barouche or operating table, with the hip and knee in a position of 90 degrees of flexion. With one hand on the front of the ankle and the other on the calf of the affected leg, the surgeon can easily control the position of the leg, while directing an anterior reduction forced to the hip. In this technique the surgeon has the advantage of working in line with gravity.

An alternative method of production was described by Allis. In this technique, which is the author's preferred choice, the patient is left supine. The surgeon stands over the patient and pulls on the affected leg, against gravity, in the line of the deformity. When necessary, an assistant can apply countertraction to the pelvis. In large patients, when a lot of force is required, the assistant can gain a better hold by placing a towel over the skin first, before applying counter traction. The surgeon places one hand behind the calf and the other hand over the front of the ankle of the affected leg. By this means the position of the leg can be controlled, while an anterior reduction force is applied through the hip. When the surgeon has to apply greater force, various techniques can be used to gain a mechanical advantage. Bending forward at the waist, the surgeon can strut one elbow on an ipsilateral knee, placing the volar aspect of the forearm under the calf of the patient's affected leg. An anterior reduction force can then be applied by the surgeon flexing that elbow (Figure 12.50.4). When even greater force is required, the surgeon can use this same technique bilaterally. The ankle of the patient's affected leg is propped between the surgeon's knee and forearm. The patient's calf is supported in the surgeon's hands. An anterior reduction force can then be applied by the surgeon clasping both hands together and flexing both elbows (Figure 12.50.5). These techniques allow the surgeon to use safe back practices by applying traction through a technique of elbow flexion and not through back extension.

After reduction of the hip has been verified radiographically, the stability of the hip must be assessed clinically, under continued sedation or anaesthesia. This assessment is contraindicated in the presence of radiographic evidence of instability.
including large displaced fractures of the posterior or posterosuperior acetabular wall, displaced fractures of the acetabular columns, or in the presence of a femoral neck fracture. The assessment of stability is made by applying a strong posteriorly directed force through the knee, with the hip flexed to 90 degrees in a neutral position of rotation and abduction/adduction. If any evidence of subluxation is detected, a CT scan is required.

**Box 12.50.3 Indications for traction**

- If the hip is stable, simple skin traction will suffice
- If the hip is unstable, skeletal traction should be used
- A posteriorly unstable hip should be treated in external rotation
- An anteriorly unstable hip should be treated in internal rotation.

Successful reduction of a dislocated hip and grading of the dislocation should be immediately confirmed with plain radiographs, including an anteroposterior and lateral view of the hip and an anteroposterior view of the pelvis. The radiographs should be carefully reviewed for evidence of incongruence or fractures of the acetabulum, femoral head, or femoral neck. If a previously unrecognized fracture of the acetabulum is diagnosed, additional Judet views should be obtained. A CT scan of the involved hip should be obtained for all dislocations of the hip associated with fractures (Levin types II–V) or when the presence of an intra-articular loose body is suspected.

Following closed reduction and assessment of hip stability, the affected leg is placed in traction. If the hip is stable, simple skin traction will suffice. If the hip is unstable, skeletal traction should be used. A posteriorly unstable hip should be treated in external rotation. An anteriorly unstable hip should be treated in internal rotation. Rotation of the hip can be controlled by applying a traction cord to one end of the traction pin. Placement of a traction pin must be correctly inclined to achieve this.

**Box 12.50.2 Investigations and management**

- Anteroposterior view of the hemipelvis and two 45-degree oblique views—Judet views
- CT scans
- Hips with >55% of the remaining posterior acetabulum will be stable.
- If closed reduction is unsuccessful, an open reduction must be performed.

Widening of the hip joint is not radiographically (Box 12.50.4) evident on plain radiographs when fragments measuring 2mm are present in the hip joint. Therefore widening of the joint space on plain radiographs is a poor indicator of small loose bodies within the traumatized hip joint. Furthermore, although widening of the joint space is demonstrable when 4-mm fragments are interposed with in the hip joint, the widening does not equal the size of the fragment. There is a high risk of developing traumatic arthritis when patients with intra-articular fragments are treated in traction. Consequently it is imperative that the diagnosis of small loose bodies in the hip joint is not missed. Small loose bodies can be diagnosed by a CT scan taken with fine slices through the entire acetabulum. The scan should be processed for bone and soft tissue windows. When non-osseous loose bodies are present, MRI may be a useful alternative.

**Box 12.50.4 Principles of treatment**

- Treatment goals: anatomical reduction, restoration of hip joint stability, and removal of all interposed bone fragments
- Posterior hip dislocations with neurological deficit should be reduced as a surgical emergency
- Concomitant injuries may occur to the patella, femoral, or tibial condyles, or knee ligaments.

Once the radiographic imaging and clinical assessment of stability has been performed, the Levine grading of the dislocation can be completed. Management of the dislocation is largely determined by the Levine grading.

**Type I dislocations**

Type I injuries are pure dislocations or dislocations in which there is no significant associated fracture (Figure 12.50.6). A congruent reduction is obtained and the dislocation is stable after reduction. No surgical intervention is required. The patient is treated in gentle skin traction such as Hamilton–Russell traction. Active and passive range of motion exercises are permitted, but flexion beyond 90 degrees and internal rotation beyond 10 degrees are avoided for 6 weeks. Patients are mobilized weight-bearing as tolerated, once hip irritability resolves and leg control is regained.
Type II dislocations

In type II dislocations there is an irreducible hip dislocation (Figure 12.50.7). No significant associated fractures are present. The irreducibility is therefore due to the interposition of soft tissues, such as largely cartilaginous osteochondral loose bodies, the labrum, tendons, or muscle. An open reduction is required, with exposure of the hip joint on the side of the dislocation. If the hip remains unstable after reduction, further surgical exploration is required. If large tears of the capsule and labrum are present, these must be repaired. Concentric reduction of the hip joint must be confirmed radiologically in the operating room before surgical closure is performed.

Type III dislocations

In type III dislocations the hip is clinically unstable after reduction, or postproduction imaging demonstrates joint space widening or incarcerated fragments of bone or cartilage in the joint (Figure 12.50.8). The instability may be due to subluxation of the femoral head by incarcerated fragments, extensive labral detachment, or disruption of the capsuloligamentous attachments of the hip joint. Plain radiographs or CT scanning demonstrate bony fragments incarcerated in the articular space. Cartilage or soft tissue fragments are demonstrated best in MRI studies.
Minor capsuloligamentous disruptions or detachments of the acetabular labrum may be managed by non-surgical means, including bed rest or bracing of the hip within its stable arc of motion. Extensive labral tears may require surgical reattachment.

Fragments of tissue left incarcerated in the hip joint may damage the articular cartilage of the apposing femoral head and acetabulum. These fragments must be surgically cleared from the hip joint. Large fragments may be replaced where this is surgically possible. Smaller fragments must be removed, either arthroscopically or by an open procedure. When an open procedure is performed, the surgeon should choose the surgical exposure which offers the most direct approach to the offending fragment. Concentric reduction of the hip must be demonstrated radiographically before wound closure. The stable range of hip motion must be determined by stability examination before the patient leaves the operating room. Postoperatively the patient is placed in Hamilton–Russell traction. Active and passive range of motion exercises are permitted within the clinically determined stable range of hip motion. Once hip irritability resolves and leg control is regained patients are mobilized weight-bearing as tolerated. A hip brace may be used when the stable range of hip motion would leave the patient vulnerable to redislocation when walking.

Type IV dislocations

Type IV dislocations are associated with fractures of the acetabulum requiring reconstruction to restore joint congruity or hip stability (Figure 12.50.9). Prolonged dislocation of the hip joint should be prevented whenever possible. The author initially places the patient in skeletal traction and performs a gentle closed reduction at the time of insertion of the traction pin. Definitive surgical management should be dictated by the acetabular fracture and not the hip dislocation.

Type V dislocations

Type V dislocations are associated with fractures of the femoral neck (Figure 12.50.10) or femoral head (Figure 12.50.11). The mechanism of injury in femoral head fractures is the same as that of hip dislocations. Typically the injury occurs with the femur in a
neutral position with reference to abduction and relatively less flexion than in pure dislocations of the hip.

Fig. 12.50.10
Posterior hip dislocation with associated acetabular and femoral neck fractures (Levin type V). The classification assumes the grading of the most severe (femoral neck) injury.

Fig. 12.50.11
Cleavage fracture of the femoral head cephalad to the fovea (Pipkin type II), post-reduction of posterior hip dislocation.

The majority of hip dislocations are posterior. The incidence of femoral head fractures associated with posterior dislocations has been reported at 7–13%. Femoral head fractures have been reported in up to 68% of anterior hip dislocations, but the number of reported cases is small. Femoral head fractures may result from indentation (Figure 12.50.12) or cleavage (Figures 12.50.11 and 12.50.13) of the femoral head by the acetabular lip at the time of dislocation, or from avulsion by the teres ligament.

Fig. 12.50.12
Fracture dislocation left hip treated by closed reduction of hip dislocation and open reduction and internal fixation of transverse acetabular fracture. Note indentation on lateral portion of femoral head.
Pipkin classified cleavage fractures of a femoral head into four types according to the position of the fracture and the presence of a femoral neck or acetabular fracture (Table 12.50.2). In a type I injury the fracture of the femoral head is caudad to the fovea (Figure 12.50.14 and 15A). In type II injuries the fracture of the femoral head is cephalad to the fovea (Figures 12.50.11 and 12.50.15B). A type III injury is a type I or a type II fracture with an associated fracture of the femoral neck that results in a segmental fracture of the femoral head (Figure 12.50.15C). A type IV injury has an associated fracture of the acetabular rim (Figures 12.50.13 and 12.50.15D).

Fig. 12.50.14
Type I fracture of the femoral head, caudad to the fovea, with associated acetabular fractures (Pipkin type IV).
Pipkin’s classification of femoral head fractures. A) Pipkin type I. The femoral head fracture lies caudad to the fovea. B) Pipkin type II. The femoral head fracture lies cephalad to the fovea. C) Pipkin type III fractures have a fracture of the femoral neck associated with a type 1 or type II fracture of the femoral head. D) Pipkin type IV fractures have a fracture of the acetabulum associated with a type 1 or type II fracture of the femoral head.

Type 1 Pipkin fractures have been treated by closed reduction and traction. If postproduction radiographs demonstrate incongruence of the hip or the presence of intra-articular fragments, operative excision was previously recommended. Following experience gained in surgical hip dislocation the preferred treatment is open reduction and internal fixation for non-comminuted fractures sufficiently large to provide purchase for screw fixation.

Type II Pipkin fractures have been treated by closed reduction and traction, closed reduction and excision of the fragments, or open reduction and internal fixation. Following reduction the patient is treated in traction and early range of motion exercises are commenced.

Type III Pipkin fractures have been treated by closed reduction and traction, closed reduction and excision of the fragment, open reduction and internal fixation, and primary arthroplasty. Any attempt at closed reduction must be performed gently to avoid displacement of a femoral neck fracture, or the production of an iatrogenic fracture. If the attempt at reduction is unsuccessful, the surgeon should proceed to open reduction rather than resort to an excessively forceful closed reduction.

Type IV Pipkin fractures have been treated by closed reduction and traction, closed reduction and excision of the fragment, and open reduction and internal fixation. The acetabular fractures should dictate the treatment protocol. Undisplaced acetabular fractures may be treated non-operatively. When the indications for open reduction and internal fixation of the acetabulum are present, the fracture should be treated operatively and the femoral fracture can then be treated along the lines of type I and II fractures. Postoperative management is determined by the acetabular fracture.

Posterior hip dislocations may result in impaction (Figure 12.50.12) or cleavage fractures (Figures 12.50.13 and 12.50.14) of the femoral head that lie anteriorly. A surgical hip dislocation is ideal for operative reduction and internal fixation of these fractures and provides ready ease of access to the whole femoral head (Figure 12.50.16). Ganz and Beck have modified the technique by incorporating a step-cut of the greater trochanter. Placing the distal half of the trochanteric osteotomy deeper than the proximal portion, the intervening step between the two provides a mechanical block to proximal migration of the osteotomized trochanter after internal fixation. The patient’s ipsilateral knee is flexed and the tibial shaft used as a reference to the plane of the osteotomy. In contrast, anterior hip dislocations are characterized by cleavage or impaction fractures on the posterosuperior and lateral portion of the femoral head.
Outcomes and complications (Box 12.50.4)

Treatment goals of anatomical reduction, restoration of hip joint stability, and removal of all interposed bone fragments have resulted in an improved prognosis of femoral head fractures. In general, the outcomes of Pipkin type I and II fractures are similar and are better than those of Pipkin type III and IV fractures.

Sciatic nerve injury

The sciatic nerve is frequently injured in hip dislocations. The peroneal component is most commonly affected. The reported incidence varies from 8–19% of patients with hip dislocation. Damage to the nerve may be secondary to pressure ischaemia or directly from laceration or impalement by bone fragments. Nerve tissue has little tolerance to ischaemia. Posterior hip dislocations with neurological deficit of the sciatic nerve should therefore be reduced as a surgical emergency. Increasing sciatic nerve dysfunction in the presence of displaced posterior wall or transverse acetabular fractures should be treated emergently by acute open reduction and internal fixation of the fracture. Paresis may develop acutely after reduction of a hip dislocation and warrants surgical exploration. Causes include:

- Entrapment of the nerve in the joint
- Redislocation of an unstable hip
- Redisplacement of associated fractures
- Haemorrhage, especially with anticoagulation prophylaxis to thromboembolic disease.

Missed knee injuries

Posterior hip dislocations commonly results from a forceful blow to the front of the knee. Concomitant injuries may therefore occur to the patella, the femoral or tibial condyles, or to the knee ligaments. Posterior cruciate ligament injuries and posterolateral rotatory instability are the most common ligamentous injuries associated with posterior hip dislocation. Associated collateral knee ligament injury may occur when the causative force is applied to the tibia and not directly to the knee.

Avascular necrosis of the femoral head

Avascular necrosis of the femoral head occurs more commonly after posterior hip dislocations than after anterior dislocation. The reported incidence after posterior hip dislocation varies from 3–50%. Changes occur in the extrascapinous blood flow of the common femoral and circumflex vessels to dislocated hips. Internal rotation of the femur, posterior dislocation of the hip, and lateral displacement of the femur produces traction to the deep branch of the medial circumflex femoral artery, which have shown to be the major blood supply to the weight bearing portion of the femoral head. Delay in reduction may lead to avascular necrosis by prolonging ischaemia and by causing progressive arterial damage in the common femoral and circumflex vessels. The commencement of early weight bearing does not increase the incidence of avascular necrosis but may modify the severity of this complaint.

Recurrent dislocation

Recurrent hip dislocation may result from a deficiency of the bony and capsuloligamentous restraints of the hip joint, or an alteration of local muscle forces. Impaction fractures of the femoral head may also lead to recurrent dislocation in a manner similar to dislocation of the humeral head resulting from a Hill–Sachs lesion.

Heterotopic bone formation
The reported incidence of heterotopic bone formation associated with hip dislocation is 2%. The incidence increases after open reduction of dislocations, open reduction and internal fixation of associated fractures, delayed surgery, and in patients with a hip injury. Surgical excision may be warranted when heterotopic bone formation is disabling, but should be delayed until the process is quiescent. A bone scan may be helpful to confirm this.

Post-traumatic arthritis

The reported incidence of post-traumatic arthritis following uncomplicated hip dislocation varies around 11–16%. When hip dislocation is associated with acetabular fractures the incidence of post-traumatic arthritis rises markedly and has reached 88% in severe acetabular fractures. The incidence of post-traumatic arthritis decreased to 10% or less with accurate open reduction and internal fixation of acetabular fractures, but increased with age.

**Box 12.50.4(b) Long term complications**

- Avascular necrosis of the femoral head more common after posterior hip dislocations
- Recurrent hip dislocation
- Heterotopic bone formation
- Post-traumatic arthritis.

**Conclusion**

Appropriate management of hip dislocation requires a clear understanding of the mechanisms of injury, early recognition of systemic injuries, accurate diagnosis and grading of dislocations, and prompt effective treatment. Problems and complications must be anticipated to prevent their occurrence or to allow early and effective treatment when they occur. A comprehensive approach to the injury complexes associated with hip dislocation is mandatory for an effective outcome of treatment.

Chapter: Femoral neck fractures

Author(s): Martyn J. Parker

DOI: 10.1093/med/9780199550647.003.012051

Summary points

- Intracapsular fractures are classified by division into those fractures that are essentially undisplaced and those that are displaced.
- Undisplaced fractures are generally treated by reduction and internal fixation.
- Displaced fractures may be treated by reduction and internal fixation but this incurs the potential complications of redisplacement of the fracture, non-union, and avascular necrosis.
- Displaced fractures in the elderly are generally treated with a replacement arthroplasty.

Epidemiology (Box 12.51.1)

Fractures in the elderly, particularly hip fractures, constitute one of the major current orthopaedic problems. The expected increase in the number of elderly persons, as well as an increasing age-specific incidence of hip fractures, make this already large problem even more important. Worldwide, an estimated 1.3 million hip fractures occurred in 1990. As more of the world’s population reach their eighties, global numbers of hip fractures will increase to between 7 and 21 million by 2050. Much of this increase will occur in South America, India, and the Far East. Europe and North America can still expect an increase in numbers, but not by such dramatic amounts.

Having sustained a hip fracture there is an increased risk of later sustaining a similar type of fracture of the contralateral hip. The most plausible cause for this is the differences in femoral neck lengths, with a long femoral neck predisposing to an intracapsular fracture. Other causes may be the different degrees of osteoporosis in the femoral neck (cortical bone) and trochanteric area (cancellous bone), or the mechanism of the fall. Arthritis of the hip reduces the risk of an intracapsular fracture occurring but not an extracapsular fracture.

Box 12.51.1 Epidemiology of femoral neck fractures

- Average age is about 80 years, 75% female
- Major and increasing problem
- Risk increases exponentially with age
- Increasing incidence as more of the population live to their 80s
- The age-specific incidence is increasing particularly in developing countries.

Aetiology

Three principle factors are responsible for the occurrence of hip fractures in the elderly. These are a tendency to have falls with ageing, a diminution of protective mechanisms in falling (such as using their hands to cushion the impact of the fall), and weakening of the bone with ageing (Figure 12.51.1). Those who sustain a hip fracture tend to be frailer with more associated medical conditions than their age-matched peers.
Fig. 12.51.1
Differences in the fall characteristics for a wrist and hip fracture. The more elderly who sustain a hip fracture do not have the forward momentum and lack the protective mechanism from the upper limb to cushion the impact of the fall. The fall is directly onto the hip.

**Classification**

Proximal femoral fractures or ‘hip fractures’ can be primarily divided into two groups. Fractures proximal to the femoral attachment of the joint capsule are termed intracapsular (femoral neck, cervical) fractures, whilst those between the hip joint capsule insertion to a line 5cm distal to the distal part of the lesser trochanter are termed extracapsular fractures (Figure 12.51.2). Even this primary classification may cause confusion because fracture lines may cross these anatomical boundaries. In these circumstances the area in which the fracture line crossing the femur is predominately found should be taken. Where the fracture is situated running along the intertrochanteric line at the base of the femoral neck it is termed a basal fracture. These fractures are usually treated as trochanteric fractures (Box 12.51.2).

![Basic classification of proximal femoral fractures.](Click to view larger)

**Box 12.51.2 The approximate incidence of the different fracture types**

- Undisplaced intracapsular fractures: 14%
- Displaced intracapsular fractures: 42%
- Basal fractures: 3%
- Trochanteric two part: 12%
- Trochanteric multifragment: 25%
- Subtrochanteric fractures: 4%.

Ideally any classification of intracapsular fractures should be able to predict fracture healing complications, namely non-union and avascular necrosis. Unfortunately no system where radiographs are evaluated can reliably predict this outcome. In addition, most of the current classifications fail to reach acceptable degrees of intra- and interobserver variation. Garden classified cervical fractures into four groups depending on degree of dislocation evaluated on an anteroposterior (AP) radiograph (Figure 12.51.3). Whilst this is the most frequently quoted classification, in clinical practice there is poor interobserver agreement. Furthermore grade 2 fractures are rare and difficult to distinguish from the impacted grade 1 fractures. In addition the difference between the displaced fractures of grade 3 and 4 is of questionable value. Therefore the classification is only of value in differentiating between those fractures that are essentially undisplaced (Garden grades 1 and 2) and those that are displaced (Garden grade 3 and 4).
Garden’s classification of femoral neck fractures. Grades 1 and 2 are undisplaced fractures; grades 3 and 4 are displaced fractures.

The Pauwels classification of femoral neck fractures is based on the angle of the fracture line with the horizontal. Whilst biomechanical studies indicate that those fractures with the more vertical angle (type 3) have greater shearing forces across the fracture. Garden grade 1 impacted fractures are included in the classification and will invariably be type 1, whilst displaced fractures are type 2 or 3. Clinical studies have failed to find any difference in fracture healing complications between types 2 and 3. Essentially the classifications system is again dividing fractures into displaced and undisplaced fractures.

The more recent AO classification has nine subdivisions. These subdivisions have not been shown to be of value in predicting fracture healing complications and the system has been shown to have unacceptable intra- and interobserver variation. In summary, it is recommended to simply classify intracapsular fractures into those that are essentially undisplaced and those that are displaced.

**Diagnosis**

After falling, the patient, who is usually an elderly woman, lies on the floor unable to get up by themselves. The leg is usually shortened and the limb externally rotated with all movements causing pain. The fracture is diagnosed by an AP and lateral radiograph of the hip. Occasionally, for an undisplaced fracture the radiographic signs may be minimal causing a delay in diagnosis, during which time the fracture becomes displaced. A third radiograph with the hip in 10 degrees of internal rotation and the film centred on the hip may be useful to make the diagnosis (Figure 12.51.4).

An undisplaced intracapsular fracture which was not readily apparent on the initial x-rays taken in the position of comfort (external rotation). Taking an additional view in internal rotation reveals an undisplaced and impacted intracapsular fracture. There is loss of the cortical continuity laterally and an area of impacted bone (arrow). The trabeculae of the femoral head now have an angle of 170 degrees (normal 160 degrees) as the femoral head has tilted.

For those patients in which a hip fracture is suspected but there is no apparent abnormality on the plain radiographs additional investigations are required. A magnetic resonance imaging (MRI) scan of the hip is now the investigation of choice (Figure 12.51.5). In addition to revealing a hip fracture, this investigation will reveal alternative diagnoses such as a bone haematoma, pubic rami fracture, or soft tissue injuries.
Alternative investigations that may be used are an isotope bone scan or computed tomography (CT) scan of the hip (Box 12.51.3). If bone scintimetry is used, this should ideally be undertaken at least 2 days after the injury to reduce the risk of a false negative result.

**Box 12.51.3 Investigations of femoral neck fractures**

- Radiographs are indicated in any patient complaining of hip or groin pain after a fall who is unable to weight bear
- If initial pelvis and lateral views are normal, a third film with internal rotation can be taken
- MRI is the investigation of choice to detect fractures not evident on plain films
- Alternative investigations are isotope bone scan or CT scan.

**Management (Box 12.51.4)**

Thromboembolic prophylaxis for hip fracture patients remains a controversial topic. The progressive improvements in hip fracture management, with an increasing proportion of patients having early surgery and mobilization, has markedly reduced the incidence of thromboembolic complications. Furthermore the frail elderly patients who sustain a hip fracture are at increased risk of adverse bleeding complications (intestinal, intracerebral, and wound) from pharmacological prophylaxis. This means that there will be a fine balance between the adverse effects of prophylaxis and the benefits. The Cochrane review of randomized trial of heparins, demonstrated a reduction in thromboembolic complications with heparin but a tendency to an increased mortality to those allocated to receive prophylaxis. Aspirin has been recommended as an alternative to heparin by one clinical guideline. The largest clinical study on this indicated a reduced incidence of thromboembolic complications (2.5 to 1.5%), but an increased risk of wound haematoma (2.4 to 3.0%) and a tendency to a reduced mortality with aspirin. Mechanical prophylaxis appears to be effective but is costly and time consuming. Antembolism stocking have not been proven to be effective for hip fracture patients.

Traditionally, traction was applied to the limb with the aim of decreasing pain while waiting for surgery and to reduce the fracture and thereby improve the femoral head circulation. Randomized trials have since demonstrated that traction has no effect on the degree of discomfort encountered. No clinical studies have evaluated the effect of traction on femoral head blood flow.

If the fracture is to be managed surgically, then if possible this should be undertaken within 48h of the injury. Delaying surgery further will increase the complications of recumbency (pressure sores, thromboembolic complications, pneumonia), prolong the pain, and increase hospital stay. There will be a small group of patients (5–10%) in whom surgery needs to be delayed to improve their fitness for surgery (Box 12.51.5). Anaesthesia for hip fracture is invariably by means of general anaesthesia or a regional block with spinal anaesthesia. Spinal anaesthesia may have marginal benefits over general anaesthesia but the evidence base for this is limited.

**Box 12.51.5 Acceptable reasons for delaying surgery include:**

- Significant anaemia
- Hypovolaemia and/or severe dehydration
- Severe electrolyte imbalance
- Untreated cardiac failure
- Correctable cardiac arrhythmia
- Uncontrolled diabetes mellitus
- Severe hypertension
- Sepsis at the site of surgery.

**Pathophysiology**

Fracture healing for a femoral neck fracture is dependent on a stable fracture position and good circulation. The femoral head receives its blood supply from three sources:

- Through the marrow vessels. This is disrupted for all fractures
Assessment

- Diagnosis established
- Examination of the patient for associated injuries
- Review for medical conditions that may require treatment or influence management
- Consideration for possible aetiological factors for the fall
- Assessment of the patient’s prefracture mobility and mental state
- Record home circumstances and social history.

Initial management

- Pain relief (oral, parental, or nerve block)
- Intravenous fluids started in the emergency department
- Undertake routine biochemistry, haematology, and group and save
- ECG recorded
- Pressure relieving mattress used
- Chest x-ray presurgery if clinically indicated
- Nutritional support as indicated
- Thromboembolic prophylaxis
- Avoid excessive delays in transfer from the orthopaedic ward.

Surgical management

- If surgery is proposed, plan within 48h if possible
- Perioperative antibiotic prophylaxis
- Early and unrestricted mobilization after surgery
- Information for the patient and relatives and reassurance
- Early planning for rehabilitation and discharge.

The main complication after internal fixation is non-union of the fracture which occurs in about a third of patients. Early redisplacement of the fracture is generally included within the term non-union. Avascular necrosis or late segmental collapse of the femoral head is caused by the damage to the blood supply to the femoral head and generally presents 1–2 years after the injury. Non-union is a more common complication in the elderly whilst avascular necrosis is more common in younger patients.

Click to view larger

Fig. 12.51.6
Blood supply to the femoral head.
Operative versus conservative treatment

Undisplaced (including impacted Garden grade 1) intracapsular hip fractures may be managed conservatively. This entails a short period of bed rest followed by protected mobilization. The risk of the fracture displacing is markedly increased for conservative treatment compared with that after internal fixation (20–50% vs 5–10%). This increase is higher in the elderly and frail. Therefore non-operative treatment for an undisplaced fracture is only recommended if the patients several weeks after the episode of trauma or occasionally in younger individuals.

If a displaced intracapsular fracture is treated conservatively, non-union of the fracture is inevitable. This results in a painful hip with limited function. Conservative treatment may be used for those of limited life expectancy, but even for those of limited mobility, surgery is useful as it relieves pain, and provides a limb that can be used for walking and transfers. Excision arthroplasty, which is removing the femoral head, has been suggested as a means of providing pain relief for those that are immobile, but there is a limited published evidence to support such a method of treatment.

Osteosynthesis

Surgical treatment of an intracapsular hip fracture is either internal fixation to preserve the femoral head or a replacement arthroplasty. This remains an area where there is still controversy as to which patients should have their intracapsular fracture fixed or replaced. The problem with this fracture is the difficulty in achieving a secure and stable fixation for this fracture and the poor blood supply of the femoral head. This leads to a high incidence of fracture healing complications and has led to many surgeons favouring arthroplasty. In clinical practice there are a number of specific situations in which internal fixation is indicated, some in which arthroplasty is appropriate, and for a number of patients both methods of treatment may be used to good effect.

Indications for internal fixation

The situations where internal fixation of a femoral neck fracture is appropriate are:

Undisplaced intracapsular fractures

The term undisplaced fractures refers to those fractures that show no displacement in the AP and lateral radiographs, but also includes those in which there is impaction of bone (see Figure 12.51.4). These fractures do not require any reduction at the time of surgery. Non-union of the fracture is the most common complication of this procedure with an expected incidence of 6%, although this will be influenced by the age and sex of the patient (Figure 12.51.7). Arthroplasty for an undisplaced intracapsular fracture is inappropriate as it is a more extensive procedure with a higher risk of complications.

Mildly displaced intracapsular fractures

Occasionally the clinician is presented with the radiographs of an intracapsular fracture in which the fracture is essentially undisplaced on one of the radiographs but is beginning to displace on the other view. This is normally the lateral view in which the fracture is beginning to ‘open’. Such fractures are easily treated by internal fixation with an incidence of fracture healing complication only slightly more than that for an undisplaced fracture.

Displaced intracapsular fractures in the young

Two factors favour internal fixation in the young. Firstly the incidence of non-union of the fracture is lower in the younger patient (Figure 12.51.8). Secondly the increased life expectancy of the patient means that if an arthroplasty is undertaken there is a definite possibility of the patient requiring a revision arthroplasty in the future. These two factors meant that reduction and internal fixation is the method of choice for the young patient. What constitutes a young patient is debatable with young being defined as somewhere between 60 and 70 years but others give a limit of up to 75 years. A physiological assessment may be more appropriate, rather than a chronological one. Both fracture healing complications of non-union and avascular necrosis are less common in men compared to women.
Approximate incidence of non-union for displaced intracapsular fractures for men and women related to age.

Displaced intracapsular fractures in the very elderly

For the very frail elderly of limited life expectancy the lesser surgical procedure of reduction and internal fixation in comparison to arthroplasty may give a greater chance of the patient surviving. In addition, Figures 12.51.7 and 12.51.8 indicate that with increasing age the incidence of non-union falls. This is due to the death of patients before non-union occurs.

Displaced intracapsular fractures in specific situations

There may be a number of unusual but difficult situations in which reduction and fixation may be preferred to arthroplasty. Examples include a person with sepsis nearby. Internal fixation has a lower risk of sepsis. Patients with an increased risk of bleeding or wound haematoma may also be better treated with internal fixation.

Choice of implants

In 1931, Smith-Petersen described the technique of open reduction and fixation with a solid flanged nail. Johansson later improved the method by giving the nail a central channel which made it possible to position it over a guide wire. Since then, more than 100 different varieties of nails, screws, and pins have been used. Most implants consist of parallel pins or screws, inserted with the aid of the image intensifier.

Because of differences in patient selection and operative procedures, valid comparisons between different implants can only be made using a randomized controlled trial. All these studies to date have been summarized within the Cochrane review on the subject. This found that multiple parallel screws and the sliding hip screw were the most studied methods of fixation. The sliding hip screw was found to have a marginally lower risk of fracture healing complications to that of a multiple parallel screw technique (28% vs 33%), but requires a slightly larger surgical exposure to insert.

Timing of surgery

Debate exists as to how urgent surgery should be for a displaced femoral neck fracture. Early surgery may restore femoral head blood flow that was impeded by stretched vessels. Reports from one centre have supported early surgery within 6 hours of injury. However, other reports with large patient numbers, suggest that a delay of up to 7 days has only minimal effect on the incidence of fracture healing complications. After a delay of more than 1 week, closed reduction of the fracture becomes more difficult and an open reduction may be required.

Prediction of fracture healing complications

Various investigations have been used to try to predict the occurrence of fracture healing complications. To date, none have been shown to be reliable enough for routine clinical use. Preoperative scintimetry using 99Tc99m and postoperatively at 2–4 weeks postoperatively has been reported. If uptake on the fractured side is the same as than on the normal side, the fracture will heal without problems in over 90% of cases. More recently MRI has been used with a sensitivity of 81%. Other investigative methods that have been tried are intraosseous venography, intraosseous pressure measurement, arteriography, and injection of dye into the femoral head.

Surgical technique

The surgeon should supervise the transfer of the patient to the fracture table to guard against undue and excessive movements at the fracture site. The blood circulation to the femoral head via the capsular vessels along the femoral neck is vulnerable and could be impaired by sudden forceful movements of the hip during the reduction or by excessive traction causing fracture diastasis. Reduction is usually done in two stages. Firstly with the patient positioned in the fracture table, gentle traction is applied to the outstretched leg. Whilst this is done the fracture is screened with the image intensifier to ensure the leg is brought out to length. Traction is continued until the medial parts of the femoral neck (the calcar region) are approximated (Figure 12.51.9). Over-reduction must be avoided. Following this the fracture is reduced on the axial view by internal rotation (Figure 12.51.10). This part of the reduction can be looked upon as similar to closing a book. Full internal rotation may be required to complete this manoeuvre.
Reduction on the AP view. Gentle traction is applied to restore femoral length. The ideal reduction trabeculae angle should be 160–170 degrees.

Reduction on the lateral view. Internal rotation of the limb ‘closes the book’. The ideal reduction angle should be 180 degrees.

The goal is to restore the alignment of the femoral neck to an anatomical or slight valgus position. The ideal Gartland alignment angle should be 160–170 degrees (Figure 12.51.9). On the lateral a straight line bisects the femoral head, the trochanteric region, and the shaft (Figure 12.51.10). After reduction, some slackening of the traction allows impaction to occur and reduces the risk of femoral head rotation during surgery. Failure to achieve an acceptable reduction by closed means may lead to an open reduction. This is achieved via a small anterior approach to the hip and reducing the fracture under direct vision.

Rarely for a late presentation (over 1 week from injury), in a young patient with a displaced cervical fracture, consideration should be given to undertaking open reduction and insertion of a vascularized pedicle graft to the fracture. The aim is not only to reduce the fracture but to restore the femoral head vascularity. A number of different grafts may be use. The most commonly reported method is a posterior approach to insert a graft based on quadratus femoris muscle.

The positioning of the implant used is the subject of more dogma than science. If a multiple pin or screw method is used, general advice is that the inferior screw or pin should rest along the calcar. The lateral insertion point on the femur should not be lower than the lower border of the lesser trochanter to reduce the risk of causing a subtrochanteric femur fracture. On the axial view, inferior calcar support is again recommended and there should be spread of the screws into different segments of the femoral head. The tips of the screws or pins should be 3-5mm from the subchondral bone to obtain the best purchase on the femoral head (Figure 12.51.11 and Box 12.51.6). Hammering to insert the implant or cause impaction of the fracture is not recommended.

AP and lateral view of a femoral neck fracture fixed with a screw and plate device.
Femoral neck fractures: internal fixation

- Optimum reduction angle is 160–170 degrees on the AP and 180 degrees on the lateral radiograph
- Open reduction only required if unable to reduce fracture closed
- Lower screw or pin on the calcar on the AP view
- Implant tips must be close to the subchondral bone
- Reduction and implant positioning affect outcome
- Non-union is expected for 6% of undisplaced fractures and 33% of displaced fractures.

Bleeding from a haematoma trapped inside the capsule can produce an increase in pressure sufficiently high to cause tamponade to those vessels located along the femoral neck and impede the circulation to the femoral head. Aspiration of the haematoma with a large-bore needle or even a limited open capsulotomy has been advocated. Clinical studies have indicated that this will reduce capsular pressures and improve femoral head circulation but it has yet to be proved that this leads to a reduced incidence of fracture healing complications.

Postoperative care

No restrictions on hip movements are necessary after internal fixation. Limited studies have addressed the role of restricted weight bearing, and to date no study has demonstrated any reduction in the occurrence of fracture healing complications with either non- or partial weight bearing. Therefore, weight bearing should be allowed after internal fixation, but for the younger patient with a displaced intracapsular fracture partial weight bearing may be recommended.

Complications of internal fixation

Early redisplacement of the fracture and non-union may be treated either by repeat internal fixation or arthroplasty. Repeat fixation is more likely to be used in the younger patient in which femoral head preservation is desired. An osteotomy such as that described by Pauwels may be used to increase the chance of the fracture healing. An alternative is a pedicle bone graft. For more elderly patients, replacement arthroplasty is generally recommended.

Avascular necrosis occurs in about 10% of undisplaced fractures and 12–16% for displaced fractures (Figure 12.51.12). However, it only causes sufficient symptoms to merit surgical intervention in about a third of cases. Treatment is generally with a replacement arthroplasty, although in the younger patient an osteotomy or revascularization procedure may be considered. The other complication after internal fixation is refracture of the femur below the implant. This has an incidence of approximately 1%.

Arthroplasty

Indications (Box 12.51.7)

Arthroplasty is only indicated for a displaced femoral neck fracture in specific situations. This includes the older patient (aged over 65–75 years). For these patients arthroplasty has a lower reoperation rate and better function outcomes. Patients with rheumatoid arthritis have an increased risk of fracture healing complications as do those patients with chronic renal failure, hyperparathyroidism, and metabolic bone disease, making arthroplasty the more favourable option. Patients with a pathological femoral neck fracture are best treated with an arthroplasty, which may need to be a long-stem implant.
Box 12.51.7 Indications for arthroplasty (displaced fractures only)

- The elderly (aged over 65–75 years)
- Pathological fractures
- Fractures secondary to Paget’s disease
- Metabolic bone disease
- Hyperparathyroidism
- Rheumatoid arthritis
- Symptomatic arthritis of the hip
- Delayed presentation.

Surgical approach

A number of different surgical approaches to the hip have been described. Most are divided into those via the posterior capsule (posterolateral exposure) and those via the anterior capsular (anterolateral and anterior). The anterolateral approach is generally favoured as there is a lower risk of postoperative dislocation (5% vs 2%). The anterolateral approach does have the disadvantages of requiring a greater tissue dissection with possible damage to the abductors, slightly larger blood loss, and more restricted access to the femoral canal. Regardless of the approach used, the hip joint capsule should always be preserved and repaired to reduce the risk of dislocation.

Cement

Cementing the stem leads to less residual pain and improved mobility; therefore, in general, all arthroplasties for hip fracture patients should be cemented in place. Cementing does add extra technical difficulties to the surgery and adds the risk of a major adverse reaction to the cement during surgery. Modern cementing techniques are recommended, particularly the use of the cement gun. For the very frail elderly in whom there are concerns about the safety of cement, consideration should be given to using either an uncemented prosthesis or undertaking reduction and internal fixation.

Unipolar, bipolar, or total hip arthroplasty

The most common types of hemiarthroplasty still used are those of Moore and Thompson, introduced in the 1950s. Many other stem types are now available including many of the stems used for total hip replacements. The early stems were designed before cement was introduced and generally have collars. The use of these older designs should be reduced in favour of the more modern stems (Figure 12.51.13).

More recently bipolar hemiarthroplasties have been introduced. They have a double articulating joint of an inner metal head on high-density polyethylene in addition to the outer metal shell articulating with the acetabulum. The intention is to decrease the movement between prosthesis and acetabular cartilage and thereby reduce the degree of acetabular wear and possible pain from this. Clinical studies to date have failed to demonstrate any benefit from this bipolar joint. The risk of dislocation is the same for a bipolar as compared with a unipolar prosthesis, but if a bipolar prosthesis dislocates it is more likely to require an open reduction. The bipolar prosthesis is also more expensive than the unipolar prosthesis. Therefore the use of a bipolar prosthesis cannot be justified.
Total hip replacement for hip fracture has been recently reported in a number of case series reports. These highlighted the increased risk of dislocation with this method of treatment with reported rates of about 10%. Recent randomized trials have, however, suggested improved functional outcomes and less residual pain for those treated by a total hip replacement in comparison to a hemiarthroplasty. Many of the patients in these studies were a slightly younger and fitter group of patients than the average hip fracture patient and therefore better able to recover from the more extensive operation of total hip replacement. It is likely that this method of treatment will become more extensively used in the future.

Postoperative care

Modern surgical techniques should allow early mobilization with full weight bearing. Repair of the capsule in combination with an anterolateral approach reduces the risk of dislocation, therefore restriction on hip movements and the use of abduction wedges is generally not necessary.

Complications of arthroplasty

Early surgical complications after arthroplasty are dislocation (2–5%), haematoma (2–10%), and wound sepsis (1–5%). Later complications are acetabular wear (5–40%), loosening of the prosthesis (2–20%), and fracture around or below the implant (1–5%). The complications of loosening and fracture around the implant are increased for an uncemented implant in comparison to a cemented implant. Acetabular wear and loosening are more common within the younger active group of patients. Revision arthroplasty to a total hip replacement is generally required for the late complications.

Rehabilitation

The goal is to rehabilitate the patient to the same functional level as before the hip fracture. An adequate operation is a prerequisite to achieving this. The main task of the orthopaedic surgeon is to perform an operation which gives the patient a hip that allows immediate postoperative weight bearing to start on the day after surgery. The different models of rehabilitation that have been described are detailed in Box 12.51.8.

Box 12.51.8 Different models of rehabilitation

♦ Admission to and discharge from an acute orthopaedic ward
♦ Admission to and discharge from a specialized hip fracture ward
♦ Admission to and discharge from an acute orthopaedic ward with geriatric support
♦ Admission to an acute orthopaedic ward and later transfer to a rehabilitation ward
♦ Admission to an acute orthopaedic ward and later transfer to a skilled nursing facility
♦ Early hospital discharge schemes with community rehabilitation.

It remains unproven which model of care produces the foremost outcomes. Much will depend on the local facilities available. Transferring a patient to another ward will inevitably lead to a delay in the rehabilitation process, increase the length of hospital stay, and result in fragmented care. The optimum method of rehabilitation is therefore most likely admission to a specialized orthopaedic geriatric ward that is able to provide the acute care and the rehabilitation needed for these patients along with assessment for falls and further fracture prevention. Such a unit can be developed into a specialized hip fracture unit and be supported by additional community support teams to enable the early discharge of patients.

Secondary fracture prevention

A full description of the methods used for falls assessment and to reducing the occurrence of further fractures is beyond the scope of this article. The essence of this assessment is listed in Box 12.51.9.

Box 12.51.9 Factors that may be used to reduce the risk of further fractures

♦ Home assessment for hazards
♦ Review of medications that may be implicated in falls or osteoporosis
♦ Review of medical conditions causing falls or osteoporosis
♦ Cardiovascular assessment
♦ Assessment of gait and balance
♦ Testing of vision and correction as indicated
♦ Provision of appropriate walking aids
♦ Provision of correct footwear
♦ Optimization of mobility
The appropriate treatment of osteoporosis is still the subject of controversy. At present, the mainstay of treatment is the bisphosphonate drugs. These are being increasingly used in those patients over the age of 60 after a fall and fracture. A relative risk reduction of 45% and an absolute risk reduction of up to 6% may be expected. The role of these drugs in those aged over 80 years has not been so well evaluated and they may be less effective. The effectiveness of calcium and/or vitamin D remains controversial with some limited evidence suggesting that a combination of these drugs may be effective for the elderly living in institutional care. Hip protectors do not appear to be effective in reducing the incidence of hip fractures due to the problem of compliance with wearing them.

### Prognosis

The reported mortality and morbidity after a hip fracture varies widely between different studies. This may be due to the different characteristics of patients within the different geographical areas or the different selection of patients to be included. Regarding mortality, this is generally reported as being between 20–30% at 1 year from injury. Most of these deaths are from other conditions associated with ageing, rather than the hip fracture itself.

For the survivors, most will be left with some degree of discomfort in the hip, although for the majority this will be fairly minimal. Whilst up to 80% of patients should eventually be able to return to the same residence as before the fracture, many will be more dependent on walking aids and require more assistance; 10–25% will need to a more supportive residence or require institutional care.

### Further reading

Summary points

- Traction is not useful for trochanteric fractures
- Surgery should not be delayed unless the medical condition of the patient can be improved
- Dynamic implants are best (sliding hip screw best)
- Early full weight bearing should be achieved
- Most patients return to their own home.

Epidemiology

In 1824, Sir Astley Cooper stated that trochanteric fractures occurred infrequently and mainly in adults under 50 years of age, whilst intracapsular hip fractures were more prevalent. Since that time there has been a progressive increase in the incidence of trochanteric fractures particularly in those aged over 70 years. Currently, approximately half of all hip fractures are extracapsular, with an incidence as high as 50 in 100 000 in some countries.

Imaging (Box 12.52.1)

The diagnosis of an extracapsular femoral fracture is invariably confirmed by radiography of the hip. Almost all extracapsular fractures are radiologically apparent but occasionally the diagnosis may be missed for one of the following reasons.

1) Failure to radiograph the hip because the patient experiences pain only in the knee. This is due to the shared sensory innervation of the hip and the knee
2) Failure to take radiographs in two planes. Both an anteroposterior and lateral view of the hip are essential
3) Inability to visualize the trochanteric or subtrochanteric region due to incorrect radiographic exposure. Occasionally repeat films with different exposures are necessary.

Only rarely are additional investigations required to establish the diagnosis of an extracapsular fracture. A magnetic resonance imaging (MRI) scan is the investigation of choice, with alternatives being an isotope bone scan or a computed tomography (CT) scan. These investigations, particularly the MRI scan may also reveal other cases for the hip pain such as an incomplete trochanteric fracture or other injuries in close proximity.

Classification (Box 12.52.2)

Extracapsular fractures may be subdivided into trochanteric and subtrochanteric fractures. The term ‘intertrochanteric fracture’, if used precisely, refers to a fracture running transversely in between (but not through) the lesser and greater trochanter, whilst the term ‘pertrochanteric’ pertains to a fracture running obliquely and through the greater to lesser trochanter. To avoid confusion the term trochanteric is easier to use. Basal fractures (also termed basicervical), relates to a two-part fracture in which the fracture line runs along the intertrochanteric line. They are considered by some as intracapsular fractures and others as extracapsular. As the treatment and prognosis of a basal fracture is akin to that of a trochanteric fracture they should be considered as extracapsular. Subtrochanteric fractures should only include those fractures in which the fracture line traversing the femur is predominately within the 5cm length of femur immediately distal to the lesser trochanter.

Numerous other methods of classifying and subdividing extracapsular fractures exist. The most frequently used is the Jensen–Michaelsen modification of the Evans classification of trochanteric fractures and the Seinsheimer classifications of subtrochanteric fractures. The more recently introduced AO classification of fractures may become more frequently used, but to date there is little published evidence of its reliability or effectiveness in determining treatment or prognosis.
Box 12.52.2 Classification

- Trochanteric, subdivided into two part (stable), comminuted (unstable), and reversed fracture line
- Subtrochanteric, distal to lesser trochanter, but within 5cm of it
- Fracture pattern determines treatment.

For the orthopaedic surgeon it is important to recognize a number of specific fracture types (Figure 12.52.1), which will determine the choice of implant and surgical technique. Occasionally a fracture may show characteristics of more than one fracture type or the exact type of fracture may not be evident on the initial radiographs and only becomes apparent during surgery. This determination of the fracture pattern is the key to treatment.

Fig. 12.52.1
Fracture patterns that dictate the method of treatment: A) basal; B) undisplaced two-part trochanteric; C) displaced two-part trochanteric; D) displaced and comminuted trochanteric; E) comminuted trochanteric with loss of lateral support; F) reversed fracture line; G) subtrochanteric extension; H) 'high' subtrochanteric; I) 'low' subtrochanteric.

Management

Operative versus conservative treatment

Treatment options for extracapsular fractures may be conservative or operative. Conservative treatment for an extracapsular fracture may take one of two forms.

'Skilful neglect'

This method of management is only appropriate for the patient who is completely immobile prior to the fracture. Such ‘treatment’ involves nursing the patient in bed with appropriate analgesia. The fracture will usually unite after a period of some months, albeit with considerable shortening and an external rotational deformity of the limb. Nursing care of such patients may be difficult, and there is a continued need for analgesia. These factors may mean that surgical fixation of the fracture is generally still indicated even for a completely immobile patient.

'Active' conservative treatment

This involves reducing the fracture by means of traction applied to the limb. Regular radiographs are required to check the fracture position whilst the traction is maintained for a period of 2–4 months. The only noteworthy randomized study to compare this method of treatment with a modern method of internal fixation showed no difference in mortality but a greatly increased proportion of patients who had a prolonged hospital stay (and presumably were unable to return home), following conservative treatment. A later study based on this evidence demonstrated clear cost/benefit advantages for operative treatment. Given this clear superiority of operative treatment, conservative treatment should be retained for only the following indications:

- Patient unfit for any form of anaesthesia
- Patient refuses to consent to surgery
- Lack of modern surgical facilities
- Lack of appropriate surgical implant
- Absence of experienced surgeon.
The technique of conservative treatment entails applying traction to the leg using either a tibial pin or skin tapes and bandages. This may then be continued as simple traction over a pulley at the end of the bed or in the Hamilton Russell or 90 degree/90 degree traction. Alternatively, balanced traction with a Thomas splint may be used. A useful alternative form of skeletal traction is Perkins traction, which enables quadriceps power to be retained.

**Operative treatment**

**Preoperative preparation (Box 12.52.3)**

The majority of hip fractures occur in the frail elderly who invariably have many other medical problems associated with ageing. The medical assessment and management of these patients is therefore fraught with problems, yet this is an area that is frequently ignored by orthopaedic surgeons and delegated to the most junior member of the team. The optimum care of these patients is probably best served by having their medical care supervised by a specialist.

Preoperative assessment must include an assessment of associated medical conditions and medications. Resuscitation of all patients with an extracapsular fracture using intravenous fluids is essential. This should be started in the emergency room. Blood loss at the fracture site may exceed 1L, and in an elderly patient who is not drinking with impaired physiological response mechanisms, hypovolaemic shock is inevitable. Fluid correction should be adjusted to the patient’s condition using crystalloids, colloid, and blood replacements. Monitoring of progress is essential to avoid precipitating cardiac failure.

Traction has not been shown to be of benefit for trochanteric fractures. The choice of thromboembolic prophylaxis is controversial and is still the subject of research. The most favoured pharmacological methods are either low-molecular-weight heparin or low-dose aspirin. The timing of surgery is important. It should be performed after the patient is resuscitated and a good urine output has been established but generally within 48h of admission. Only those patients in whom the medical condition can be further improved should have their surgery delayed (Box 12.52.4). For those patients in which surgery is delayed the haemoglobin will fall from continued blood loss at the fracture site and preoperative transfusion may be required.

**Box 12.52.4 Legitimate reasons for delaying surgery**

- Hypovolaemia
- Acute dehydration
- Haemoglobin less than about 90–100g/L
- Severe electrolyte imbalance
- Congestive cardiac failure
- Uncontrolled hypertension
- Rectifical cardiac arrhythmia
- Acute chest condition
- Unstable diabetes mellitus.

**Choice of implant (Box 12.52.5)**

The implants available can be grouped into five types.

**Extramedullary fixation**

Extramedullary fixation refers to applying a side-plate to the proximal femur attached to a lag screw or pin which is passed proximally across the fracture site up the femoral neck. Such implants may be ‘static’ or ‘dynamic’. Static implants have no capacity for sliding and therefore cannot allow for any bony collapse that occurs at the fracture site. Examples are the Jewett, Thornton, Holt, and McLaughlin nail plates. Dynamic implants have the capacity for sliding at the plate–screw junction and thereby allow for collapse at the fracture site. Examples of dynamic implants are the Pugh nail, the Massie nail, and the sliding hip screw (also termed the dynamic hip screw and the Ambi hip screw).

**Box 12.52.3 Essential preoperative preparation**

- Medical assessment
- Anaesthetic assessment
- Resuscitation with intravenous fluids
- Analgesia
- Thromboembolic prophylaxis
- Surgery with 48h of admission if possible
- Perioperative antibiotic prophylaxis
- Treatment of associated medical condition.
Static implants have been comprehensively demonstrated to be inferior to dynamic implants. The complications encountered with static implants were mainly related to penetration of the implant into the hip joint as the fracture collapsed, but in addition there were problems with breakage of the implant and loss of fracture position. Therefore static implants should not be used. Numerous reports, many of them randomized trials, have demonstrated dynamic implants to be the implant of choice for the fixation of the majority of extracapsular femoral fractures.

Cephalic–condylar intramedullary nails

This refers to an intramedullary implant that is passed distally within the femur from an insertion point in or near the greater trochanter. A cross-screw or blade is passed through or around the nail into the femoral neck and head. Early examples of one these nails are the Küntscher Y nail and the Zickle nail. There has been considerable development of these nails over recent years and the more recent designs include the Gamma nail, the proximal femoral nail, and the intramedullary hip screw.

A summary of the results of all randomized trials comparing intramedullary nails with the sliding hip screw for trochanteric hip fractures found no major difference for blood transfusion requirements, length of surgery, lag screw cut-out rate, or mortality. However, there was an increased fixation failure rate and reoperation rate for the intramedullary nails because of the occurrence of secondary fractures around the nail. The controversy between intramedullary and extramedullary fixation is likely to continue with improvements in implant design and surgical technique. Until this issue is resolved it has to be concluded that the sliding hip screw has a lower incidence of complications and therefore is to be preferred for the majority of trochanteric fractures. The evidence in favour of the sliding hip screw hip screw applies for basal fractures and both stable and unstable trochanteric fractures. However, there are specific fracture types in which intramedullary fixation may have advantages and this is discussed next.

Box 12.52.5 Choice of implant

- Extramedullary implant: dynamic implant superior (sliding hip screw); usually implant of choice
- Cephalic–condylar intramedullary nails: higher failure rate than sliding hip screw but may be better for certain fracture types
- External fixation: may have a role in selected cases
- Arthroplasty: probably best reserved for revision surgery.

External fixation

A number of recent reports have described the use of an external fixator. This can if necessary be applied under local anaesthesia using two proximal pins in the femoral neck and head, and two pins distally. The frame is then retained for about 2–3 months. Complications relate to loss of fracture position and pin tract infection. This method may have a role for those who are very frail and considered at high risk from regional or general anaesthesia.

Arthroplasty

There have been a small number of reports using a long-stem cemented hemiarthroplasty for comminuted trochanteric fractures. Results appear to be comparable with those of internal fixation, but because the number of reports is limited, definite conclusions cannot be made on the place of arthroplasty for extracapsular fractures. At the present time arthroplasty is probably best reserved for revision surgery after failed internal fixation.

Condylar–cephalic intramedullary nails

The two types of condylocephalic nails that have been described are Ender nails and the Harris nail. Ender nails are prebent slightly flexible nails which are passed proximally from an entry point at the femoral condyle up the femur. The aim is to spread the tips of the nails out in the femoral head and stack the femur with three to five nails. The Harris nail is a single larger nail.

Numerous case series and randomized trials have consistently shown that these implants lead to problems with loss of fixation, fracture of the femur at the knee, residual pain at the knee, and an increased reoperation rate. Because of the clear superiority of other implants condylar–cephalic nails should no longer be used.

Surgical technique

The high prevalence of this condition in the elderly has dictated an evolution of treatment which enables immediate mobilization after surgery with full weight bearing. The current armament of implants and developments in surgical techniques allows this to be possible in the vast majority of cases, regardless of the extent of fracture comminution or the degree of osteoporosis. Immediate and unrestricted mobilization following surgery is therefore the aim of modern orthopaedic treatment. The method of treatment will be determined primarily by the fracture types illustrated in Figure 12.52.1.

Basal fractures

These two-part fractures can be treated similarly to that of a two-part trochanteric fracture using a sliding hip screw. The only
difference is that during surgery care should be taken to avoid rotating the femoral head. A supplementary guide wire may be placed across the fracture or an additional screw placed above the lag screw.

Undisplaced two-part trochanteric fractures

These account for approximately 5% of extracapsular fractures. The fracture line may be barely visible and result in the diagnosis initially being missed. The fracture pattern is stable and treatment may be either conservative or operative. For a fit person who is able to comply with a period of protected mobilization, conservative treatment may be considered. Careful follow-up is required and internal fixation is indicated if the fracture displaces, or if pain persists which restricts mobilization. Internal fixation is indicated for the elderly patient who is unable to comply with restricted mobilization.

Surgical treatment with a four-hole sliding hip screw is recommended. Surgical principles are simplified as the fracture need not be reduced.

Displaced two-part trochanteric fractures

These account for approximately 10% of extracapsular fractures. Again a sliding hip screw is the implant of choice. The fracture must first be reduced using the fracture table to either an anatomic position or a position of slight valgus. The most frequent mistake in surgical treatment is failure to reduce the fracture fully from a varus position. The best way to measure adequacy of reduction is using the trabeculae angle which must be between 160–175 degrees following fixation (Figure 12.52.2).

Comminuted trochanteric fractures

This is the most frequent fracture pattern accounting for approximately half of all extracapsular fractures. These fractures can be described as three-part fractures with loss of either lateral support (the greater trochanter), medial support (the lesser trochanter), or as four-part fractures (both the lesser and greater trochanters constitute separate fragments).

The sliding hip screw is again the implant of choice. The most important surgical principle is ensuring adequate fracture reduction. On the anteroposterior view the trabeculae angle must be between 165–170 degrees (Figure 12.52.2). The reduction of the fracture to a slight degree of valgus is recommended, as it offers mechanical advantages in creating stability and significantly reduces the chance of fixation failure. This valgus reduction is normally easily achieved by applying sufficient longitudinal traction to the limb using the fracture table. There is no indication for using an osteotomy with a sliding hip screw or for interoperative compression of the fracture.

A gap at the medial fracture margin may appear on the operative and immediate postoperative radiographs (Figure 12.52.3). This can worry surgeons who have been used to the concept of reconstituting medial bony support when using a fixed nail plate. When a modern dynamic implant is used, the controlled collapse of the fracture that occurs with weight-bearing rapidly results in the restoration of medial bony continuity. In addition a valgus reduction will reduce the chance of leg shortening as the fracture collapses.
Fig. 12.52.3
A valgus reduction to a trabeculae angle of 170 degrees creates a gap at the medial side of the fracture (arrow), but bony continuity is rapidly restored as the fracture collapses.

On the lateral radiograph it is essential to reduce the fracture to enable the femoral head, neck, trochanteric region, and shaft to be in a straight line (Figure 12.52.4). Longitudinal traction is generally all that is required to achieve this although occasionally ‘sag’ at the fracture site needs to be corrected during surgery by open reduction.

Fig. 12.52.4
On the lateral radiograph a straight line will bisect the femoral head, neck, trochanteric region, and femoral shaft with the lag screw placed centrally.

The position of the lag screw is important in reducing the risk of implant cut-out. All clinical studies on this issue indicate that the placement of the screw should be central/inferior on the anteroposterior radiograph and central on the lateral radiograph. It is essential that superior, anterior, or posterior placement of the screw is avoided at all times. The tip of the lag screw should be 3–7mm from the hip joint. This close placement to the joint ensures maximal hold on the stronger subchondral bone. An assessment of screw placement can be made by measuring the distance from the tip of the lag screw to the apex of the femoral head on both the anteroposterior and lateral radiographs. Cut-out is unlikely if the distance is less than 25mm after correction for magnification. A four-hole plate to achieve a hold on eight femoral cortices distal to the fracture is normally adequate for fixation of this fracture. A plate angle of 135 degrees appears to be optimum, with a higher risk of lag screw malpositioning and cut-out for the higher-angled plates.

Subsequent displacement of the fracture or cutting out of the implant will be rare if the following criteria for adequate fixation are satisfied:

- Reduce the fracture to a trabeculae angle of between 165–170 degrees on the anteroposterior radiograph
- On the lateral radiograph align the femoral head, neck, and shaft in a straight line
- Place the lag screw centrally/inferior on the anteroposterior radiograph
- Place the lag screw centrally on the lateral radiograph
- Medial tip of lag screw should be 3–8mm from the joint
- Lag screw tip–apex distance less than 20mm
- A minimum of eight cortices fixed distal to the fracture.

Comminuted trochanteric fractures without lateral support (Box 12.52.6)
This type of fracture pattern is rare, accounting for approximately 5–10% of extracapsular fractures (Figure 12.52.5). Recognition of this fracture pattern may only be apparent during surgery, but there are a number of radiographic characteristics listed in Box 12.52.6, some of which may be apparent preoperatively. This fracture differs from a trochanteric fracture where the greater trochanter is a separate fragment (Jensen type 3), in that the lateral femoral cortex at the site of insertion of a 135-degree lag screw is also fractured. It has previously been described as an internal rotation fracture type or a type II trochanteric fracture. This fracture pattern presents considerable technical problems in treatment and unless special care is taken in fixation there is a high risk of fixation failure.

Fig. 12.52.5
A comminuted trochanteric fracture without lateral support.

Box 12.52.6 Characteristics of a comminuted trochanteric fracture without lateral support

♦ A shortened proximal fragment lying horizontally on the anteroposterior radiograph
♦ Extensive comminution of the lateral femoral cortex at the site of the lag screw insertion
♦ Medial migration of the femoral shaft may occur particularly if a sliding hip screw is used
♦ Angulation at fracture site on the lateral radiograph
♦ Increases osteoporosis
♦ Technically harder fractures to achieve adequate fixation
♦ Greatly increased risk of fixation failure
♦ Comminuted fractures without lateral support.

If a sliding hip screw is used to fix this fracture, at operation the guide wire and lag screw will be inserted directly into the proximal part of the fracture (Figure 12.52.6). There is no lateral femoral cortex to ream prior to insertion of the lag screw. On applying the plate and releasing the traction then the distal fragment invariably displaces medially as there is no lateral cortical support to prevent this. This results in two adverse effects. Firstly, the lag screw rapidly runs out of slide and may penetrate into the joint. Secondly, the medial displacement of the distal fragment reduces the area of bone to bone contact between fragments causing delayed fracture union. These two factors cause an increased incidence of fixation failure.

Fig. 12.52.6
Fixation of a comminuted trochanteric fracture with a sliding hip screw.

Invariably the length of lag screw of the sliding hip screw used for this type of fracture will be 80mm or less. If a long barrel (38mm) plate is used there is only 17mm of available slide. As this type of fracture rapidly collapses due to the lack of lateral support the standard sliding hip screw soon runs out of slide. If a sliding hip screw runs out of slide before fracture healing has occurred then invariably the lag screw will cut-out or the plate will come away from the femur. A short barrel (25mm) plate is recommended as it will increase the amount of available slide to 30mm (Figure 12.52.6).

Other than using a short barrel sliding hip screw the same surgical principles listed previously should be followed. Additional care needs to be taken as the lack of soft tissue attachment to the proximal fragment may allow this to rotate, leading to non-union or avascular necrosis. In order to prevent this rotation a supplementary guide wire across the fracture can be inserted during the operation.

Despite the use of this short barrel plate there is still a significant risk of fixation failure caused by the excessive medial displacement of the femur. Attempts have been made to prevent this femoral medialization with a number of new implants, but to date their effectiveness remains unproven. A trochanteric stabilizing plate is an add-on feature for the sliding hip screw plate. It clips over a standard sliding hip screw plate to provide additional lateral stability. In addition, a supplementary screw may be placed proximal to the lag screw to reduce the risk of rotation of the proximal fragment. The percutaneous compression plate (PCCP) is another alternative that has an extension of the slide plate proximally to resist femoral medialization. A two-way sliding Medoff plate is another alternative implant with theoretical advantages as sliding can occur in a longitudinal direction.

Alternatively, a cephalic–condylar intramedullary nail has theoretical advantages in this type of fractures as the proximal portion of the nail will prevent the excessive medial displacement of the femur. In addition, assuming the nail is not locked distally in a static mode, collapse and compression of the fracture can also occur in a longitudinal direction. Because of the increased risk of fixation failure for this particular fracture pattern, primary prosthetic replacement has even been advocated in a small number of studies. A long-stem cemented hemiarthroplasty is generally described as the implant of choice, reconstructing the greater trochanter with wires.

Reversed fracture line (Box 12.52.7)

This is also an unusual fracture pattern, accounting for less than 5% of extracapsular fractures, but recognition is important as it dictates the correct method of treatment. The fracture traversing the femur runs either transversely at the level of the lesser trochanter or distally in a medial to lateral direction, in contrast to the normal lateral to medial direction of a trochanteric fracture. The fracture line may extend into the subtrochanteric zone. The nature of the fracture means that there is no bony support to prevent medialization of the femur due to the pull of the adductors. Therefore the problems encountered in fixation are similar to a trochanteric fracture with lack of lateral support.

Internal fixation with a sliding hip screw may still be used to good effect, but as the fracture line moves more distally the argument for using an intramedullary nail becomes more compelling. At present however there is inadequate evidence to suggest which method of fixation is best. The use of a static fixation implant such as a dynamic compression plate (DCP) or blade plate has been demonstrated to have a markedly increased risk of fixation failure in comparison to an intramedullary nail.

Trochanteric fracture with subtrochanteric extension

An extension of the fracture line from the trochanteric region to the subtrochanteric region occurs in approximately 5–10% of trochanteric fractures. In other respects this fracture may resemble one of the fracture types described and treatment should be as detailed earlier. The only difference is if a sliding hip screw is used then the length of the plate must be long enough to enable a minimum of eight cortices (four screws) to be anchored in the distal side of the fracture.

‘High’ subtrochanteric fractures

This fracture has an incidence of approximately 5% of extracapsular fractures. The essential point to differentiate this fracture from a ‘low’ subtrochanteric fracture is shown in Figure 12.52.7. If a sliding hip screw is used to fix a high subtrochanteric fracture then a dynamic fixation is normally achieved and the surgical principles listed above should be followed. The length of plate used should be sufficient to ensure that four screws are distal to the fracture. Static implants, such as the 95-degree AO blade plate or the dynamic condylar screw should be avoided because of the higher risk of fixation failure compared with the sliding hip screw.
More recently attention has been focused on intramedullary fixation of subtrochanteric fractures and as the fracture becomes more distal the argument for such a fixation becomes more convincing.

**Box 12.52.7 Reversed fracture line**

- Less than 5% of extracapsular fractures
- Distal fragment may displace medially
- Increased rate of fixation failure.

**'Low' subtrochanteric fractures (Box 12.52.8)**

These are infrequent fractures accounting for less than 5% of extracapsular fractures. Regardless of which method of treatment is chosen a significant incidence of healing complications including malunion, non-union, and implant breakage has been reported. This is because the bone in this area is subject of high mechanical forces with compressive stresses on the medial side and tensile stresses on the lateral side.

Conservative treatment has been described for this fracture. However, this involves a prolonged period of traction which, as previously discussed, reduces the prospect of successful rehabilitation. Therefore conservative treatment should be reserved only for those indications listed earlier. Operative treatment for this fracture may be either extramedullary or intramedullary fixation.

Extramedullary fixation of this type of fracture with a sliding hip screw will result in a ‘static’ fixation. The surgical principles of using a sliding hip screw for fixing this fracture therefore differ considerably from those listed previously. Valgus reduction of the fracture is not indicated as it results in a gap at the fracture site medially, which will not be closed by collapse at the fracture site, and an increased risk of non-union and fixation failure is to be expected. Therefore anatomic reduction of the fracture should be performed. It is essential that the sliding hip screw lag screw is inserted at exactly 135 degrees (or whichever angle of plate is used), otherwise the long sliding hip screw plate used will cause displacement at the fracture site. Supplementary fixation of additional fragments to restore medial bony support may not be necessary and may even delay healing by devascularizing bony fragments.

**Box 12.52.8 Low subtrochanteric fracture**

- Are probably best treated with an intramedullary nail
- Closed reduction and fixation should normally be possible
- If fixed with an extramedullary implant needs an anatomic reduction.

Intramedullary fixation of 'low' subtrochanteric fractures has now been well described. The Zickel nail was one of the earliest designs of such a nail but it has now been superseded by improved nail designs. It is essentially that any type of nail has adequate proximal fixation with a lag screw or pin passed up the femoral neck, instrumentation to assist fracture reduction and nail insertion and the capacity for distal locking.

If the lesser trochanter is intact and proximal to the fracture then the proximal femur will become flexed and externally rotated. This
means that reduction of the fracture on the fracture table may not be fully possible and the limb may need to be placed in a position of slight external rotation, rather than the neutral position used for a trochanteric fracture. The insertion point on the tip of the greater trochanter for the nail may need to be adjusted to compensate for this. Generally the fracture can be reduced by closed means using a reduction device or over the nail. The value of supplementary fixation to aid fracture reduction is unproven.

**Rehabilitation (Box 12.52.9)**

As discussed earlier, the elderly do not tolerate bed-rest well and neither are they able to comply with protected weight-bearing. The objective of any surgical fixation of a hip fracture is not just to stabilize the fracture, but to achieve a fixation that is sufficiently strong enough to allow full weight-bearing. This must be the aim at the outset of surgery and given the current options of modern surgical implants and operative techniques should be achieved in all cases. Failure to be confident enough to allow immediate and unrestricted mobilization following surgery should be considered as a failure of treatment.

![Click to view larger](Fig. 12.52.8)

*Fig. 12.52.8* Intramedullary nail used to fix a subtrochanteric fracture.

Both pre- and postoperatively it is important to discuss rehabilitation and discharge arrangements immediately. Many elderly people on sustaining a hip fracture foresee either death or permanent disability. Patients should therefore be mobilized immediately and told that they cannot damage the security of the fixation. Goals of treatment and rehabilitation plans should be set with the aim for discharge back home as soon as is practicable. This rapid discharge of patients back to the community is to be pursued and has been shown to result in an improved outcome.

**Complications**

A number of complications related to fracture healing may be encountered after an extracapsular fracture:

- Limb shortening
- Rotational deformity
- Non-union
- Avascular necrosis
- Cut-out of the implant
- Refracture
- Detachment of the implant from the femur
- Breakage or disassembly of the implant
- Sepsis.

**Limb-shortening**

This is invariable after conservative treatment as the fracture will heal in a varus position. For operative treatment some collapse may occur at the fracture site as the fracture heals, resulting in about 1–2cm of shortening. This may be reduced if a valgus reduction has been performed. For those situations in which operative treatment fails to maintain fracture reduction, varus angulation will occur which will result in a more noticeable shortening in excess of 2cm.

**Rotational deformity**

An external rotational deformity is common after conservative treatment. Correct positioning of the patient on the fracture table with the patella lying horizontally should prevent this complication occurring with surgical treatment.
Rehabilitation

- Fixation should allow full weight bearing
- Early mobilization
- Discharge planning on admission.

Non-union

Non-union should only be diagnosed in those fractures which show failure of radiographic union at least 6 months from injury. Before this time, failure for the fracture to unite should be termed delayed union. An increased risk of non-union is associated with subtrochanteric fractures and the use of a fixed nail plate. When a dynamic implant is used to treat a trochanteric fracture non-union is rare, occurring in about 1% of cases.

Non-union is generally symptomatic and should be treated by revision internal fixation and possible also bone grafting the fracture site.

Avascular necrosis

This is a rare complication of a trochanteric fracture in adults and tends to occur mainly in basal fractures in which damage of the blood supply to the femoral head has occurred. A possible iatrogenic cause of avascular necrosis is rotation of the femoral head during insertion of the lag screw. Overall the reported incidence is about 0.5% and treatment, if symptoms indicate, is generally by arthroplasty as for an intracapsular fracture.

Cut-out of the implant

This is the most common problem encountered by both extramedullary and intramedullary implants. It refers to both cut-out of the lag screw from the femoral head and screw penetration into the hip joint. The incidence is much higher for static implants (10–20%) than dynamic implants where, with the correct surgical technique and implant, the incidence should not exceed 3–4%.

Management of cut-out will depend on the degree of symptoms that the patient experiences. If the patient is able to continue to mobilize, the implant should be retained and then removed if necessary once the fracture has healed. Severe symptoms will necessitate surgical revision which may take the form of repeat internal fixation or replacement arthroplasty.

Refracture

This may take the form of fracture above, around, or below an implant or previous fracture. Fracture proximal to the lag screw is uncommon and in some cases has been attributed to failure to place the tip of the lag screw in the subchondral bone. Fracture immediately below an extramedullary fixation implant is rare. The use of a short intramedullary nail is, however, associated with an approximate risk of 2% for fracture around the distal part of the implant. Such fractures may be treated either conservatively with traction or, more commonly, with repeat internal fixation.

Detachment of the implant from the femur

This complication of extramedullary fixation has an incidence of about 1–3%. It is associated with either femoral medialization and consumption of lag screw slide, non-union of the fracture, or a subtrochanteric fracture extension.

Breakage or disassembly of the implant

Breakage of the older fixed nail plates such as the McLaughlin and Thornton nail plates is well documented with an incidence of 5–10%. Breakage of the newer implants is, however, rare and when it does occur it is invariably associated with delayed union of the fracture. Treatment is therefore similar to that for non-union of the fracture. Disassembly of the implant is rare with modern implants and is generally due to imperfect surgery.

Outcome

- 1-year survival is 70%
- 10% mortality from hip fracture
- 80–90% of survivors return to original residence.

Sepsis

Sepsis is rare after conservative treatment. After internal fixation the incidence of deep sepsis (infection around the implant) is approximately 0.5% and that for superficial sepsis around 4%. There is no difference in the risk of sepsis between extramedullary and intramedullary fixation.
Superficial sepsis may be treated with antibiotics and wound debridement if indicated. Deep sepsis is a more devastating complication, but fortunately the hip joint is generally not affected and may be preserved. Occasionally the implant may be retained whilst the fracture heals, but generally it needs to be removed and the fracture left to heal by conservative methods.

**Outcome (Box 12.52.10)**

The prognosis after an extracapsular fracture is worse than after an intracapsular fracture. The reason for this is that patients with an extracapsular fracture tend to be older and frailer than those with an intracapsular fracture. Overall reports of mortality and morbidity after a hip fracture vary considerable. At 1 year from injury about 30% of patients will have died, but in many cases the death can be attributed to other causes associated with aging. The actual mortality attributed to the hip fracture will be about 10%.

Regarding morbidity, it should be possible for about 80–90% of the survivors to return to their original residence, albeit generally with increased social support and assistance. The remaining patients will need a change of accommodation to a more dependent environment. Long-term pain in the hip is uncommon and less prevalent with an extracapsular fracture compared with an intracapsular fracture.

Summary points

- The tibia is the most commonly fractured long bone
- The orthopaedic surgeon needs to be familiar with all of the management options available in order to effectively manage the simple and complex cases
- Problems associated with the soft tissue envelope are frequently encountered.

Introduction (Box 12.57.1)

The tibia is the most commonly fractured long bone in the body. The majority of tibial shaft fractures result from high-energy road traffic and sports-related injuries. They tend to occur in the young, active, and economically productive population. The average age of the patients in a large published series was 37.2 years. Tibial fractures result in a significant number of hospital admissions and surgical operations. The goal of the treatment is to achieve union of the fracture with minimal complications and to help return the patients to the best possible functional state. The current trend is to treat most displaced tibial fractures by internal fixation.

Surgical anatomy

One-third of the tibia is subcutaneous in its entire length on the anteromedial surface. For this reason, it is more susceptible to open fractures than any other long bone. The posterior tibial artery through its nutrient branch is the main source of endosteal blood supply to the tibial shaft. The source of periosteal blood supply is from the anterior tibial artery. The blood flow through an uninjured tibia is centrifugal. After a fracture, the pressure head reverses to a centripetal flow. The periosteal vessels are therefore an important source of blood supply after displaced fracture of the tibia. The importance of preserving the soft tissue envelope at surgical fixation of the tibia cannot be overemphasized.

The tibial diaphysis is triangular in its cross-section with an anteriorly directed apex. The majority of the diaphyseal medullary canal is round and symmetric, a configuration amenable to intramedullary nailing. The medullary canal has a narrow isthmus in the middle third with a proximal and distal metaphyseal flares. An intramedullary nail used for either proximal or distal fractures has minimal cortical purchase in these locations, which contributes to high rates of malunion when nailing proximal or distal fractures.

The soft tissue envelope covering the tibia is divided by the interosseous membrane and the intermuscular septa into four closed osteofascial compartments (Figure 12.57.1). The anterior compartment contains tibialis anterior, extensor hallucis longus, extensor digitorum communis, and anterior tibial vessels. The deep peroneal nerve also courses through this compartment and supplies an autonomous sensory zone on the dorsum of the foot between the first and second toes. In the proximal third of the anterior compartment, the neurovascular bundle lies on the interosseous membrane and courses more anteriorly as it proceeds distally.

The lateral compartment envelops the fibula and contains the peroneus brevis and longus muscles. The common peroneal nerve runs under the peroneus longus, winds round the neck of the fibula and divides into superficial and deep branches. The superficial peroneal nerve lies within the lateral compartment.
The superficial posterior compartment contains gastrocnemius and soleus muscles and the sural nerve. The deep posterior compartment contains the tibialis posterior, flexor hallucis longus and flexor digitorum, and posterior tibial vessels and nerve. Each compartment contains a nerve with its own autonomous area of supply. Careful assessment of sensations in these autonomous zones may aid in diagnosing involvement of that particular compartment.

The thick interosseous membrane connects the posterolaterally oriented fibula to the tibia. The fibula also articulates with the tibia at the proximal and distal tibiofibular joints. The fibres of the interosseous membrane run downwards and laterally and are torn in major torsional fractures of the tibia and fibula.

The anterior tibial artery enters the anterior compartment at the superior margins of the interosseous membrane and is at risk of injury with proximal tibial fractures and proximal tibiofibular joint dislocations. The common peroneal nerve is also at risk with these fracture patterns, especially with fibular neck fractures. It is also vulnerable to direct blows or undue pressure from cast, splints, or constricting wraps.

The distal third of the tibial shaft has particularly poor soft tissue cover. The majority of the soft tissue in this area is tendinous and thus the extraosseous blood supply is minimal. The nutrient artery narrows as it reaches the distal third of the shaft and anastomoses with the distal metaphyseal endosteal vessels. If a displaced fracture occurs in this region, this small nutrient artery is often damaged resulting in loss of endosteal blood supply downstream from the site of injury. This lack of intramedullary blood supply combined with tenuous soft tissue envelope may account for delayed unions and non-unions, which occur frequently following high-energy distal-third tibial shaft fractures.

### Associated pathology

The tibial shaft fractures are most commonly associated with open wounds and varying degrees of soft tissue injury. The degree and the extent of the soft tissue injury dictate the functional outcome. Fractures that present with high-grade soft tissue injuries, either open or closed, usually result from high-energy trauma. Up to 30% of tibial fractures occur in multiply injured patients. When evaluating these fractures the surgeon should carefully examine and record the neurovascular status of the limb and look for the presence of an associated compartment syndrome. Diligent clinical examination and compartment pressure monitoring in unresponsive or unconscious patients is essential to diagnose this devastating complication.

High-energy tibial fractures may also be associated with ipsilateral knee dislocations or femoral shaft fractures. The so-called ‘floating-knee’ injury (ipsilateral tibial and femoral fractures) can also occur in concert with ligamentous disruption about the knee. In addition, fractures and dislocations about the ankle may also occur in association with tibial shaft fractures, and therefore routine radiographs of the tibia should always include the knee and ankle.

Fractures at the diaphyseal–metaphyseal junction should be carefully evaluated for any extension into the articular surfaces. These fracture lines may be subtle and not readily apparent on standard anteroposterior (AP) and lateral radiographs. Preoperative computed tomography (CT) scanning may be helpful to identify an undisplaced fracture line, and assists in preventing displacement of such occult fracture during surgical intervention.

High-energy tibial shaft fractures are also associated with vascular injury. High index of suspicion is essential, particularly when evaluating tibial fractures in polytrauma patients. Early diagnosis and urgent involvement of vascular surgeon is essential for limb saving.

### Mechanism of injury

Tibial shaft fractures associated with low-energy injury usually have little associated soft tissue injury and the interosseous membrane is intact and provides some degree of inherent stability, which may allow for conservative management.

Falls from a great height, direct blows, and motor vehicle-related injuries are high-energy mechanisms, which impart more kinetic energy in producing a fracture. The fracture patterns reflect this energy expenditure and have primarily a transverse orientation that may be accompanied by butterfly fragments or comminution, depending on the magnitude of the bending force. Fractures produced by crushing injuries or high-velocity gunshot projectiles are often the most severe. The fracture patterns are highly comminuted and may be segmental. The soft tissue component of the injury may be vastly underestimated, especially with crushing injuries, which often present as a closed de-gloving type of injury.

The level of the fibular fracture may indicate the type of injury mechanism, i.e. direct injury results in a fracture of both tibia and fibula at the same level, whereas fractures at a different level result from indirect forces or rotation.

‘Stress’ fractures are caused by repetitive stress, particularly in endurance athletes. Stress fracture management should take into consideration the injury site (low risk vs high risk), grade (extent of microdamage accumulation), and the individual’s competitive situation. This separation into two groups is based on the biomechanical environment and natural history of the fracture. The anterior tibial shaft stress fractures are considered high-risk fractures. The undertreatment of high-risk stress fractures can lead to catastrophic bone failure and/or prolonged loss of playing time. Overtreatment of low-risk stress fractures can result in unnecessary loss of physical conditioning and activity.

### Classification

Tibial fractures have been traditionally described in terms of their anatomical location—proximal, mid, or distal third fractures. The amount of initial displacement is recorded as a percentage of the diameter of the bone. The fracture pattern is described as spiral,
oblique, or transverse with further description of the presence and extent of comminution, which correlates with absorbed energy and is an indicator of fracture severity.

**Box 12.57.1 Tibial shaft fractures**

- Most commonly fractured long bone
- Most common open fracture among long bones
- Mostly involve young and productive population
- Majority result from road traffic accidents/sports related injuries.

The AO/Orthopaedic Trauma Association (OTA) comprehensive classification system (Figure 12.57.2) is commonly used to classify tibial fractures. This classification scheme does not account for the degree of soft tissue injury.

Unstable fractures are less conducive to non-operative management. Severe soft tissue injury, extension into or involvement of either the proximal or distal tibial articular surfaces, 100% initial displacement of the fracture, comminution of more than 50% of the bone circumference, and transverse fracture orientation are all hallmarks of an unstable fracture pattern. The presence of a fibular fracture in association with a tibial fracture at the same level often indicates an unstable injury from a high-energy mechanism (Figure 12.57.3).

Critical review of comparative studies reveals that non-operative treatment of high-energy tibial fractures is associated with high prevalence of malunion, stiffness of the knee and ankle joints, and poor functional outcome. Therefore classification of tibial shaft fractures into stable and unstable types may be more practical and useful when considering treatment options.
Clinical evaluation

History

determining the mechanism of injury is critical during the initial stages of patient evaluation. A cooperative conscious patient who has had a minor slip-and-fall accident is managed differently from an unconscious victim of a motor vehicle versus pedestrian accident. In the face of a high-energy injury, the examiner will not only focus on the tibial fracture, but will evaluate the patient for other associated injuries.

The time between injury and evaluation is important, especially for fractures associated with open wounds, arterial disruption, and compartment syndromes. The patient’s previous medical history should be noted, in particular conditions causing immunocompromise. Social history including occupation, smoking, drug and alcohol use all affects treatment decisions and the outcome.

Physical examination

High-energy tibial shaft fractures in multiply injured patients should be managed as per Advanced Trauma life support (ATLS®) guidelines. Deformed limbs should be gently splinted in relatively straight alignment. A visual inspection should reveal any obvious open wounds or exposed bone.

Lacerations, puncture wounds, and abrasions should not be probed or rigorously explored. The presence of such wounds in the vicinity of a fracture is considered to be open fracture. The vascular status should be documented by assessing the presence or absence of palpable pedal pulses, capillary refill, skin colour, and skin temperature.

Loss of motor function and sensation to the foot is a sign of injury or significant limb ischemia. Neurological examination should evaluate the tibial and peroneal nerves and limb ischemia should be ruled out as the cause of any neurologic dysfunction.

Compartment syndrome is common in all tibial fractures and should be assessed on a regular basis. Mangled extremity severity score (MESS) or Ganga Hospital Injury severity score can be used to assess the open tibial shaft fractures. Ganga Hospital Injury severity score has been shown to be more sensitive and specific and help in determining treatment strategies (see Further reading).

Investigations

Imaging

Once the leg is splinted, an AP and lateral radiographs should be obtained for all tibias in which a fracture is suspected. The knee and ankle should be included to detect fracture-dislocations or articular extension.

Cone-down or magnification spot radiographs or CT scans are useful to evaluate subtle fracture lines, callus formation, or stress fractures.

CT scanning has been shown to be useful to determine the adequacy of fracture reduction, including rotational alignment as well as limb length. Additionally, CT imaging has been shown to be useful for those transitional injuries (junction of diaphysis and metaphysis) that present with extension into the articular regions. CT scanning has now replaced plain linear tomography for the routine evaluation of non-unions.

Other studies

If diminished pulses are present, the ankle pressure index has been shown to correlate highly with the presence or absence of arterial disruption. Doppler-assisted blood pressure is obtained at the ankle and brachial arteries. A ratio of ankle to brachial systolic pressure below 0.9 indicates a probable arterial injury.

Arteriography is indicated when arterial disruption is suspected. Direct compartment pressure monitoring is routinely performed, especially when patients are unable to cooperate with the physical examination or where the surgeon has a high index of suspicion.

Diagnostic ultrasound is used to assess the early presence of callus and is predictive of fracture healing in situations where hardware, such as intramedullary nails and complex external fixators, occlude adequate routine radiographic evaluation.

Management

All closed fractures are immobilized initially with an above the knee splint. Appropriate imaging is obtained in order to plan definitive treatment.

Non-operative treatment (Box 12.57.2)

Non operative treatment in the form of casting should be considered in all isolated tibial fractures which are either stable or undisplaced.
Fractures with stable configurations as seen on the initial radiographs merit treatment by closed reduction and application of a long leg cast. Careful and regular follow-up with serial weekly radiographs is essential to detect secondary displacement and angulation within the cast. Any residual angulation can be corrected to an acceptable degree by wedging of the plaster cast. A functional cast brace (patellar tendon bearing cast) and early weight bearing is encouraged when the fracture becomes "sticky".

If wide displacement or significant shortening is seen on initial screening radiographs, it is unlikely that even an anatomical initial reduction will be maintained throughout the course of treatment found that there was no difference between the amount of shortening seen on the initial versus final radiograph in over 80% of cases. There is experimental data to indicate that as the level of deformity approaches the distal one-third of the tibia, even a small degree of malalignment can affect the loading of the ankle joint. Most surgeons strive to achieve alignment with less than 5 degrees of angulation in any plane and 10 degrees of rotation. However, these values for acceptable reduction are not based on any hard data and good long term function has been reported with angulation of up to 10–15 degrees.

Excellent results have been reported with the use of closed reduction, casting, and subsequent functional bracing in over 1000 closed tibial fractures. Initial treatment was with closed reduction and long leg casting. Weight-bearing was permitted in the cast as tolerated. If length and alignment were acceptable and pain and swelling had subsided, patients were then converted to a fracture brace at an average of 3.7 weeks. In 96% of the fractures, the final amount of shortening was up to 12 mm (average 4.28 mm). Final angular deformity was less than 6 degrees in 90% of patients. In this series, the rate of non-union was less than 1.1%. This form of treatment was recommended for those closed injuries with no more than 15 mm of initial shortening or stably reduced transverse fractures (Figure 12.57.4). Tibial fractures with an intact fibula were a relative contraindication to functional bracing because significant varus deformity (more than 5 degrees) was more likely to develop.

Excellent results have been reported with the use of closed reduction, casting, and subsequent functional bracing in over 1000 closed tibial fractures. Initial treatment was with closed reduction and long leg casting. Weight-bearing was permitted in the cast as tolerated. If length and alignment were acceptable and pain and swelling had subsided, patients were then converted to a fracture brace at an average of 3.7 weeks. In 96% of the fractures, the final amount of shortening was up to 12 mm (average 4.28 mm). Final angular deformity was less than 6 degrees in 90% of patients. In this series, the rate of non-union was less than 1.1%. This form of treatment was recommended for those closed injuries with no more than 15 mm of initial shortening or stably reduced transverse fractures (Figure 12.57.4). Tibial fractures with an intact fibula were a relative contraindication to functional bracing because significant varus deformity (more than 5 degrees) was more likely to develop.

Other authors have noted the hazards of treating tibial shaft fractures with intact fibulae. Delayed or non-union was reported in 26% of adult patients with fractured tibia with intact fibula treated with cast immobilization. Sixty-one per cent experienced one or more complications during conservative treatment. The intact fibula prohibits axial loading of the tibia and therefore decreases the weight-bearing axial stimulus to healing (Figure 12.57.5).

A prospective randomized study has compared the results of application of the patellar ligament-bearing cast with those of operative treatment with closed interlocking intramedullary nailing. This study revealed longer healing times and increased residual angular deformity, limb shortening, and disability in the group treated conservatively. Hindfoot stiffness occurred in 15% of the patients treated in casts. Twenty-two per cent of patients in the closed-treatment group eventually underwent operative intervention for failure to maintain adequate reduction.

There are numerous limitations to the treatment with casts and functional braces. Loss of reduction as well as a residual limb length discrepancy is common. Prolonged treatment with a cast may result in excessive stiffness of the knee, ankle, hindfoot, or
all three, which may require extended rehabilitation to regain the patient’s pre-injury level of function. Even with earlier weight-bearing, residual joint stiffness has been reported in approximately 20–30% of patients treated conservatively.

Fractures that are associated with serious soft tissue compromise are not easily treated conservatively. Effective casting or bracing is highly dependent on the ability of the soft tissues to tolerate a well-contoured device. Limb oedema, contusions, abrasions, etc., may inhibit the early application of sufficient external support. Failure and complications of non-operative treatment indicate that there are many tibial fractures that benefit from operative treatment.

Some studies have suggested the benefit of pulsed, low-intensity ultrasound in shortening the time to healing in non-operative treatment.

**Operative management**

Unstable tibial shaft fractures, fractures with associated ipsilateral lower limb fractures, tibial shaft fractures in multiply injured patients, and fractures extending to either knee or ankle joints generally require surgical stabilization. Open tibial shaft fractures and fractures associated with neurovascular injury or impending compartment syndrome are dealt with emergency surgical management. Surgery should also be considered in fractures where attempts at non-operative management have failed and when secondary displacement and angulation occurs in follow-up radiographs. Occasionally, operative intervention is recommended for non-compliant patients. The goals of operative treatment should be to restore the length and alignment of the limb, stable fixation to allow early mobilization, and rapid return to pre-injury function with no or minimal complications.

**Box 12.57.2 Conservative treatment**

- Undisplaced or stable tibial fractures without significant soft tissue injury
- Shortening on initial films usually predicts final shortening
- Intact fibula is a relative contraindication because of varus malunion
- Initial long leg cast followed by Sarmiento cast once fracture is ‘sticky’
- Acceptable reduction:
  - Coronal plane <5 degrees
  - Sagittal plane <10 degrees
  - Rotation <10 degrees
  - >50% cortical contact in both AP and lateral views
- Serial wedging of cast may help correct the deformity.

**Box 12.57.3 Intramedullary nailing**

- Most common operative treatment
- Best for unstable diaphyseal fractures
- Reaming has biomechanical and biological advantages and reduces non-union rates
- Newer-generation nails are effective in metaphyseal fractures.

**Intramedullary nailing (Box 12.57.3)**

Locked intramedullary nailing has become the ‘gold standard’ treatment for most of the unstable tibial diaphyseal fractures. Interlocking intramedullary nails maintain axial alignment and provide rotational stability. The nails are either statically or dynamically locked depending on fracture configuration. The new-generation intramedullary nails that allow placement of distal locking screws near the end of the nail have helped extend the indications for nailing to metaphyseal fractures even with intra-articular extension (Figure 12.57.6). The current literature indicates high rates of fracture union in closed tibial diaphyseal fracture treated with intramedullary nailing.
A) Tibial shaft fracture extending very low into the distal metaphysis. B) Fixed with a newer-generation nail with the distally placed screws. C) Healed fracture with no complications.

Intramedullary nail insertion has traditionally involved the use of a fracture table to effect reduction. The time necessary for a fracture table set-up and correct positioning of the patient may be prohibitive when treating a multiply injured patient. In addition, complications such as nerve palsy and compartment syndrome have been related to the use of excessive traction.

Techniques have been developed to achieve and maintain reduction during intramedullary nailing when operating on a standard radiolucent orthopaedic table. Devices such as the femoral distractor or a temporary external fixator can serve this purpose. Accurate alignment without traction-related complications has been reported with the use of these reduction techniques (Figure 12.57.7).

Fig. 12.57.7
A) A simple two-pin fixator is placed with one pin in the calcaneal tuberosity and an additional pin proximally at the level of the fibular head, posterior to the entrance point of the nail. B) Longitudinal distraction through the two radiolucent connecting bars reduces the fracture; once alignment and rotation is corrected, the nailing can proceed with the use of the awl positioned at the entry site.

The correct placement of the entry portal is an important technical consideration. It must be placed centrally in line with the medullary canal. Because of the wide discrepancy in tibial morphology, the centre of the tibial canal may be variable in its relationship to the patella and patellar tendon. The actual insertion site may be located lateral, medial, or directly posterior to the patellar tendon and should be verified with an image intensifier. Failure to place the entry portal centrally will result in varus or valgus malalignment. Entry portal can be placed either on the medial aspect of the patellar tendon or through a transpatellar tendon approach. Anterior knee pain is a common problem following intramedullary nailing with some reports showing an incidence of greater than 50%. In those patients whose work involves kneeling, consideration should be given to alternative methods of treatment. The relationship of the approach to postoperative anterior knee pain has been an area of controversy. However, recent randomized control studies have not demonstrated any correlation between the approach and anterior knee pain.

The major concern with operative management of tibial shaft fractures is the additional disruption of the blood supply caused by the operative procedure itself. Reaming the medullary canal desvascularizes the inner two-thirds of the cortex, rendering the endosteal surface of the cortex ischaemic. Devascularization is reduced to one-third when the nail is inserted without reaming. Additional devascularization occurs through the entire cortex at the region of the fracture site. However, the relative avascularity is temporary and the medullary blood vessels regenerate after a relatively short time. Although reaming disrupts the blood flow to the cortex, reaming induces a sixfold increase in the periosteal blood flow. The periosteal blood supply compensates initially for the disruption of the intramedullary blood supply. Disruption of the intramedullary blood supply is usually not a concern for closed injuries that have a competent soft tissue envelope. However, in the treatment of open or high-energy fractures where the soft tissues including the periosteum may be completely disrupted, medullary reaming could further devascularize the fracture site.

Reaming during intramedullary nailing has biomechanical and biological advantages. Reaming allows insertion of a larger-diameter nail hence increasing its load sharing capacity. The biological effect of the increased periosteal vascularity is well known. Moreover, reaming has been shown to have faster rates of union and reduce the incidence of non-union.

Unreamed nailing has the advantage of being less time consuming offers advantages in the emergency setting for stabilizing polytrauma patients. Unreamed nails when used as a definitive method of fixation have a reduced incidence of reoperations, superficial infections, and malunions, when compared with external fixators.

Reaming allows the insertion of a bigger nail and locking bolts. Fatigue failure of small-diameter unreamed nails and/or interlocking screws has been reported in many series if union of the fracture is not achieved early. However failure of interlocking screws in some cases may facilitate fracture healing by autodynamization (Figure 12.57.8).
A recent large multicentre randomized study involving 1226 patients has compared reamed versus unreamed intramedullary nails. The study suggested that reamed nails offer a benefit in closed fractures with regard to further events (surgical intervention or autodynamization) within 1 year. Most of the difference was attributed to an excess of dynamizations (both surgical and autodynamization) in the unreamed group. A non-significant increase in number of postoperative events was noted in open fractures treated with a reamed nail. The authors note that overall the number of events for this study was less than previous randomized controlled trials. Previous grade II evidence, randomized controlled trials have shown that reamed nails have an advantage over unreamed nails with regard to rate of union and non-union.

Compartment syndrome has been reported following intramedullary nailing of the tibia. It is thought to be multifactorial and could be associated with excessive traction on the limb, limb tourniquet, and extravasation of the reamings. The type of anaesthesia and the postoperative analgesic regimen has been attributed to a delay in diagnosis of compartment syndrome.

The indications for intramedullary nailing have been extended to include very proximal and distal metaphyseal fractures. Nailing of proximal one-third tibial metaphyseal fractures are fraught with potential complications, primarily valgus malunion, anterior translation, and apex anterior deformities of the proximal segment. Review of proximal shaft fractures treated with intramedullary nailing found that 84% of these patients had residual angulation of more than 5 degrees and that 25% lost proximal fixation primarily related to the placement of a single proximal locking screw. Non-union rates have been reported as high as 26%.

Surgical errors consisting of a medialized nail entry portal and a posterior and laterally directed nail insertion angle, all contribute to the malalignment. Suggested techniques for the successful nailing of proximal shaft fractures include a lateral entry portal, use of Poller’s ‘blocking screws’ and adjunctive antiglide plates located at the level of the fracture apex. This small plate serves to prevent translation and apex anterior angulation of the proximal fragment (Figure 12.57.9).

Contiguous ipsilateral distal intra-articular fracture extension and non-contiguous ipsilateral ankle fractures in concert with diaphyseal injuries can be successfully treated with intramedullary nailing techniques. Distal articular extension displaced less than 5mm, may be treated with mini open reduction and internal fixation of the articular component followed by intramedullary nailing. Non-contiguous ipsilateral ankle fractures may be treated with fixation of the ankle prior to or after insertion of the intramedullary nail. Technically, it is important to keep the articular lag screws in subchondral bone to allow room for nail insertion. It is also important to secure alignment of the entire fracture construct prior to nail insertion using a two-pin fixator, a femoral distractor, or calcaneal pin traction (Fig. 10).
Plate fixation (Box 12.57.4)

The traditional open reduction and internal fixation with plates and screws is not a preferred option for high-energy tibial shaft fractures. This method of fixation requires extensive exposure and additional soft tissue stripping resulting in secondary devascularization of the soft tissues and fracture fragments. Reports in the literature quote high rates of complications such as wound break down, infection, aseptic and septic non-union of the fracture.

With the advent of minimally invasive plate osteosynthesis (MIPO) using locking plates, plating has regained its popularity. This technique utilizes the principles of biological fixation. The fracture is realigned in all planes utilizing indirect reduction techniques. The adequacy of reduction and the plate position are confirmed by image intensifier. Depending upon the personality of the fracture the definitive fixation is planned. In simpler fracture configuration (AO/OTA 32A and B) primary fracture fixation is carried out by using lag screws through small incisions. A precontoured plate is then tunnelled extraperiostally along the medial aspect of the tibia through a small skin incision, distant from the zone of injury. This plate is then fixed with locking screws percutaneously through stab incisions and acts as a neutralization device. In complex fractures (AO/OTA 32C) only MIPO plating is performed without any attempt at direct reduction of the fracture fragments. Here the plate acts as a bridge bypassing the area of comminution whilst stabilizing the fracture (Figure 12.57.11). The MIPO technique can also be carried out with usage of low-profile standard plates in non-osteoporotic bones. The main advantage of MIPO is that the fracture haematoma and the soft tissue envelope around the fracture are not disturbed. This method of fixation results in secondary bone healing by callus response. Review of recent literature confirms the efficacy of this fixation method and encourages its usage. A recent comparative study has shown the that plate fixation in distal tibial shaft fractures (4–11cm above the plafond) produced better rate of union as compared to intramedullary nails. Complications such as delayed union, malunion, and secondary procedures were more frequent after nailing.

![Click to view larger](Fig. 12.57.11)

External fixation (Box 12.57.5)

External fixation is carried out for both emergent and definitive management of tibial shaft fractures. In the initial management of open tibial fractures and in tibial fractures associated with polytrauma, skeletal stabilization is achieved in a rapid manner by using an external fixator assembly. This temporizing device is assembled with use of multiple Schanz pins inserted into the major fragments preferably outside the zone of injury. Such fixation allows wound care and subsequent reconstruction of the soft tissue envelope in open fractures. External fixation in multiply injured patients allows early mobilization and better nursing care and shown to have reduced mortality and morbidity. These devices can be exchanged to intramedullary nails within 2 weeks of index operation (Figure 12.57.12).

![Click to view larger](Fig. 12.57.12)

A) Clinical photograph showing monolateral external fixator used for distal third tibial shaft fracture. Note the ‘near- far’ pin placement. B) Clinical photograph showing the hybrid external fixator used for open tibial shaft fracture.

The use of an intramedullary nail following failed external fixation has demonstrated variable results. In general, if the external fixator is in place for less than 1–2 weeks, conversion to an intramedullary nail appears to have a low rate of associated infection. However, as the time period of external fixation increases, the risk of infection with immediate exchange to an intramedullary nail increases dramatically. Infection rates as high as 50% have been reported for patients who have had this immediate exchange. If this type of treatment is contemplated, patients who have a latency period of more than 1 month following removal of the external
fixator and prior to intramedullary nailing have a marked decrease in their rates of infection as well as increased rates of union. Although a delay of several weeks or months between fixator removal and nailing may decrease the risk of infection, there remains some elevated risk. Deep infection rates of 17% have been demonstrated in open tibial fractures treated with secondary intramedullary nailing (IMN) after external fixation (EF). All deep infections occurred in Gustilo type III fractures (22.6%, 7/31). They concluded that early skin closure within 1 week is the most important factor in preventing deep infections when treating open tibial fractures with secondary IMN after EF.

The external fixation techniques have been successfully used for definitive management of closed tibial fractures. External fixation does not cause additional disruption of the soft tissue envelope or the vascularity of the fracture fragments or other osseous structures. Axial and rotational stability can be achieved by using ring fixators, monoplanar or multiaxial external fixator constructs. In high-energy fractures, particularly with fractures associated with bone loss, an external fixator is used not only to acutely stabilize the fracture but also to aid in fracture union and bone transportation in restoring bone loss (Figure 12.57.13).

With other fracture fixation methods, additional bracing or casting is often necessary to maintain a stable construct. With rigid internal fixation, primary bone healing demands that weight-bearing be delayed until full reconstitution of the cortex has been completed. Weight-bearing stimulates fracture healing. A major advantage of using adjustable external fixators is the ability to load the limb actively. Even in the most comminuted fractures, patients can begin at least partial weight bearing immediately after surgery without any supplementary casts or braces. Most frames allow for dynamization restoring cortical contact, achieving a more stable fracture construct, and decreasing the pinbone stresses. By subsequently disassembling external fixation frames, progressive dynamization leads to a less stiff frame, which facilitates secondary callus formation and bone healing.

Box 12.57.4 Plating

- Regained popularity with advent of MIPO
- Indicated for some metaphyseal fractures without severe soft tissue injury
- Good results in translated non-unions (not amenable to nailing) and after failed external fixation
- Good results in distal tibial metaphyseal fractures with MIPO.
Box 12.57.5 External fixation

- Indicated in severe open fractures
- Temporary or definitive management
- Advantage of no additional soft tissue damage
- Pin track infection is the most common complication
- Can be exchanged to nail within 2 weeks
- Ring or hybrid fixator used in septic/aseptic non-union, malunion, and for bone transportation in case of bone loss.

In general, closed fractures heal with external fixation on average within 4 months. The rates of non-union have been reported as high as 5% for closed fractures. In most series, it was felt that early dynamization or gradual frame disassembly should be performed in an effort to load the fracture and promote secondary callus formation. The most common complication was minor pin tract infection, which is seen in the majority of patients. Major pin-site infections requiring secondary surgical procedures were noted to be less than 5% in most series and none appeared to have led to any serious sequelae. Most authors agree that although external fixation requires closer patient monitoring and pin care, external fixation is a safe and reliable device for treating tibial shaft fractures.

Open tibial shaft fractures (Box 12.57.6)

The tibial shaft is the most common site for open fractures of the long bones. Most of the open tibial shaft fractures occur in young and active population as a result of high-energy injury and are particularly associated with road traffic collisions. The standard treatment consists of: early debridement of the open wound; thorough surgical toilet; antibiotics; stabilization of the fracture; adequate and early soft tissue coverage; successful reconstruction of the limb and subsequent fracture healing (see Chapter 12.7).

It has been shown that definitive stabilization by reamed intramedullary nail for low-grade open fractures produces satisfactory outcomes. The infection rate has been shown to be less than 3% for grade I open fractures. However, when reamed intramedullary nailing was performed on severe open fractures (grade IIIB), the rate of infection has previously been reported as high as 23%. Open tibial fractures stabilized with unreamed interlocking nails have reported rates of union greater than 96%, a low rate of malunion, and rates of infection in the range of 4–8% for grade IIIB fractures. More recent studies have shown that results of reamed nailing for grade IIIB fractures are comparable to unreamed nails in terms of union rates and complications.

Box 12.57.6 Open fractures

- Early debridement, skeletal fixation, and soft tissue cover
- Adequacy rather than time of debridement influences infection rates
- Primary closure is debatable. Closure within 1 week reduce infection rates
- Contraindications to primary closure:
  - Skin loss primarily or during debridement
  - Gross contamination with faeces, dirt, stagnant water
  - Farm-related injuries, fresh water-related accidents
  - Delay in antibiotic initiation >12h
  - Extensive tissue necrosis at debridement
- Secondary procedures frequently necessary.

Randomized prospective studies have been performed comparing the results of unreamed interlocking nails with external fixation for the treatment of open fractures. All of these studies demonstrated similar rates of infection and non-union for both treatment modalities, but a significantly higher prevalence of malunion with external fixation. The major advantage to intramedullary nailing is that it facilitates soft-tissue procedures, and delayed bone and skin grafting without the hindrance of an external fixation device. Recent evidence supports the usage of unreamed solid nails in stabilizing open grade IIIb and IIIc fractures.

External fixation is still considered a good choice for highly contaminated open fractures or fractures associated with prolonged delay prior to operative intervention (Figure 12.57.14). Rates of infection with external fixation for grade III injuries has ranged from 4 –7%. This relatively low rate of infection has been offset by the increased rate of malunion that has been reported when treating open tibial shaft fractures to completion with an external fixator.
Postoperative care

When the tibial shaft fractures are treated conservatively, early weight bearing is encouraged. As soon as the patient is comfortable in the long leg cast and the swelling has subsided, conversion to a patellar tendon bearing cast is usually indicated. This will occur at 3–6 weeks. Following a short period of patellar tendon-bearing cast immobilization, the patient should be converted to a total-contact orthoses and full weight bearing encouraged.

The management of fractures treated with intramedullary nails can be varied depending on the fracture pattern, and configuration and morphology of the nail used. In general, reamed medullary nails are larger diameter and have bigger locking screws. When large locking screws are used the patient may be considered for early weight bearing. Regardless of the size of the nail and screws, if the fracture pattern is axially stable, the patient is allowed to progress to, at least, 50% weight bearing immediately after surgery. For fracture patterns with comminution or segmental injuries, which are axially unstable, then non-weight bearing should be maintained for at least 6 weeks. For the axially stable fracture patterns, full weight bearing can be initiated once progressive callus is seen on radiograph. For the axially unstable injuries, delaying full weight bearing for at least 3 months may need to be considered. Throughout the course of treatment, fracture healing should be monitored in order to avoid fatigue failure of the nail or locking bolts, especially for small nails. Early intervention is necessary to avoid these complications.

For tibial fractures treated with plate fixation, patients are usually immobilized either in a removable splint or cast until the incision heals. Soft tissue concerns are paramount in the early postoperative period to ensure that the wound heals without complications. Because the plate is a load-bearing device, weight bearing must be delayed. For the first 6–8 weeks, patients should be maintained as strict non-weight bearing, and if patient compliance is an issue, then long leg casting should be maintained with the knee flexed in order to prevent unrestricted weight-bearing. If the patient is reliable, then toe-touch non-weight bearing can be initiated immediately. In approximately 6–8 weeks when early cortical bridging and diminution of the fracture line is seen on radiograph, the patient can be advanced to 50% partial weight bearing. This may sometimes need to be augmented with a patellar tendon bearing orthosis or short-leg walking cast. When recorticalization is complete, the patient may progress to full unrestricted weight-bearing at approximately 4–6 months.

Postoperative management of external fixation is often problematic with respect to the management of the pin sites. In the case of circular small-wire external fixators for extra-articular injuries, full weight bearing may be initiated immediately after surgery. For most monolateral frames with dynamization capabilities, once early callus formation is noted the frames can be dynamized or sequentially disassembled to transfer more of the load to the fracture site itself and promote axial micromotion to facilitate healing. Following the removal of the external fixation device, a short period of orthotic management is required. Regardless of the methodology of fracture fixation utilized, physical therapy should be initiated immediately to maintain knee and ankle range of motion. In cases of severe soft tissue injury and open fractures treated with external fixation, the foot should often be included in the fixation frame to avoid progressive equinus contracture due to the long period of non-weight bearing status necessary. Physical therapy should concentrate on maintaining a plantigrade foot. This is best established by allowing the patient to place the foot on the ground. This allows the foot to be placed in a plantigrade position while still avoiding full loading activities.

Complications (Box 12.57.7)

Complications of tibial shaft fractures include compartment syndrome, non-union, malunion, and infection. Arrest of the bony repair process with the formation of intervening fibrous or cartilaginous tissue is defined as a non-union. The usual time frame for this diagnosis is 6–8 months. Non-union most commonly occurs following open tibial shaft fractures, which have been treated with external fixation.
Secondary procedures have been advocated to promote union and avoid hardware failure in cases where delayed healing is likely. Nail dynamization, exchanged reamed nailing, open bone grafting, and fibular osteotomy all have been used alone or in combination to promote union (Figure 12.57.15).

Fig. 12.57.15
A) This open fracture progressed to a nonunion after being treated with a statically locked unreamed nail. B) Following exchange nailing with a reamed nail of a larger diameter and a fibular osteotomy, complete healing occurred.

Exchange nailing is a standard method of treatment for aseptic non-union. Progressive reaming until bone is seen on the flute of the reamer and exchange to a larger-diameter nail is recommended. Such nailing offers the unique biomechanical advantages of an intramedullary device, together with the osteoinductive stimulus of the by-products of reaming. A larger diameter nail also allows early weight-bearing and active rehabilitation. Following intervention it can be expected that 90% of non-unions will be united at an average of 3.5 months.

There is no consensus about the definition of malunion. The accepted arbitrary values for tibial shaft malunion are more than 10 degrees of angulation in sagittal plane, more than 5 degrees in coronal plane, and greater than 10 degrees of rotational malalignment. However, long-term follow-up studies have failed to establish any correlation between malunion and development of subsequent arthritis of ankle or subtalar joints. Established malunion is treated by corrective osteotomy along with refixation either by intramedullary or extramedullary devices.

Post-traumatic osteomyelitis occurs either after open fractures or surgically treated closed fractures. Treatment of an infected fracture utilizes a staged reconstruction protocol. If there is wound breakdown along with superficial infection, implants should be left in place in order to provide a stable fracture configuration. If the implant provides no stability at the time of debridement, all hardware should be removed. Furthermore, at debridement, all necrotic bone should be excised. Stabilization is necessary and is usually provided by external fixation. Serial debridements may be necessary to obtain a biologically sound wound. Dead-space is managed by using antibiotic beads or open-wound packing. Eventual soft tissue closure may be achieved with rotational flap or free-flap or coverage. Antibiotics directed at deep culture specimens should be administered for 4–6 weeks. Following resolution of the infection and healing of the soft tissues, delayed skeletal reconstruction is performed.

**Overview**

There are several well-accepted methods of treatment of tibial fractures. Orthopaedic surgeons tend to be preoccupied with the mechanics of fracture management and specifically with the implants to be utilized. However, there is no substitute for a thorough understanding of the so-called ‘personality’ of the fracture to help determine the best choice in treatment. Conservative management utilizing casts and functional orthoses is indicated for minimally displaced and axially stable fractures. Prospective studies indicate that intramedullary nailing with and without reaming both produce excellent results with high rates of union and low rates of occult infection. Reamed nailing has been shown to have shorter times to union and lower non union rates. Unstable closed fractures and open grades I, II, and IIIA fractures can be safely treated with reamed nails. External fixation, reamed and unreamed nails can be considered in grade IIIB fractures.

**Box 12.57.7 Compartment syndrome**

- Maintain high index of suspicion
- Increased incidence associated with traction and reaming
- Extra vigilance in unconscious and unresponsive patients
- Look for serial rise in pressure
- Avoid postoperative patient-controlled analgesia to prevent delays in diagnosis
High-energy tibial shaft fractures pose a therapeutic challenge to the treating health-care professionals. These injuries are often seen in the context of polytrauma. Astute decision-making, collaboration with plastic surgeons, timely surgical intervention, and respect for soft tissue envelope of the leg will result in successful functional outcome. The recent development of minimally invasive fracture surgery will no doubt have a positive impact on the management of the tibial shaft fractures.

Supracondylar fractures of the femur

DOI: 10.1093/med/9780199550647.003.012054

Summary points

- Supracondylar fractures of the femur are seen in the young (high energy) and the old (low energy). Both groups have their own specific problems.
- The advantages and disadvantages of each surgical option must be considered in relation to the individual patient and their fracture pattern.

Introduction

Supracondylar fractures in their true sense are non-articular distal metaphyseal femoral fractures. However, they may extend into the intercondylar (epiphyseal) region of the femur which in turn is usually intra-articular.

Results of treatment of these fractures are dictated by numerous factors, including pre-injury state of the knee, severity of the injury, and associated injuries. The presence of femoral implants such as intramedullary devices or total knee prosthesis also dictates management and outcome of these complex fractures.

Incidence and prevalence

The incidence of distal femoral fractures ranges from 4% of all femoral fractures in patients over 16 years, and 31% when hip fractures are excluded. These fractures predominantly occur in two patient groups: 84% mainly in elderly females with osteoporosis, average age 65 years and injury due to moderate-energy trauma; and the remainder mainly in young men due to high-energy trauma.

Anatomy

Normal anatomy

The detailed anatomy of the distal femur can be found in any standard textbook of anatomy. The transition zone between the distal diaphysis and the femoral condyles makes up the supracondylar area (Figure 12.54.1). At this point the metaphysis flares, especially on the medial side. Anteriorly, the patella articulates with the condyles in the trochlear groove. Between the two condyles posteriorly, there is the intercondyloid notch. On the medial aspect, there is the prominent adductor tubercle at the point of maximum flare of the metaphysis.

Fig. 12.54.1
Anatomic representation of the distal end of the femur and deformities resulting from unbalanced muscle action. A) Sketch of an anteroposterior radiograph of the metaphysis. The segment between the dashed lines is the supracondylar zone. B) Sketch of a lateral radiograph demonstrating muscle attachments and bone displacement. (Reproduced from Krettek and Helfet (2003)). C) Sketch of femur & muscle attachments. (Reproduced from Court-Brown et al. (2003)).

The distal femur serves as origin and insertion to several powerful muscles and ligaments. After a fracture these muscles usually cause characteristic deformities (Figure 12.54.1).

The mechanical and anatomical axes of the femur differ. The mechanical axis passes through the head of the femur and the middle of the knee joint, and subtends an angle of 3 degrees from the vertical. The anatomical axis is an average of 9 degrees valgus to the vertical axis. The axis of the knee joint is parallel to the horizontal (Figure 12.54.2). During fixation of these fractures all attempts should be made to restore these relationships. Approximately 10cm above the knee joint, the femoral artery passes into the popliteal fossa as it emerges from the adductor canal in the adductor magnus.
Pathological anatomy

Like any other bone in the body, the distal femur is also affected by osteoporosis which causes thinning of the cortices and expansion of the medullary cavity resulting in decreased bone stock and increased bone fragility. This is believed to contribute significantly to the age-related increase of distal femoral fractures, especially in elderly women, from minor trauma such as falls.

Associated pathology

Patients with supracondylar femur fractures who have been involved in high-energy trauma, frequently sustain both remote life-threatening (head, chest, and major vascular) and other local injuries. Soft tissue structures in and around the knee (skin, joint surface, menisci, cruciate, and collateral ligaments) are no exception. The incidence of associated vascular injury is low. The popliteal artery is more often at risk when an associated posterior dislocation of the knee occurs. Other associated fractures include condyles, tibial plateau, patella, ipsilateral femoral shaft and tibial shaft fracture creating a ‘floating knee’. Ipsilateral acetabular, femoral head and neck fractures, and hip dislocation should be actively sought to avoid overlooking these frequently missed associated injuries.

About 5–10% of these fractures are complicated by an open wound.

Mechanisms of injury

Most supracondylar fractures occur with the knee flexed. At low energy in the elderly, the patient usually stumbles and falls onto the knee. The high-energy injuries are usually dashboard injuries in motor vehicle collisions where the flexed knee impacts the dashboard. These high-energy injuries are often open and associated with a multiply injured young patient.

Figure 12.54.1 shows characteristic fracture displacement after injury.

Classification

Several classification systems have been proposed, however, the AO/OTA classification is the most comprehensive. This classification is useful in determining treatment and prognosis. It is based on the location and pattern of the fracture and considers all fractures within the distal femur (Figure 12.54.3). Type A fractures involve the distal shaft only with varying degrees of comminution. Type B fractures are condylar fractures; type B1 is a sagittal split of the lateral condyle, type B2 is a sagittal split of the medial condyle, and type B3 is a coronal plane fracture. Type C fractures are T-condylar and Y-condylar fractures; type C1 fractures have no comminution, type C2 fractures have a comminuted shaft fracture with two principal articular fragments, and type C3 fractures have intra-articular comminution.
Initial evaluation is performed using ATLS® guidelines to ensure life-threatening injuries are identified and prioritized. The history of injury is usually either motor vehicle collision in a young person or a fall onto a flexed knee in an elderly person. The knee will be swollen and deformed. Evidence of neurological deficit, vascular injury, compartment syndrome, open fractures, and previous surgery (knee replacement in the elderly) should be identified.

Investigation

Imaging

Plain radiographs should include anteroposterior and lateral views of the entire limb, especially in high-energy trauma to rule out more proximal or distal associated fractures or dislocations. These should be repeated after initial reduction and application of traction or splint. The latter radiographs often supply more information about the anatomy of the fracture. Radiographs of the normal or uninjured opposite femur may be taken for comparison to help in preoperative planning.

CT scans are used when further evaluation is necessary for surgical planning especially when intra-articular extension is noted or suspected. Coronal plane fractures coexist in a significant proportion of patients and if posterior fractures are approached through a medial or lateral parapatellar approach it will lead to extensive incisions and soft tissue stripping.

MRI is used only occasionally to evaluate the knee ligaments prior to definitive surgical intervention.

Other studies

If vascular injury is suspected, Doppler pulse recording of the popliteal and distal pulses should be documented. In dislocation and gross displacement, consideration should be given to performing arteriography.

Whenever there is a clinical suspicion of compartment syndrome, especially in an obtunded patient, compartment pressure monitoring is indicated.

Management

Initial

Primary

The femur should have been splinted prior to transportation. On arrival in the emergency department ATLS® guidelines dictate early prioritization and management of associated injuries. Following treatment of life threatening injuries, urgent limb-threatening injuries (vascular, compartment syndrome) are then managed. Management of open injuries is described in Chapter 12.7. In patients with severe multiple injuries, damage control orthopaedics may be appropriate. This usually entails using external fixators for the initial rapid stabilization of fractures, along with soft tissue care such as decompression of compartment syndrome and wound debridement (Figure 12.54.4). Definitive fracture fixation and complex reconstructive work can then be performed when the patient is physiologically stable.
Definitive treatment

Non-operative

Undisplaced fractures in elderly, high-risk patients may be treated in a cast brace. Subsequent displacement is an indication for fixation.

Operative

The principles of management of these injuries follow that of any long-bone fracture involving the metaphyseal region, namely anatomical reconstruction of the articular surface if involved and accurate realignment in all axes of the metadiaphyseal segment. The introduction of anatomical precontoured locking plates has greatly facilitated this task. The development of submuscular percutaneous plating, indirect reduction techniques, and limited arthrotomies allows the uninjured tissues to remain relatively inviolate (Figure 12.54.5).

Box 12.54.1 Distal femur fixation options

- Antegrade intramedullary nailing (Figure 12.54.4C)
- Retrograde intramedullary nailing (see Chapter 12.53)
- Locked plating (Figure 12.54.4C)
The priority flow of definitive management of these fractures begins with articular reduction and absolute stability of the joint reduction, and metaphyseal/diaphyseal bridging with either an intramedullary or extramedullary implant (relative stability), taking care to use a soft tissue sparing technique.

Antegrade and retrograde intramedullary nailing are usually preferred for A type fractures (extra-articular) or simple C fractures in the hands of enthusiastic proponents of nailing. Conventional plating using the blade plate, dynamic condylar screw, and condylar buttress plate have been reported extensively. The new millennium has seen several reports of the growing use of internal fixators or locked plates, coupled with minimally invasive techniques of application (Figure 12.54.5).

There is considerable confusion regarding the use of locked plates through open and percutaneous approaches, and the number, sequence, placement, and type of screws used in fixation of these fractures. The influence of permutations of these variables on the type of healing achieved is debated. Clarity is sought on the degree of construct stiffness required to optimize rapid callus formation, and the influence of screw type and position on the stiffness of the construct.

Alignment of the meta/diaphyseal segment remains of paramount importance, and single pass image intensifier screening is relatively inaccurate in judging long-bone alignment. The use of a ‘horizontal plumb line’ such as a diathermy cable or proprietary Perspex sheets with fine radio-opaque wires embedded helps get the ‘big picture’.

Some locked internal fixators have cut-outs to allow screw placement to reconstitute the articular block. The placement of the screws requires meticulous planning. Despite this, certain complex fracture patterns may have bone loss/fracture lines in these locations, preventing optimum entry point use. An easy option is to introduce the lag screws from the medial side, taking care to avoid prominent medial metal.

Reduction is greatly aided by large pointed clamps. Special minimally invasive osteosynthesis instrument sets are commercially available to facilitate reduction and provisional stabilization. The large ball-pointed clamps from the pelvic and acetabular set are very useful in obtaining a hold on the articular block. Manual traction, the use of ankle strap distraction over a bolster, reduction triangles, and the use of completely radiolucent pelvic surgery table are invaluable in any attempt to obtain minimally invasive reduction and fixation.

**Special circumstances**

**Open wounds**

Management of open fractures is described in Chapter 12.7.

**Ligamentous injuries**

In the acute fracture setting, ligamentous injuries are very difficult to detect clinically. Most are due to fracture propagation with avulsion of the ligaments (collateral and cruciate) from the distal femur, especially in type C fractures. Magnetic resonance imaging (MRI) scans may also be difficult to interpret at this time. With good fracture reduction and fixation along with functional bracing, most of these ligaments heal. The knee is further evaluated at the time of fracture healing when any necessary ligament reconstruction can be undertaken.

**Patella fractures**

Patella fractures are managed in the standard fashion with accurate reduction and stable fixation to assure patellofemoral joint congruity. These are usually addressed at the same time as the fixation of the distal femur fracture. With extensive comminution of the patella, a partial or total patellectomy may have to be undertaken.

**Associated fractures**

An ipsilateral proximal femur fracture is also usually repaired at the same time. Most other associated fractures such as tibial plateau, tibia shaft, and ipsilateral acetabular fractures are usually repaired in a timely manner as patient fitness for surgery allows. In the case of a ‘floating knee’ (distal femur fracture and ipsilateral tibial shaft fracture) some surgeons may elect to fix both fractures under one anaesthesia or delay the tibial fixation depending on the patient’s fitness.

**Vascular and nerve injuries**

A vascular injury is an emergency, and should therefore be treated well within 6h to avoid an ischaemic limb disaster. After repair of the vessels, a fasciotomy should be carried out to avoid compartment syndrome from reperfusion. Fracture stabilization is necessary to protect the repair.

Repair of nerve injuries should be undertaken as soon as possible, but is not an emergency.

**Articular surface loss**

Loss of articular cartilage is treated according to the patient’s age and feasibility of carrying out a reconstruction. In the young patient, the defect, if large, should be reconstructed when the acute injury has settled.
Osteoporotic bone and the elderly

In the elderly, for a previously symptomatic arthritic knee that has sustained a complex articular fracture, a case can be made for a primary stemmed, stabilized, or partially constrained knee replacement. Multifragmentary metaphyseal fracture patterns (A3) can be spanned or replaced with modular segments.

Extensive comminution and bone loss

Extensive comminution of the metaphyseal region requires judgement to obtain accurate alignment in all three axes, as well as regain leg length. This may require screening the opposite leg to match the length.

Total knee prosthesis

Periprosthetic supracondylar femur fractures following total knee arthroplasty are an infrequent, but devastating, complication. Because of the poor results of non-operative management, internal fixation of these fractures is recommended. Depending on the fracture pattern and the type of prosthesis, these fractures may be fixed with retrograde intramedullary nailing or open reduction and internal fixation. If the prosthesis is loose then it is recommended to perform a revision using the appropriate implant after careful planning (Figure 12.54.6).

![Fig. 12.54.6](https://example.com/fig12546.png)

A) and B) Supracondylar (S/C) periprosthetic fracture in rheumatoid arthritic patient. Loose, lytic SC area. C) Bad hip above (A) and (B). Patient had two attempts at revision. D) and E). Final hip and knee revised with interconnecting femoral segment.

Post-treatment care

Internal fixation of type A fractures commences with immediate postoperative mobilization of the knee. In A1 fractures, early touch weight bearing progressing to weight bearing to tolerance over 4–6 weeks with the help of walking aids.

A2 and A3 fractures with significant metaphyseal comminution partially weight bear until early signs of callus formation, concentrating on range of movement and quadriceps exercises.

Articular fractures (B and C) are mobilized with immediate range of movement exercises and touch weight bearing for 10–12 weeks.

Tenuous fixation leading to subsequent immobilization is likely to lead to stiffness and non-union, and is best revised early to allow compliance with immediate unrestrained access by the physiotherapist.

Complications

Failure to achieve pre-accident levels of form and function in the affected limb is partly determined by the nature of the injury. The iatrogenic component (Box 12.54.2) of this complication relates to infection, malunion, non-union, hardware failure, and stiffness.

Box 12.54.2 Iatrogenic causes of poor outcome

- Injudicious exposure
- Imperfect timing of surgery
- Failure to recognize one’s surgical limitations
- Failure to recognize and deal with axis orientation.
- Incorrect choice of implants
- Incorrect use of appropriate implant
- Lack of clarity of thought in determining method of healing to be desired.

All of these are directly related in some degree to imperfections in the treatment algorithm.
Early complications

This is a common injury in the fragile elderly population, and myocardial infarctions, chest infections, and deep wound infections are the commonest afflictions.

Late complications

Malunion, non-union, and hardware failure may require reoperation.

Results

The outcome following treatment of supracondylar fractures of the femur is multifactorial (Box 12.54.3).

Box 12.54.3 Outcome

- Initial injury severity
- Accuracy of articular reconstitution and axis realignment
- Maintenance of local tissue vascularity and viability
- The outcome measure chosen.

The authors could find only one randomized controlled trial of operative (dynamic condylar screw) versus non-operative management (Thomas’ splint with a Pearson knee flexion attachment) of displaced fractures of the distal femur. Fewer complications, shorter length of stay, and better outcomes demonstrated the clear advantages of internal fixation.

Antegrade intramedullary nailing for supracondylar and intercondylar fractures is accomplished by either percutaneous or open reduction of the articular surface and fixation with screws followed by nailing. Ninety-four per cent good or excellent results are reported as is a good range of knee movement.

Retrograde nails are also extensively reported in these fractures with favourable results.

In a review of publications between 1989 and 2005 operative treatment results in a 32% reduction in the risk of a poor result. They also concluded that experienced surgeons significantly reduce the risk of revision surgery. They could find no evidence of difference between implants in predisposing these fractures to non-unions, infections, and fixation failures.

Summary

Improved implant technology coupled with the general acceptance of soft tissue preservation principles in trauma surgery have made fixation of these difficult fractures in a fragile population less onerous. The economics of today’s health care and the gradual erosion of traditional nursing skills dictate that this trend will continue and fixation of undisplaced supracondylar fractures in elderly osteopenic people will pose a lesser risk than nursing them in bed.

Patella fractures and dislocations

DOI: 10.1093/med/9780198550647.003.012055

Summary points

- Differentiate multipartite patella from fracture
- Non-operative treatment results satisfactory if extensor mechanism intact
- Avoid total patellectomy if possible
- Modified AO technique allows tension wires to be placed through cannulated screws
- Results of dislocation independent of duration of immobilization
- Osteochondral fractures should be either removed or internally fixed.

Introduction

Acute injuries to the extensor mechanism of the knee include patella fractures and dislocations and quadriceps and patella tendon ruptures. Despite their common occurrence, there is much controversy regarding the management of many aspects of patella injuries. Hardware irritation, loss of reduction, and recurrent dislocation continue to be common complications.

Anatomy

The patella, the largest sesamoid, is invested within the strong fascia of the extensor mechanism. Its shape is that of a pear turned upside down, with a broad proximal pole and narrower distal pole. The quadriceps insert into the proximal pole while the patella tendon originates from the inferior pole (Figure 12.55.1). The proximal three-quarters of the posterior patellar surface is composed of articular cartilage and articulates within the trochlear groove of the femur. The articular surface is divided by a vertical ridge into larger lateral and smaller medial facets. The inferior pole, which encompasses one-quarter of the patella, contains no articular surface. The patella serves four functions:

- Enhances the mechanical advantage of the quadriceps
- Protects the underlying femoral articular surface and knee joint
- Aids nourishment of the femoral articular surface
- Provides the bony contours for a ‘normal’ cosmetic appearance to the knee.

Patella fractures

Incidence and prevalence

Patella fractures account for approximately 1% of fractures. Although they occur in patients of all ages, most occur in the third through fifth decades of life.
Pathological anatomy (Box 12.55.1)

The majority of patella fractures disrupt the extensor mechanism, albeit to varying degrees. With increasing amounts of fragment separation, there is greater injury to the adjacent medial and lateral retinacula signifying a greater disruption of the extensor mechanism. Direct contact injuries are undoubtedly associated with patellar and trochlear cartilage injury.

Box 12.55.1 Patella fractures

- 1% of all fractures
- Usually disrupt knee extensor mechanism
- Assume articular cartilage injury with direct contact injuries.

Box 12.55.2 Injury mechanism in patella fractures

- Three-point bending—results in transverse fracture
- Direct contact—comminuted fracture
- Combines three-point bending and direct contact
- Knee flexed—proximal pole fracture
- Knee extended—distal pole fracture.

Mechanism of injury (Box 12.55.2)

Patella fractures result from both direct and indirect forces. A direct force applied to the anterior surface of the patella typically causes a comminuted, minimally displaced fracture pattern (Figure 12.55.2). Tensile and three-point bending forces indirectly produce patella fractures. With the knee in extension, the quadriceps transmits tensile forces to the patella. With increasing knee flexion, the patella engages in the trochlear groove. During a violent quadriceps contraction against a fixed, flexed lower extremity, as would occur from a fall from a height, the patella receives a combination of these indirect forces (tension and three-point bending) that typically creates a displaced, transverse fracture that may have a variable amount of comminution of the articular surface (Figures 12.55.3 and 12.55.4). The anterior surface fails in tension resulting in the transverse component while the posterior surface experiences compression accounting for the comminution.

Fig. 12.55.2
A comminuted, minimally displaced patella fracture sustained from a fall onto a flexed knee (i.e. direct impact injury).
Indirect forces causing patella fractures. With knee flexion, the femur applies an anteriorly directed force while the quadriceps and patella tendon provide posteriorly directed tension forces at the superior and inferior poles, respectively. This further increases tension along the anterior surface and creates compression along the articular surface.

A significant number of patella fractures occur as a result of combined direct and indirect forces (namely motor vehicle collisions—with the flexed knee striking the dashboard as the quadriceps contracts). These fractures also consist of both transverse and comminuted sections.

With increasing knee flexion, the patellar articular contact area shifts from distal to proximal. Therefore inferior pole fractures result from injuries that occur with the knee relatively extended and proximal fractures occur when the knee is in greater flexion.

**Classification**

Patella fractures are classified according to the morphology of the fracture pattern and the presence or absence of displacement. Common fracture patterns include transverse, vertical, comminuted or stellate, osteochondral, and sleeve fractures (Figure 12.55.5).
Clinical evaluation (Box 12.55.3)

The patient usually describes the acute onset of knee pain and swelling after a direct or indirect mechanism of injury, and is often unable to bear significant weight on the injured knee.

The patient’s ability actively to extend the leg must be assessed, as the inability to extend the knee against gravity signifies a significant disruption of the extensor mechanism that may require surgical intervention. When pain is prohibitive, aspiration of fracture haematoma and intra-articular injection of local anaesthetic may be indicated to make the patient more comfortable and allow for a more accurate examination.

Investigation

Plain radiographs (anteroposterior, lateral, and Merchant (45-degree axial) views) are usually all that are needed to treat patella fractures. The anteroposterior view is assessed for patella position, displacement, and comminution. A bipartite or multipartite patella (Figure 12.55.6A) is distinguished from a fracture (Figure 12.55.6B) by its typical location (superolateral), smooth borders, and frequent bilateral occurrence. The lateral projection usually provides the best view of fracture lines and should be scrutinized for patella height, displacement, and comminution. The Merchant view (Figure 12.55.7) is often the only projection that will demonstrate vertical and osteochondral fractures.

Box 12.55.3 Evaluation of patella fractures

- Must assess ability to extend knee against gravity
- Anteroposterior, lateral, and Merchant radiographs.

A classic multipartite patella (A) is distinguished from an acute fracture (B) by the typical superolateral location and smooth borders of the fragments. An acute fracture (B) may occur in a similar location, but the borders are sharp and often associated with some degree of fracture comminution.
Management (Box 12.55.4)

The treatment goals for most patients with patella fractures are to maintain or restore a stable extensor mechanism and a smooth articular surface.

Non-operative

Non-operative treatment produces excellent results in carefully selected patients; namely those with a functional extensor mechanism and minimal fracture displacement (Figure 12.55.8). The knee is immobilized in extension for 6 weeks followed by progressive active range of motion exercises. Full weight bearing and isometric quadriceps exercises are begun several days after injury. Radiographs must be obtained weekly for 3 weeks to rule out fracture displacement.

Operative

Displaced patella fractures with disrupted extensor mechanisms should be treated operatively with techniques ranging from reduction and fixation of all displaced fragments to total patellectomy.

Transverse fractures

Reduction and fixation of transverse fractures must withstand not only the considerable tension forces exerted by the quadriceps but also, if early knee motion is desired, the three-point bending forces which create additional tension along the anterior surface and compression along the articular surface. The modified tension band wiring technique as described by the AO group (Figure 12.55.8) has been clinically successful and is relatively simple and familiar to most surgeons. Two vertical 1.6-mm (0.062-inch) K-wires are placed parallel to each other across the reduced fracture. An 18-gauge wire is then placed directly posterior to the K-wires at their entrance into the superior pole, wrapped over the anterior surface of the patella in a figure-of-eight or box configuration, passed directly posterior to the K-wires at their point of exit at the inferior pole, and then twisted until appropriate compression is achieved across the fracture site.

Box 12.55.4 Treatment of patella fractures

- Non-operative (6 weeks immobilization) for intact extensor mechanism and <2-3mm fragment displacement
Transverse tension band around parallel wires or through screws for transverse fractures
- One comminuted pole—partial patellectomy
- Avoid total patellectomy if possible.

The AO technique has been modified by replacing the K-wires with cannulated screws. The 18-gauge wire is threaded through the screws, rather than around the K-wires, before passing over the anterior surface of the patella in a similar figure-of-eight configuration (Figure 12.55.9). The screws produce interfragmentary compression across the fracture site while the wire neutralizes the tension forces across the anterior patellar surface. Mechanical testing has shown that this construct provides the strongest initial fixation. The use of an arthroscope to assess the reduction allows the possibility of a truly percutaneous approach to reduction and fixation. This technique needs further assessment but is attractive in cases where there are abrasions or other skin problems over the anterior surface of the patella.

![Click to view larger](Fig. 12.55.9)
A displaced transverse fracture treated with two cannulated screws and an anterior tension band wire placed through the screws.

Vertical fractures

Vertical fractures are rarely displaced. When displaced they are best treated with anatomical reduction and lag screw fixation.

Comminuted or stellate fractures

When possible, vertical fracture lines should be rigidly fixed with lag screws with the objective of creating two large pole fragments. These two fragments can then be fixed like a transverse fracture (Figure 12.55.10). When comminution severity precludes this technique, all attempts should be made to save some portion of the articular surface with the hope of maintaining patella function. This frequently involves partial patellectomy and reattachment of the patella or quadriceps tendon to the salvaged fragment (Figure 12.55.11). Total patellectomy is performed when there are no large articular surface fragments that can be congruently reconstructed.

![Click to view larger](Fig. 12.55.10)
A) and B) A displaced comminuted fracture treated with lag screw fixation and C) and D) the modified tension band wire technique. The lag screws were used to fix the comminuted fractures, thus creating large superior and inferior pole fragments. These two fragments were then treated as a transverse fracture with the modified tension band wire technique.
A displaced comminuted fracture indicated for partial patellectomy. Attempts to fix the distal comminution would likely be fraught with complication. Excision of the distal comminution and reattachment of the patella tendon to the large proximal fragment is indicated.

Controversy exists regarding the proper site to reattach the patella tendon when inferior pole fragments are excised. Most authors have recommended that the tendon be reattached immediately adjacent to the articular surface in order to minimize the step-off between the tendon and articular cartilage, and prevent the posterior tilting and subsequent edge loading reported to occur with anterior reattachment. However, it has been demonstrated that when the tendon is reattached anteriorly there are smaller decreases in patellofemoral contact area and smaller increases in contact pressure compared to posterior reattachment. The author reattaches the patella tendon through drill holes in the central portion of the fracture surface of the residual proximal fragment.

Post-treatment care

The knee is immobilized and rehabilitated postoperatively based on fracture configuration and stability of fixation. Patients with severely comminuted fractures, tenuously fixed fractures, partial patellectomies, and total patellectomies are treated for 4–6 weeks with the knee immobilized in extension, followed by a gradual progressive range of motion and strengthening program.

For stable well-fixed transverse fractures, the current trend is to begin early active-assisted range of motion limited to 90 degrees. Gradual and progressive strengthening is begun at 6 weeks.

Special circumstances

Open fractures

Seven per cent of all patella fractures are open. Similar to other open fractures, antibiotics should be started and the fracture should be immediately irrigated, debrided, and rigidly internally fixed if the wound is clean. The wound should be closed or covered with a flap within 3–5 days of injury. The incidence of deep infection is correlated to the magnitude of soft-tissue injury with rates ranging from 0–10.7%.

Associated ipsilateral femoral shaft fracture

Ipsilateral femoral shaft and patella fractures are not uncommon. These tend to be high-energy injuries associated with more severe soft tissue trauma. Both fractures should be stably internally fixed to allow early knee motion and prevent quadriceps adherence at the femoral fracture site.

After bone–patellar tendon autograft anterior cruciate ligament reconstruction

Transverse patella fracture has been reported as a complication of bone–patellar tendon graft harvest. The fractures are usually associated with trauma and occur in the early months after the anterior cruciate ligament surgery. Standard treatment of the patella fracture leads to generally satisfactory results.

Results (Box 12.55.5)

Non-operative treatment

Appropriately indicated patella fractures (namely those with minimal displacement and an intact extensor mechanism) have good results when treated non-operatively, with 99% good and excellent results (average 8.9-year follow-up) reported. In a study of 40 patients (average of 30.5 months after injury), 80% were pain free and 90% had full knee range of motion.

Operative treatment
The results of operatively-treated patella fractures are more related to the severity of injury and associated injuries than to the method of fixation. High-energy injuries, open fractures, comminution, and the presence of concomitant injuries have been found to be predictive of a poor result. Although residual articular displacement has also been associated with worse results, these findings have not been universal.

**Open reduction and internal fixation**

Most authors report 70–80% good and excellent results after open reduction and internal fixation of patella fractures. Perfect reduction has been found to be necessary to optimize outcomes. If precise reduction was not achieved, the results were better in patients treated with patellectomy. These results should be considered when attempting to fix comminuted cases internally. Good results after internal fixation have been reported even in elderly patients.

**Partial patellectomy**

Despite biomechanical studies which demonstrate decreased patellofemoral contact area and increased pressure after partial patellectomy, this procedure has resulted in outcomes comparable to those after open reduction and internal fixation, and the results appear to be maintained over time. At an average 8.4-year follow-up, 78% good and excellent results and an average quadriceps strength of 85% of the opposite side, has been reported. Partial patellectomy resulted in better outcomes than total patellectomy for the treatment of comminuted displaced fractures.

**Box 12.55.5 Results of treatment of patella fractures**

- Open fractures (Gustilo type 1 and 2): low infection rate when fixed
- Non-operative treatment (undisplaced/minimally displaced)
- 99% good/excellent results
- Poor results associated with:
  - High-energy injury
  - Open fractures
  - Concomitant injuries
  - Communion
- Open reduction and internal fixation:
  - 80–90% good/excellent results
  - Precise reduction essential
- Partial patellectomy:
  - 78% good/excellent results
  - Quadriceps power, 85%
- Total patellectomy:
  - 60–80% good/excellent results
  - Quadriceps power, 50–75%
  - Functional limitations.

**Total patellectomy**

Patella fractures treated by total patellectomy have less predictable outcomes than after other treatments, with reports ranging from 61–88% good and excellent results. Pain has not been a major long-term problem, and patients continue to make functional improvements for up to 2–3 years postoperatively. Most patients have some quadriceps weakness (50–75%) and are functionally limited (running, squatting, ascending and descending stairs) after patellectomy. There is some evidence that newer operative techniques (e.g. vastus medialis obliquus advancement and cruciform repair) and aggressive rehabilitation result in improved outcomes.

**Complications (Box 12.55.6)**

**Hardware irritation**

Operative treatment of patella fractures is often complicated by hardware irritation because the patella is located subcutaneously and stabilized with wires that become prominent. Trimming excessive length from K-wires, bending prominent wire ends away from the subcutaneous tissues, and keeping suture and wire knots off the anterior surface of the patella may help to limit these problems.
Loss of fixation is usually related to poor patient compliance, unrecognized comminution, poor bone quality, or poor surgical technique (i.e., improper placement of the tension band wire). It has been reported that fracture fragments separated (up to 2mm) in 22% of transverse fractures treated with open reduction and internal fixation. Placing the non-compliant patient in a long leg cast for a limited period of time (3–4 weeks) may prevent fixation failure. Efforts to reconstruct severely comminuted fractures should be abandoned in favor of partial patellectomy. Tension band wires must be placed in direct contact with the patellar poles, posterior to longitudinal K-wires, and over the anterior surface of the patella. When fractures widely redisplace, they must be treated with repeat open reduction and internal fixation or partial patellectomy.

**Box 12.55.6 Complications of patellar fractures**

- Prominent metalwork
- Loss of fixation:
  - 22% incidence of separation up to 2mm
  - immobilization may prevent loss of fixation
  - avoid fixing severely comminuted fractures
  - figure-of-eight wire contact with bone
- Arthritis—radiographic arthritis is relatively common
- Stiffness
- Infection is uncommon
- Non-union: 2–12%

**Post-traumatic osteoarthritis**

In a 10- to 30-year follow-up, 45 of 64 injured knees had patellofemoral osteoarthritis compared to only 23 contralateral, uninjured knees. There is an increase in the frequency of osteoarthritis after high-energy injuries, open fractures, comminuted fractures, operatively treated fractures, and fractures with 1mm or more of articular incongruity. However, these radiographic findings often bear no relation to clinical results.

**Knee stiffness/loss of range of motion**

Fractures stabilized with current operative techniques and mobilized early in the postoperative period are generally considered to result in less knee stiffness and decreased range of motion. Some loss of flexion is expected after operative treatment, but is rarely of functional significance. When functionally limiting stiffness occurs, the knee should be aggressively rehabilitated. If it does not respond, it should be manipulated under anesthesia and refractory cases should have adhesions lysed arthroscopically.

**Infection**

Infection following operatively-treated patella fractures is uncommon. Superficial infections should be treated with antibiotics and local wound care. Deep infections should be aggressively irrigated and debrided and the patient should be placed on intravenous antibiotics. All attempts should be made to preserve the patella, but patellectomy is inevitable in some cases of deep infection.

**Non-union**

Although patella non-unions are considered uncommon when fractures are treated with current techniques, reported rates have ranged from 2.7–12.5% of all fractures. Minimally symptomatic patients have been successfully treated non-operatively, accepting failure of fracture healing. Symptomatic non-unions can be expected to have improved knee function when treated with open reduction and internal fixation, partial patellectomy, or total patellectomy.

**Future directions**

Patella fractures have been treated using the same principles for the past three decades. The use of bioabsorbable implants may eliminate the need for hardware removal. The arthroscope has revolutionized surgery around the knee joint, allowing major surgery to be performed through small incisions in an almost percutaneous fashion and this technique may have increased use in fractures of the patella.

**Summary**

Patella fractures are common injuries caused by both direct and indirect trauma. They are classified based on the fracture pattern and presence of displacement. The status of the extensor mechanism is determined by physical examination and radiographic analysis. Surgical intervention is indicated for those patients with displaced fractures and disrupted extensor mechanisms. All attempts should be made to salvage a significant portion of the articular surface.
**Incidence and prevalence**

Acute lateral patella dislocations are relatively uncommon injuries. However, in many patients the patella relocates prior to presenting for medical care so the true incidence is unknown. Most dislocations occur in patients during their second and third decades of life and there is a slight female predominance.

**Pathological anatomy**

The patellofemoral joint is stabilized by both bony and soft tissue restraints. Bony stability is provided by the convex shape of the patellar articular surface as it articulates within the concave trough of the femoral trochlea. The quadriceps muscle group provides dynamic stability with an essential contribution from the vastus medialis obliquus. The medial and lateral retinacula along with their associated medial and lateral patellofemoral and tibiofemoral ligaments provide static stability (see Figure 12.55.1).

Many anatomical factors can predispose a patient to sustaining a patella dislocation (Table 12.55.1). Unfortunately, no single factor or combination of factors has been shown to be predictive of dislocation, redislocation, or poor outcome after dislocation.

**Box 12.55.7 Acute patella dislocations**

- Frequent predisposing anatomical factors
- Operative vs non-operative management controversial
- Look for osteochondral fractures—if present remove or internally fix
- Recurrent dislocation and persistent anterior knee pain are most frequent complications.

The medial patellofemoral ligament is a major stabilizing component of the medial retinacular complex. Several studies have shown that there is a consistent injury to the medial patellofemoral ligament after dislocation. However, whether the major injury occurs at the patellar insertion, within the midsubstance, at the femoral origin, or some combination of locations continues to be a point of controversy and is a critical piece of knowledge if one is considering operative repair. Bony injuries of the medial border of the patella represent avulsions of the medial patellofemoral ligament. Other structures commonly injured during lateral dislocation include the vastus medialis obliquus and medial patellar and lateral trochlear articular surfaces.

Most patella dislocations occur as a result of a twisting injury. Internal rotation of the femur on a fixed lower extremity while the quadriceps contracts draws the patella out of the trochlea, resulting in a lateral patella dislocation. Less commonly, a direct force applied to the medial side of the patella causes lateral dislocation.

### Box 12.55.8 Investigation of patella dislocation

- Radiograph (associated fractures)
- Joint aspiration:
  - Pain relief
  - Look for fat droplets
- MRI scan may be useful occasionally.

### Classification

Superior, medial, lateral, and intra-articular dislocations have been described. Lateral dislocations represent the overwhelming majority of these injuries.

### Clinical evaluation

The history is usually one of a twisting injury to the knee associated with collapse, acute pain, and swelling. A sensation that something ‘popped’ out of place is common. If the knee remains flexed, the patella will be visualized on the lateral side of the knee. With knee extension (by the patient or a bystander) the patella will relocate. A history of similar previous episodes along with a history of anterior knee symptoms may be elicited.

The injured knee is assessed for patella mobility and apprehension, to localize tenderness and identify tears of the medial retinaculum–vastus medialis obliquus complex, and to exclude cruciate and collateral ligament injuries. The uninjured knee is examined for anatomical factors associated with patellofemoral disorders (Table 12.55.1).

### Investigation (Box 12.55.8)

#### Joint aspiration

Aspiration of the knee can serve three potential functions. Firstly, evacuation of the haematoma will provide pain relief for the patient. Secondly, fat droplets within the aspirate indicate the presence of an osteochondral fracture, a consideration for operative intervention. Thirdly, removal of the haematoma may aid reapproximation of the torn edges of the medial retinacular complex.

#### Radiographs

Standard plain radiographs (anteroposterior, lateral, and Merchant views) are required and should be scrutinized for osteochondral fractures and the presence of any factors known to be associated with patellofemoral disorders (Table 12.55.1). Medial extra-articular capsular avulsion fractures are pathognomonic and should be differentiated from osteochondral fractures.

Some surgeons obtain MRI examinations after patella dislocations to document osteochondral and chondral injuries not seen on radiographs, detect bone bruises, and characterize the injury to the medial patellofemoral ligament. In rare instances, an MRI may be indicated for diagnostic purposes in a patient with a haemarthrosis and confusing physical examination.

### Management

#### Initial

Patients presenting with the patella dislocated require a gentle, closed reduction as there is some evidence that the majority of osteochondral fractures occur with relocation. Using intravenous sedation to keep the quadriceps maximally relaxed, the leg is gradually extended passively until the patella reduces.

#### Definitive

**Non-operative**

Patella dislocations have traditionally been reduced and immobilized in extension for 6 weeks followed by quadriceps rehabilitation. However, several studies have shown the treatment results to be independent of the duration of immobilization. Based on these data, many have decreased the period of immobilization and focused more on rehabilitation.
Operative

Operative procedures are most commonly indicated for patients with anatomical factors associated with patellofemoral instability (Table 12.55.1). Unfortunately, no single factor or group of factors have been shown to be highly predictive of future problems, and some patients respond well to conservative treatment despite having anatomical factors associated with instability.

Repair of the medial retinaculum–vastus medialis obliquus complex has been advocated by many, especially when a palpable defect is present on examination. The addition of a lateral release with or without a distal realignment has been advocated. An isolated lateral release can be performed arthroscopically. The indications for any one or more of these procedures are controversial and have been largely based on surgeon preference.

Post-treatment care

Post-treatment care focuses on regaining quadriceps strength, with special emphasis on the vastus medialis obliquus. This requires a prolonged rehabilitation program that lasts beyond symptomatic improvement.

Special circumstances

Osteochondral fractures (Box 12.55.9)

Osteochondral fractures have been estimated to occur in 5–43% of all first-time patella dislocations. Plain radiographs have been reported to detect 20–82% of these injuries. Although MRI would aid in detecting these fractures, no clear benefit has been reported to addressing fractures not appreciated on plain radiographs.

Small fragments should be excised and larger fragments with adequate subchondral bone internally fixed.

Results (Box 12.55.10)

Non-operative treatment

Redislocation rates for conservatively treated patients range from 22–44%. Forty to seventy-five per cent of patients have persistent symptoms related to the patellofemoral joint with 25% undergoing further surgical treatment. Approximately 65% of patients are satisfied with conservative treatment alone, although 40–50% will have some limitation of function.

Operative treatment

Arthroscopically assisted lateral release alone provides no benefit over conservative treatment. Other operative treatments (incorporating medial retinacular repair) have been reported to reduce redislocation rates to 0–10%. However, residual symptoms are common with 40–70% of patients having anterior knee pain and 20–30% having symptoms of instability. Patient satisfaction rates have been slightly higher (80–90%) with operative intervention, although there are no good controlled studies to provide definitive documentation.

Complications

Recurrent dislocations and persistent anterior knee symptoms are the major problems complicating first-time dislocation. Recurrent dislocation is associated with younger age at the time of first dislocation (less than 20 years old), non-operative treatment, and anatomical factors predisposing to instability. Surgery can reduce the rate of redislocation, but does not reduce residual symptoms of pain and instability. Furthermore, many patients with multiple predisposing factors respond well to conservative treatment alone.
Future directions

The debate between operative and non-operative management of first-time dislocators will likely continue. Future work will attempt to identify specific anatomical factors predictive of redislocation and methods to more effectively treat persistent symptoms of anterior knee pain and instability.

Summary

Acute patella dislocations occur primarily in patients with anatomical predisposition. Initial treatment involves a gentle reduction. Osteochondral fractures visible on plain radiographs should be removed or replaced, depending on the size of the fragment. Non-operative treatment is indicated for most patients, emphasizing the importance of a prolonged rehabilitation program. Operative intervention is considered for those patients with large palpable medial retinaculum–vastus medialis obliquus defects along with those with persistent symptoms of pain and instability after adequate rehabilitation.

Further reading

Summary points

- Split depression pattern lateral plateau most common type
- Bicondylar and medial plateau fractures high energy injuries
- Compartment syndrome, vascular injury, and common peroneal palsy may occur with high energy patterns
- Internal fixation preferred treatment with good soft tissue envelope
- Limited internal fixation suitable for many simple patterns
- Plate fixation preferred for medial and bicondylar fractures
- External fixation used with poor soft tissues
- Fine wire external fixation should be considered for most complex patterns.

Introduction

Fractures of the proximal tibia present a challenging problem as the injury involves a principal weight-bearing joint and severe injuries can lead to functional impairment. A flexible approach is required to adapt treatment to the patient, fracture pattern, and clinical and radiological findings. The treatment options range from non-operative management through limited internal fixation to open reduction and internal fixation (ORIF) or external fixation. Regardless of the treatment method employed, the aim is to provide a stable, pain-free, and well-aligned joint whilst avoiding complications.

The aim of this chapter is to provide an overview of the injury, classification, management and technical tips in managing this type of fracture.

Epidemiology

In a consecutive series of 285 tibial plateau fractures treated at our institution, there were 168 female and 117 male patients giving a female: male ratio of 1.4:1. Most of these fractures were isolated injuries with multiple trauma accounting for only 1.4% of cases. There were 149 (49%) undisplaced fractures and 146 (51%) displaced fractures. Although the mean age of patients with plateau fractures was 58 years, there appeared to be a bimodal incidence with a peak of younger patients and a larger peak in the seventh and eighth decades of life (Figure 12.56.1). Simple falls and pedestrian accidents accounted for 70% of cases. Dogs running into their owners were a surprisingly common cause and accounted for 15% of fractures (Figure 12.56.2).
Tibial plateau aetiology.

Anatomy (Box 12.56.1)

The tibial plateau is formed by the medial and lateral condyles separated by the tibial (intercondylar) eminence. The intercondylar eminence is the site of attachment of the meniscal horns and the anterior cruciate ligament. There are important soft tissue structures that attach to the tibial plateau including the knee joint capsule, and the medial and lateral menisco-tibial ligaments. The medial collateral ligament comprises a deep and superficial layer. The lateral collateral ligament is attached from the lateral epicondyle to the fibular head. The anterior cruciate ligament is attached to the intercondylar eminence between the tibial spines and the posterior cruciate ligament arises from the posterior aspect of the plateau in the midline. Further meniscal attachment is provided by the menisco-tibial ligaments at the periphery of both sides. The attachment of the joint capsule can extend 1.5cm below the level of the joint margin, which has particular significance when using fine-wire external fixators, which are often situated, close to the joint. If they penetrate the capsule, pin track infection may result in septic arthritis.

Box 12.56.1 Anatomy of tibial plateau

- 10-degree posterior slope

- Medial plateau concave
- Subchondral bone higher on lateral side
- Load bearing on lateral side mainly through meniscus.

Three additional structures have potential significance in assessment and management of tibial plateau fractures. The fascia lata attaches at Gerdy’s tubercle, and is sometimes disrupted by the injury or requires to be released during the exposure and fixation of the fracture. The tendons of gracilis, sartorius, and semitendinosus are attached anteromedially at the pes anserinus and need to be reflected during exposure of the medial plateau.

The surface of the tibial plateau forms a 10-degree posterior slope in relation to the long axis of the tibia. The shape of the medial condyle is concave and has an average 3-mm thick hyaline cartilage articular surface that the medial meniscus covers about 50% from the periphery. It has less of a flare and as a result is less prone to the shear forces that render the lateral plateau more susceptible to fracture. The lateral plateau is convex with an average 4-mm thick hyaline cartilage that is almost completely covered by the lateral meniscus. Load bearing on the lateral plateau is transmitted mainly through the lateral meniscus, unlike the medial plateau where the load is distributed equally through the meniscus and the exposed articular surface.

The medial plateau surface is lower in the transverse plane than the lateral plateau and this can be easily seen on plain anteroposterior (AP) radiographs. This is significant when elevating a depressed segment of the plateau in assessing the accuracy of reduction and surgeons should be aware that the subchondral line on the lateral side should be higher than on the medial side. It is also important to appreciate that a screw or wire placed subchondrally on the lateral side proceeding medially, perpendicular to the tibial shaft, may penetrate the articular surface of the medial side if the location is very proximal. Ideal screw placement is in the subchondral bone just beneath the articular surface in a ‘raft’ construct.

Classification

Several classification systems of plateau fractures have been described. No one system provides a comprehensive description of all fracture patterns encountered. The Hohl and Moore, and Rasmussen systems are mainly of historical interest and no longer in widespread use. The Schatzker classification subdivides the plateau fractures into six groups and has been the most popular method of classifying tibial plateau fractures from plain radiographs and remains in common use today. However, it has some significant disadvantages. Medial plateau fractures are all classified as type IV injuries but there are a wide variety of these fractures. The oblique fractures which are a highly unstable pattern are not specifically covered by the classification (Figure 12.56.3). The type V fracture as originally described was a bicondylar fracture (Figure 12.56.4) with the interspinous eminence still in contact with the tibial diaphysis. However, this is actually a very rare pattern and in most bicondylar fractures the interspinous region is involved in the fracture and is not in continuity with the tibial shaft.

Click to view larger

Fig. 12.56.3
The more comprehensive classification is the AO/Orthopaedic Trauma Association (OTA) system which covers most fracture types and is now being used more commonly. It allows a more detailed description of fracture morphology including separate categories for oblique fractures and a number of categories for bicondylar fracture patterns. However, even this system does not describe the important posteromedial and anteromedial fractures as separate entities. It is worth noting that both classification systems are prone to inter- and intra-observer error.

AO/Orthopaedic Trauma Association classification

The AO/OTA classification is based on an alphanumeric system that assigns each major bone and the region of bone involved a number and then subdivides the injuries in that region based on severity. In the case of the tibial plateau, the bone is assigned the number 4 and proximal region is 1. Proximal tibial metaphyseal fractures, which are extra-articular, are classified as type A injuries. Type B fractures are partial articular fractures and type C fractures are complete articular fractures. All fractures involved the plateau are classified as 41 type B and C injuries. Type B1 fractures are simple splits, type B2 are pure depression, and type B3 are split depression fractures. Subdivisions of each category allow for description of whether the injury involves the medial or lateral plateau and the extent of involvement. The type C fractures are bicondylar fractures. Type C1 designates a fracture with a simple articular and metaphyseal configuration. Type C2 is a metaphyseal complex pattern with simple articular pattern and type C3 fractures are complex articular bicondylar plateau fractures.

Split fractures

- 41-B1.1 Lateral (Figure 12.56.5)
- 41-B1.2 Medial
- 41-B1.3 Oblique split.

These fractures are simple splits with no comminution or joint depression. They most commonly involve the lateral tibial plateau and usually occur in young patients with good bone stock. The most common mechanism of injury is axial loading coupled with a valgus force. The strong cancellous bone resists any surrounding articular depression that occurs in older or osteoporotic patients. Wide displacement of the split fracture may be associated with peripheral meniscal detachment and occasionally entrapment of the meniscus in the fracture may occur.
Split depression

- 41-B3.1 Lateral (Figure 12.56.6)
- 41-B3.2 Medial split depression
- 41-B3.3 Oblique split depression.

![Click to view larger](Fig. 12.56.6)

Split depression fracture of tibial plateau (AO 41-B3.1/Schatzker II).

These fractures are intra-articular fractures of the tibial plateau but in addition have an adjacent area of articular depression. These are usually found in older patients or younger patients with higher-energy injuries. They occur when the surrounding cancellous bone is unable to withstand the axial load created by the lateral femoral condyle. The same associated soft tissue injuries occur as with the split fractures.

Depression fractures

- 41-B2.1 Lateral total depression
- 41-B2.2 Lateral limited depression (Figure 12.56.7).

![Click to view larger](Fig. 12.56.7)

Depression fracture of tibial plateau (AO 41-B2.2/Schatzker III).

This is a pure depression fracture of the lateral tibial plateau and principally occurs in older patients, again due to the weaker cancellous bone. Isolated depression fractures are actually quite uncommon—the majority have a split component which is undisplaced and is recognized only on computed tomography (CT) scan or at the time of surgery.

Medial fractures

- 41-B1.2 Medial split
• 41-B1.3 Oblique involving the tibial spines
• 41-B2.3 Medial depression
• 41-B3.2 Medial split depression
• 41-B3.3 Medial split depression, oblique (Figure 12.56.8).

![Click to view larger](Fig. 12.56.8)

Medial split depression oblique fracture of tibial plateau (AO 41-B3.3/Schatzker IV).

Split or split depression fractures of the medial tibial plateau occur as a result of compression of the medial plateau by a varus force. Many of these are high-energy injuries and are associated with other soft tissue problems. Oblique medial plateau fractures that extend to the interspinous region or into the lateral plateau are fracture dislocations of the knee and are highly unstable injuries. Since all of these fractures involve application of varus force to the knee, there is a possibility of common peroneal nerve palsy.

**Bicondylar fractures**

• 41-C1.1–AO 41-C3.3 Complete articular (Figure 12.56.9).

![Click to view larger](Fig. 12.56.9)

Complete articular fracture of tibial plateau with multifragmentary metaphysis (AO 41-C2.3/Schatzker VI).

These fractures involve a bicondylar split with separation of the medial and lateral condyles and a variable involvement of the diaphysis. The proposed mechanism for this fracture is pure axial load on the extended knee. Bicondylar fractures account for 10–15% of all plateau fractures. The involvement of the intercondylar area in the fracture may compromise cruciate ligament attachments. The higher energy required to produce this fracture patterns means they are associated with greater soft tissue injury and an increased risk of compartment syndrome.
Mechanism of injury

The majority of tibial plateau fractures are isolated injuries but initial management involves careful general evaluation in line with ATLS® principles to exclude other injuries. The most common mechanism of fracture is usually a combination of an axial load coupled with a valgus force. In this situation the medial collateral ligament acts as a hinge on the medial femoral condyle that then drives the lateral femoral condyle into the lateral tibial plateau. In patients with normal bone stock, this leads to a sagittal split of the lateral plateau. Damage to the articular surface of the lateral plateau with additional comminution is frequent, leading to a split depression fracture. Elderly patients with poorer bone stock often appear to have depression of the articular surface without a split fracture. However, pure depression fractures are uncommon and even patients who appear to have isolated depression usually have an undisplaced split component present.

Varus stress in combination with compression is a much less frequent mechanism of injury but can result in a fracture of the medial plateau. Progression of varus deformity may result in disruption of the posterolateral corner structures and subsequent traction injury or even avulsion of the common peroneal nerve. Occasionally a combination of hyperextension and varus deformity can occur and this leads typically to an anteromedial plateau fracture which may be associated with a posterior cruciate ligament and posterolateral corner ligament injury (Figure 12.56.10).

High-energy injuries with axial loads in addition to valgus or varus forces usually result in bicondylar plateau fractures. These fractures are often associated with a significant degree of soft tissue injury. As a consequence of the posterior slope of the tibia, the distal femoral condyles are subsequently directed posteriorly, leading to disruption of the joint capsule, cruciate and collateral ligaments and potential injury the neurovascular bundle.

Clinical assessment (Box 12.56.2)

Careful observation of the soft tissues is required in all cases, particularly to detect blisters, devitalized skin, and open fractures all of which will influence the clinical decisions regarding management.

An assessment of the neurovascular status of the limb should be performed and documented. If there is any doubt regarding the vascularity of the limb in high-energy fracture patterns angiography is required. Injury may take the form of a thrombus, occult intimal tear or, rarely, complete disruption of the artery. Either angiography or a CT angiogram should reveal these injuries. Fractures of the medial plateau may result in traction injury or avulsion of the common peroneal nerve and is present in 10% of these fractures. The neurological status of the limb should be examined and documented on admission.

Box 12.56.2 Clinical assessment

- Examine soft tissue envelope of injured limb
- Careful neurological examination—common peroneal nerve
- Assess vascular supply of distal limb
- If any doubt over vascular supply obtain angiogram or CT angiography
- Assess for compartment syndrome.

Compartment syndrome is not commonly associated with the simpler fracture patterns (split, depression and split depression patterns). However it does occur in 5–10% of patients with bicondylar fractures and the high-energy oblique fractures and a high index of suspicion is warranted in these cases. Compartment pressure monitoring is advisable in these patients.

Investigations (Box 12.56.3)

Plain AP and lateral radiographs of the tibial plateau are required in all cases. A 'Moore' view can be added, which is an AP view taken with 10–15-degree caudal tilt (Figure 12.56.11). This accounts for the posterior slope of the tibial plateau allowing a better evaluation of the joint surface. Oblique views taken at 45 degrees and plain tomography were commonly used in the past but have
been superseded by CT scanning.

Modern CT scanning with sagittal, coronal, and three-dimensional reconstructions are not necessary for simpler fracture patterns but should be considered in more complex injuries, particularly bicondylar fractures. However, in some simple fracture patterns there may be some doubt about the diagnosis, the extent of plateau involvement or the degree of joint depression and CT scans are useful in these cases to determine the need for surgery. The coronal views show the size and location of all articular fragments.

The use of CT reconstructions, as well as intraoperative CT has been shown to be superior to fluoroscopy in assessing fracture reduction. Magnetic resonance imaging (MRI) has been used, where available, to delineate occult fractures, soft tissue disruption and impaction of the articular surface. It is most useful in fracture patterns specifically associated with ligamentous injury, particularly anteromedial plateau fractures. In these cases the ligament injury is often impossible to diagnose clinically due to the presence of the unstable fracture.

If the fracture pattern involves the anteromedial portion of the tibial plateau then a careful examination of the posterolateral corner should be undertaken. Regardless of the mode of imaging employed, the objective is to provide a full assessment of the fracture pattern and any associated soft tissue disruption, which facilitates preoperative planning.

**Management**

The management of tibial plateau fractures is determined by the clinical evaluation of the patient and the limb, and the morphology of the fracture. Factors that will have a major influence on treatment choice are the presence of an open wound, a fracture dislocation, concurrent and pre-existing health or knee problems, age and activity level, bone quality, anticipated patient compliance with rehabilitation, and treatment expectations. The successful treatment of these injuries is a dependent on careful treatment selection and a properly structured rehabilitation programme. Even when this occurs many patients take over a year to recover knee muscle function and motion. Patients over 40 years of age recover significantly slower, and some have residual impairment of movement and muscle function.

Any open fractures should be initially covered with a sterile dressing and administration of broad-spectrum intravenous antibiotics. The patient’s tetanus status should be addressed. Initial debridement and irrigation with 10L of normal saline within 6h of injury is required.

**Box 12.56.3 Investigations**

- AP and lateral x-rays ± Moore view
- CT scan ± angiogram
- Angiography
- MRI
- Compartment pressure monitoring.

If there is an associated vascular injury-requiring repair, then ideally the fracture should be stabilized first without delay. Complex fracture patterns may require temporary bridging external fixation across the knee joint. Pins should be placed as far as practical away from any future surgical incisions. Following a vascular repair, fasciotomies are commonly required, and definitive fracture fixation may be delayed 48–72h until the fasciotomies are closed.

Closed unstable fractures without vascular injury, can be fully evaluated clinically with appropriate imaging and preoperative planning prior to definitive surgery. During this time, the limb may be immobilized in a padded long leg splint. Deep vein thrombosis (DVT) prophylaxis should be prescribed and intermittent foot compression devices may be used on the contralateral foot as well.

**Non-operative treatment (Box 12.56.4)**

In the past this was a commonly employed treatment modality but with modern imaging techniques and a wider variety of surgical options, a smaller proportion of tibial plateau fractures are suitable for non-operative treatment in modern practice. Pure split, split depression, and depression fractures that are stable through 90 degrees of flexion with less than 3mm of articular depression are suitable. The bone quality, concomitant medical problems, and functional demands in elderly patients may also influence the
decision to opt for non-operative treatment. If there is any doubt regarding the suitability of the fracture for non-operative treatment, a CT scan is the most helpful additional investigation to determine the extent of joint surface involvement and the degree of depression. Central depression fractures of the lateral plateau with minimal depression of the articular surface are suitable for non-operative treatment due to the load bearing nature of the lateral meniscus that protects the damaged articular surface.

If non-operative treatment is selected there are several forms of immobilization available. A full-length cast can be used but a cast braces with a hinge at the level of the knee to allow some knee motion is preferable. Removable hinged braces that do not enclose the foot are a good choice for stable fractures in compliant patients. Accurate placement of the brace by an orthotist or surgeon is essential and the patient, or carer, must be able to reproduce correct placement of the device for this to be successful.

**Box 12.56.4 Indications for non-operative treatment**

- <3mm articular depression
- Undisplaced fractures stable 0–90 degrees
- Poor bone quality
- Severe osteoarthritis (OA)
- Low demand elderly
- High American Society of Anaesthesiologists (ASA) grade.

Patients treated non-operatively should be allowed touch weight bearing for the first 6 weeks and progression to full weight bearing over the subsequent 6 weeks is allowed provided there is radiographic evidence of fracture healing. Radiographs are required in the first 2 weeks of treatment to check for loss of fracture position. If there is any loss of position, this may necessitate conversion to operative treatment.

**Operative treatment (Box 12.56.5)**

Operative treatment is indicated in unstable fracture patterns with joint surface displacement in excess of 3mm. Operative treatment is indicated in all open fractures, and those associated with significant soft tissue problems (compartment syndrome, ligament injury, common peroneal nerve palsy, and vascular injury).

**Group 1: lateral split, split depression, and central depression fractures**

A single linear anterior paramedian incision is suitable for access. It has the advantage of being used for a subsequent knee arthroplasty should one be required. A subperiosteal exposure of the lateral plateau is readily carried out. This approach allows excellent exposure of the lateral plateau fracture and facilitates reduction of the proximal tibial condyle prior to secure internal fixation. Direct visualization of the joint reduction is best achieved with an anterolateral arthrotomy. A plane is then developed between the capsule and edge of the lateral meniscus. The meniscus is then elevated to expose the plateau by incising the lateral meniscotibial ligaments. Some authors have proposed incising the lateral horn of the meniscus but we prefer to avoid this. A curved anterolateral incision can also be used. The main drawback of this exposure is that the curved portion is not suitable for use if knee arthroplasty is needed and may increase the risk of wound complications at subsequent surgery.

The choice of fixation depends on the fracture pattern and the degree of comminution. Pure split fractures can be fixed with cannulated lag screws, buttress plating, and locking plates. Biomechanical studies have demonstrated that lag screw fixation is usually sufficient in good quality bone for fixation and plating is not generally required. If there is a single large fragment or significant comminution, particularly at the metaphyseal base, then a laterally based buttress plate or antiglide plate should be used. With split depression fractures, the depressed area needs to be elevated and fixed with a buttress plate or periarticular raft. There is usually a subchondral defect once the joint surface is restored to the anatomical position. The addition of bone graft or bone substitutes is often required in addition to fixation to support the joint surface. Bone graft substitutes are a good choice in older patients where autogenous bone graft may be of poor quality.

**Box 12.56.5 Operative techniques**

- **Approach**
  - Lateral—anterior paramedian or curved anterolateral
  - Medial—longitudinal posteromedial
  - Bicondylar—dual incisions
  - MIPO (minimally invasive plate osteosynthesis)

- **Fixation:**
  - Percutaneous screws
  - Raft screws
  - Buttress plates
• Antiglide plates
• Locking plates
• Circular frame

Surgical adjuncts:
• Bone graft and bone graft substitute
• Femoral distractor
• Arthroscopy.

Group 2: medial plateau and oblique fractures

Medial fractures are usually the result of high-energy injuries and frequently have associated soft tissue injuries. Almost all fractures of the medial plateau are unstable and require operative treatment, provided the patient is medically fit. Fractures which contain a predominantly split component, can usually be reduced indirectly with gentle traction or a femoral distractor. If the split is coronal then a posteroomedial approach may be required. A vertical incision is employed starting posteroinferior to the adductor tubercle extending distal to the joint line by 6cm. The skin flaps are raised to expose the fascia. There is no true internervous plane and the saphenous nerve crosses the approach transversely and should be protected as it emerges between gracilis and sartorius muscles. Incise the fascia over the anterior border of the sartorius and retract this muscle posteriorly along with gracilis and semitendinosus. Separate the medial head of gastrocnemius from semimembranosus to expose the posterior tibia. Further blunt dissection beneath the medial head of gastrocnemius is safe and allows access to the posterior tibia as far as the midline. Those with significant depression of the articular surface require open reduction. Fractures of the medial plateau usually have significant shear forces acting on them and as a result lag screws alone are not to provide enough stability. They require a medial buttress plate to counteract the shear forces acting.

Group 3: bicondylar fractures

Previously these fractures were treated with dual medial and lateral plates or by a combination of limited internal fixation and external fixation. Since the advent of locking plates, it is possible to fix the two condyles with 6.5-mm lag screws and stabilize the articular segment to the diaphysis with a lateral or medially placed locking plate. Having screws locked into the plate creates a fixed angle device with enough stability to counteract the forces acting on the contralateral tibial plateau. This obviates the need for a second plate with the additional soft tissue dissection this entails.

Fracture patterns that have dissociation of the metaphysis from the diaphysis, represent the most severe injuries. There is no consensus as to the definitive choice of fixation. In principle, however, they all require articular reconstruction and reconnection of the articular segment back to the tibial shaft. Most surgeons now use either locking plates or fine wire external fixation for these fracture patterns.

The method of fixation is influenced to a large extent by the status of the soft tissues. If the soft tissues are in good condition then a long locking plate after joint surface reconstruction is probably the most popular method of treatment. If the soft tissues are extensively contused or there are fracture blisters then a more cautious approach is necessary. One option is the use of a temporary external fixator spanning the fracture until the soft tissue envelope has recovered and internal fixation can be safely undertaken. The alternative is to use fine wire external fixation as the definitive method of treatment. This may be the only choice if the soft tissue injury is extensive or the bone is of poor quality.

Results

It is difficult to compare the results of different treatments reported in the published literature. There are various reasons for this, including different classification systems and outcome scoring scales being routinely employed. In general, non-displaced fractures and lower-energy fractures such as split, split-depression, and central depression types have a better prognosis. A 20-year follow-up was performed on ten patients who underwent operative fixation. These patients were originally selected for surgery as they had greater than 10 degrees of coronal plane instability in full extension at examination under anaesthesia. Good to excellent results were found in 90% of patients. For the use of limited internal fixation combined with appropriate external support, reports show 90% good or excellent results. The higher energy, more complex fracture patterns present a greater challenge to manage. The Canadian Orthopaedic Trauma Society completed a multicentre, prospective, randomized clinical trial to compare ORIF with percutaneous, limited fixation and application of a circular fixator. The fracture patterns within this series were OTA types C1–3. The follow-up of this group is short term, but at 2 years showed no significant differences with respect to quality of reduction or functional outcome. However, there were a greater number of complications in the internal fixation group and a deep infection rate of 18%. Type C3 fractures treated with medial and lateral plates showed significant residual dysfunction in patients with greater than 2mm articular surface step. This is despite associations with patient age and presence of polytrauma.

Recently there has been increased use of locking plates to treat the more complex fractures, in particular osteoporotic fractures and those with extensive comminution. These devices minimize soft tissue injury by using minimally invasive approaches in conjunction with femoral distractors, K-wires, and percutaneously applied reduction forces to control the major fragments. Results with this technique have shown a union rate of 90% and deep infection rate of 3.7%. However, malalignment has been reported in a significant number of cases. In comparison, dual plate techniques have been shown clinically to have less malalignment and less subsidence in cadaveric experiments. Although locking plates may provide a more biological solution to bicondylar plateau fractures it is clearly important to tailor the appropriate treatment to suit the patient’s individual bony and soft tissue injuries.
Complications (Box 12.56.6)

Complications can occur with any of the described fracture patterns, but are more frequent with the higher energy injuries. Prevention, where possible, is the best treatment but in principle good surgical technique, limited incisions and careful tissue handling will reduce their incidence. The outcome of tibial plateau fractures following a complication is difficult to assess due to the heterogeneous nature of the groups reported in the published literature.

Compartment syndrome

This is not frequent in most plateau fractures but must be considered particularly in higher-energy patterns of bicondylar and medial plateau fractures. The most reliable method of diagnosis is by compartment pressure monitoring. Early fasciotomy to decompress the four compartments of the leg is required. This may influence selection of fixation method. However, it does not preclude using internal fixation with a plate, although difficulty may be encountered when attempting wound closure and use of a gastrocnemius flap is occasionally necessary to cover a plate on the medial or lateral plateau.

Deep vein thrombosis

Incidence of this complication following tibial plateau fractures is reported to be 5–10% and subsequent pulmonary embolus (PE) at 1–2%. Use of anticoagulant prophylaxis, compression pneumatic stockings, and early movement should be used to reduce this complication.

Infection

The incidence of this complication correlates well with the degree of soft tissues compromise and the amount of internal fixation required. Intravenous antibiotics should be used for closed fractures treated by internal fixation. Open fractures require adequate debridement, irrigation, antibiotics, and where appropriate soft tissue coverage within 7 days. Previous treatment strategies using large open approaches to implant metalware produced infection rates up to 80%. Modern techniques place greater emphasis on managing and handling the soft tissue envelope, combined with smaller incisions. This has led to a reduction of infection rates, in high-energy fractures, to approximately 10–18%.

Non-union

The metaphyseal bone of the proximal tibia usually heals without difficulty, resulting in a very low rate of non-union for tibial plateau fractures. When it occurs it is usually with the high-energy fractures and infection must be excluded as a cause. Most of these fractures heal within 6 months. Failure of progression to union at this stage may require revision of fixation with bone grafting of the metaphyseal non-union.

Malunion

Metaphyseal malunion generally occurs as a consequence of malreduction at the time of initial fixation. Loss of fixation leading to articular incongruity occurs if the articular surface is not adequately supported after reduction but may also occur in very osteoporotic bone. The fracture must be stable from 0–80 degrees with either operative or non-operative treatment. Accurate angular alignment is difficult to maintain in bicondylar fracture patterns and fractures with metaphyseal–diaphyseal dissociation. Patients with articular incongruity may develop painful post-traumatic OA at an early stage, often within 2 years of injury. In these circumstances conversion to total knee arthroplasty may be required. Revision implants are usually necessary due to loss of bone on the tibial side.

Reduced range of motion

The majority of knees regain a function range of movement following treatment of these fractures. Range of movement exercises should be commenced as soon as possible, irrespective of the treatment option selected, to try and prevent this problem.
Energy tibial plateau fractures treated surgically have a favourable outcome at 3–5 years. Recovery tends to be slower in patients over 40 years of age and patients can take over a year to rehabilitate. In general there is significant impairment of movement and muscle function after fracture of the tibial plateau and the majority of patients have not fully recovered 1 year after their injury.

**Post-traumatic osteoarthritis**

As a consequence of these fractures there is increased chance of damage to the articular surface that can lead to post-traumatic OA. This chance is increased with bicondylar fractures and those with increased comminution. Approximately one-third of patients will develop radiological changes following this fracture and the degree of arthritis is greater with malalignment of more than 5 degrees.

**Prominent hardware**

Care should be taken to limit the amount of hardware implanted where possible. Prominent screws should be avoided as painful bursae may form over them. In carefully selected patients removal of the prominent metalware can reduce symptoms. Before removing the metalware, other sources of pain such as occult infection, non-union, malunion, neuroma, and arthritis must be ruled out.

### Summary

Tibial plateau fractures are complex problems associated with significant complication related to both the injury and treatment. In order to obtain good results, the associated injury to the soft tissue envelope must be taken into account.

Tibial shaft fractures

DOI: 10.1093/med/9780199550647.003.012057

Summary points

- The tibia is the most commonly fractured long bone
- The orthopaedic surgeon needs to be familiar with all of the management options available in order to effectively manage the simple and complex cases
- Problems associated with the soft tissue envelope are frequently encountered.

Introduction (Box 12.57.1)

The tibia is the most commonly fractured long bone in the body. The majority of tibial shaft fractures result from high-energy road traffic and sports-related injuries. They tend to occur in the young, active, and economically productive population. The average age of the patients in a large published series was 37.2 years. Tibial fractures result in a significant number of hospital admissions and surgical operations. The goal of the treatment is to achieve union of the fracture with minimal complications and to help return the patients to the best possible functional state. The current trend is to treat most displaced tibial fractures by internal fixation.

Surgical anatomy

One-third of the tibia is subcutaneous in its entire length on the anteromedial surface. For this reason, it is more susceptible to open fractures than any other long bone. The posterior tibial artery through its nutrient branch is the main source of endosteal blood supply to the tibia. The source of periosteal blood supply is from the anterior tibial artery. The blood flow through an uninjured tibia is centrifugal. After a fracture, the pressure head reverses to a centripetal flow. The periosteal vessels are therefore an important source of blood supply after displaced fracture of the tibia. The importance of preserving the soft tissue envelope at surgical fixation of the tibia cannot be overemphasized.

The tibial diaphysis is triangular in its cross-section with an anteriorly directed apex. The majority of the diaphyseal medullary canal is round and symmetric, a configuration amenable to intramedullary nailing. The medullary canal has a narrow isthmus in the middle third with a proximal and distal metaphyseal flares. An intramedullary nail used for either proximal or distal fractures has minimal cortical purchase in these locations, which contributes to high rates of malunion when nailing proximal or distal fractures.

The soft tissue envelope covering the tibia is divided by the interosseous membrane and the intermuscular septa into four closed osteofascial compartments (Figure 12.57.1). The anterior compartment contains tibialis anterior, extensor hallucis longus, extensor digitorum communis, and anterior tibial vessels. The deep peroneal nerve also courses through this compartment and supplies an autonomous sensory zone on the dorsum of the foot between the first and second toes. In the proximal third of the anterior compartment, the neurovascular bundle lies on the interosseous membrane and courses more anteriorly as it proceeds distally.
The superficial posterior compartment contains gastrocnemius and soleus muscles and the sural nerve. The deep posterior compartment contains the tibialis posterior, flexor hallucis longus and flexor digitorum, and posterior tibial vessels and nerve. Each compartment contains a nerve with its own autonomous area of supply. Careful assessment of sensations in these autonomous zones may aid in diagnosing involvement of that particular compartment.

The thick interosseous membrane connects the postero-laterally oriented fibula to the tibia. The fibula also articulates with the tibia at the proximal and distal tibiofibular joints. The fibres of the interosseous membrane run downwards and laterally and are torn in major torsional fractures of the tibia and fibula.

The anterior tibial artery enters the anterior compartment at the superior margins of the interosseous membrane and is at risk of injury with proximal tibial fractures and proximal tibiofibular joint dislocations. The common peroneal nerve is also at risk with these fracture patterns, especially with fibular neck fractures. It is also vulnerable to direct blows or undue pressure from cast, splints, or constricting wraps.

The distal third of the tibial shaft has particularly poor soft tissue cover. The majority of the soft tissue in this area is tendinous and thus the extraneous blood supply is minimal. The nutrient artery narrows as it reaches the distal third of the shaft and Anastomoses with the distal metaphyseal endosteal vessels. If a displaced fracture occurs in this region, this small nutrient artery is often damaged resulting in loss of endosteal blood supply downstream from the site of injury. This lack of intramedullary blood supply combined with tenuous soft tissue envelope may account for delayed unions and non-unions, which occur frequently following high-energy distal-third tibial shaft fractures.

### Associated pathology

The tibial shaft fractures are most commonly associated with open wounds and varying degrees of soft tissue injury. The degree and the extent of the soft tissue injury dictate the functional outcome. Fractures that present with high-grade soft tissue injuries, either open or closed, usually result from high-energy trauma. Up to 30% of tibial fractures occur in multiply injured patients. When evaluating these fractures the surgeon should carefully examine and record the neurovascular status of the limb and look for the presence of an associated compartment syndrome. Diligent clinical examination and compartment pressure monitoring in unresponsive or unconscious patients is essential to diagnose this devastating complication.

High-energy tibial fractures may also be associated with ipsilateral knee dislocations or femoral shaft fractures. The so-called ‘floating-knee’ injury (ipsilateral tibial and femoral fractures) can also occur in concert with ligamentous disruption about the knee. In addition, fractures and dislocations about the ankle may also occur in association with tibial shaft fractures, and therefore routine radiographs of the tibia should always include the knee and ankle.

Fractures at the diaphyseal–metaphyseal junction should be carefully evaluated for any extension into the articular surfaces. These fracture lines may be subtle and not readily apparent on standard anteroposterior (AP) and lateral radiographs. Preoperative computed tomography (CT) scanning may be helpful to identify an undisplaced fracture line, and assists in preventing displacement of such occult fracture during surgical intervention.

High-energy tibial shaft fractures are also associated with vascular injury. High index of suspicion is essential, particularly when evaluating tibial fractures in polytrauma patients. Early diagnosis and urgent involvement of vascular surgeon is essential for limb saving.

### Mechanism of injury

Tibial shaft fractures associated with low-energy injury usually have little associated soft tissue injury and the interosseous membrane is intact and provides some degree of inherent stability, which may allow for conservatively managed fractures.

Falls from a great height, direct blows, and motor vehicle-related injuries are high-energy mechanisms, which impart more kinetic energy in producing a fracture. The fracture patterns reflect this energy expenditure and have primarily a transverse orientation that may be accompanied by butterfly fragments or comminution, depending on the magnitude of the bending force. Fractures produced by crushing injuries or high-velocity gunshot projectiles are often the most severe. The fracture patterns are highly comminuted and may be segmental. The soft tissue component of the injury may be vastly underestimated, especially with crushing injuries, which often present as a closed de-gloving type of injury.

The level of the fibular fracture may indicate the type of injury mechanism, i.e. direct injury results in a fracture of both tibia and fibula at the same level, whereas fractures at a different level result from indirect forces or rotation.

‘Stress’ fractures are caused by repetitive stress, particularly in endurance athletes. Stress fracture management should take into consideration the injury site (low risk vs high risk), grade (extent of microdamage accumulation), and the individual’s competitive situation. This separation into two groups is based on the biomechanical environment and natural history of the fracture. The anterior tibial shaft stress fractures are considered high-risk fractures. The undertreatment of high-risk stress fractures can lead to catastrophic bone failure and/or prolonged loss of playing time. Overtreatment of low-risk stress fractures can result in unnecessary loss of physical conditioning and activity.

### Classification

Tibial fractures have been traditionally described in terms of their anatomical location—proximal, mid, or distal thirds. The amount of initial displacement is recorded as a percentage of the diameter of the bone. The fracture pattern is described as spiral, oblique, or transverse with further description of the presence and amount of initial displacement is recorded as a percentage of the diameter of the bone. The fracture pattern is described as spiral,
oblique, or transverse with further description of the presence and extent of comminution, which correlates with absorbed energy and is an indicator of fracture severity.

**Box 12.57.1 Tibial shaft fractures**

- Most commonly fractured long bone
- Most common open fracture among long bones
- Mostly involve young and productive population
- Majority result from road traffic accidents/sports related injuries.

The AO/Orthopaedic Trauma Association (OTA) comprehensive classification system (Figure 12.57.2) is commonly used to classify tibial fractures. This classification scheme does not account for the degree of soft tissue injury.

**Fig. 12.57.2**
AO classification of tibial shaft fractures. Classification is based on the orientation of the primary fracture line, the presence of associated butterfly fractures, and the presence of comminution.

Unstable fractures are less conducive to non-operative management. Severe soft tissue injury, extension into or involvement of either the proximal or distal tibial articular surfaces, 100% initial displacement of the fracture, comminution of more than 50% of the bone circumference, and transverse fracture orientation are all hallmarks of an unstable fracture pattern. The presence of a fibular fracture in association with a tibial fracture at the same level often indicates an unstable injury from a high-energy mechanism (Figure 12.57.3).

**Fig. 12.57.3**
These fractures demonstrate the hallmarks of unstable fracture patterns, which typically will require fixation techniques: A) a segmental tibial fracture with a transverse fibular fracture at the same level as the more distal tibial fracture; B) a short oblique fracture pattern with 100% cent displacement.

Critical review of comparative studies reveals that non-operative treatment of high-energy tibial fractures is associated with high prevalence of malunion, stiffness of the knee and ankle joints, and poor functional outcome. Therefore classification of tibial shaft fractures into stable and unstable types may be more practical and useful when considering treatment options.
Clinical evaluation

History

Determining the mechanism of injury is critical during the initial stages of patient evaluation. A cooperative conscious patient who has had a minor slip-and-fall accident is managed differently from an unconscious victim of a motor vehicle versus pedestrian accident. In the face of a high-energy injury, the examiner will not only focus on the tibial fracture, but will evaluate the patient for other associated injuries.

The time between injury and evaluation is important, especially for fractures associated with open wounds, arterial disruption, and compartment syndromes. The patient’s previous medical history should be noted, in particular conditions causing immunocompromise. Social history including occupation, smoking, drug and alcohol use all affect treatment decisions and the outcome.

Physical examination

High-energy tibial shaft fractures in multiply injured patients should be managed as per Advanced Trauma life support (ATLS®) guidelines. Deformed limbs should be gently splinted in relatively straight alignment. A visual inspection should reveal any obvious open wounds or exposed bone.

Lacerations, puncture wounds, and abrasions should not be probed or rigorously explored. The presence of such wounds in the vicinity of a fracture is considered to be open fracture. The vascular status should be documented by assessing the presence or absence of palpable pedal pulses, capillary refill, skin colour, and skin temperature.

Loss of motor function and sensation to the foot is a sign of nerve injury or significant limb ischemia. Neurological examination should evaluate the tibial and peroneal nerves and limb ischemia should be ruled out as the cause of any neurologic dysfunction.

Compartment syndrome is common in all tibial fractures and should be assessed on a regular basis.

Mangled extremity severity score (MESS) or Ganga Hospital Injury severity score can be used to assess the open tibial shaft fractures. Ganga Hospital Injury severity score has been shown to be more sensitive and specific and help in determining treatment strategies (see Further reading).

Investigations

Imaging

Once the leg is splinted, an AP and lateral radiographs should be obtained for all tibias in which a fracture is suspected. The knee and ankle should be included to detect fracture-dislocations or articular extension.

Cone-down or magnification spot radiographs or CT scans are useful to evaluate subtle fracture lines, callus formation, or stress fractures.

CT scanning has been shown to be useful to determine the adequacy of fracture reduction, including rotational alignment as well as limb length. Additionally, CT imaging has been shown to be useful for those transitional injuries (junction of diaphysis and metaphysis) that present with extension into the articular regions. CT scanning has now replaced plain linear tomography for the routine evaluation of non-unions.

Other studies

If diminished pulses are present, the ankle pressure index has been shown to correlate highly with the presence or absence of arterial disruption. Doppler-assisted blood pressure is obtained at the ankle and brachial arteries. A ratio of ankle to brachial systolic pressure below 0.9 indicates a probable arterial injury.

Arteriography is indicated when arterial disruption is suspected. Direct compartment pressure monitoring is routinely performed, especially when patients are unable to cooperate with the physical examination or where the surgeon has a high index of suspicion.

Diagnostic ultrasound is used to assess the early presence of callus and is predictive of fracture healing in situations where hardware, such as intramedullary nails and complex external fixators, occlude adequate routine radiographic evaluation.

Management

All closed fractures are immobilized initially with an above the knee splint. Appropriate imaging is obtained in order to plan definitive treatment.

Non-operative treatment (Box 12.57.2)

Non operative treatment in the form of casting should be considered in all isolated tibial fractures which are either stable or undisplaced.
Fractures with stable configurations as seen on the initial radiographs merit treatment by closed reduction and application of a long leg cast. Careful and regular follow-up with serial weekly radiographs is essential to detect secondary displacement and angulation within the cast. Any residual angulation can be corrected to an acceptable degree by wedging of the plaster cast. A functional cast brace (patellar tendon bearing cast) and early weight bearing is encouraged when the fracture becomes ‘sticky’.

If wide displacement or significant shortening is seen on initial screening radiographs, it is unlikely that even an anatomical initial reduction will be maintained throughout the course of treatment found that there was no difference between the amount of shortening seen on the initial versus final radiograph in over 80% of cases. There is experimental data to indicate that as the level of deformity approaches the distal one-third of the tibia, even a small degree of malalignment can affect the loading of the ankle joint. Most surgeons strive to achieve alignment with less than 5 degrees of angulation in any plane and 10 degrees of rotation. However, these values for acceptable reduction are not based on any hard data and good long term function has been reported with angulation of up to 10–15 degrees.

Excellent results have been reported with the use of closed reduction, casting, and subsequent functional bracing in over 1000 closed tibial fractures. Initial treatment was with closed reduction and long leg casting. Weight-bearing was permitted in the cast as tolerated. If length and alignment were acceptable and pain and swelling had subsided, patients were then converted to a fracture brace at an average of 3.7 weeks. In 95% of the fractures, the final amount of shortening was up to 12mm (average 4.28mm). Final angular deformity was less than 6 degrees in 90% of patients. In this series, the rate of non-union was less than 1.1%. This form of treatment was recommended for those closed injuries with no more than 15mm of initial shortening or stably reduced transverse fractures (Figure 12.57.4). Tibial fractures with an intact fibula were a relative contraindication to functional bracing because significant varus deformity (more than 5 degrees) was more likely to develop.

A prospective randomized study has compared the results of application of the patellar ligament-bearing cast with those of operative treatment with closed interlocking intramedullary nailing. This study revealed longer healing times and increased residual angular deformity, limb shortening, and disability in the group treated conservatively. Hindfoot stiffness occurred in 15% of the patients treated in casts. Twenty-two per cent of patients in the closed-treatment group eventually underwent operative intervention for failure to maintain adequate reduction.

There are numerous limitations to the treatment with casts and functional braces. Loss of reduction as well as a residual limb length discrepancy is common. Prolonged treatment with a cast may result in excessive stiffness of the knee, ankle, hindfoot, or
all three, which may require extended rehabilitation to regain the patient’s pre-injury level of function. Even with earlier weight-bearing, residual joint stiffness has been reported in approximately 20–30% of patients treated conservatively.

Fractures that are associated with serious soft tissue compromise are not easily treated conservatively. Effective casting or bracing is highly dependent on the ability of the soft tissues to tolerate a well-contoured device. Limb oedema, contusions, abrasions, etc., may inhibit the early application of sufficient external support. Failure and complications of non-operative treatment indicate that there are many tibial fractures that benefit from operative treatment.

Some studies have suggested the benefit of pulsed, low-intensity ultrasound in shortening the time to healing in non-operative treatment.

Operative management

Unstable tibial shaft fractures, fractures with associated ipsilateral lower limb fractures, tibial shaft fractures in multiply injured patients, and fractures extending to either knee or ankle joints generally require surgical stabilization. Open tibial shaft fractures and fractures associated with neurovascular injury or impending compartment syndrome are dealt with emergency surgical management. Surgery should also be considered in fractures where attempts at non-operative management have failed and when secondary displacement and angulation occurs in follow-up radiographs. Occasionally, operative intervention is recommended for non-compliant patients. The goals of operative treatment should be to restore the length and alignment of the limb, stable fixation to allow early mobilization, and rapid return to pre-injury function with no or minimal complications.

Box 12.57.2 Conservative treatment

- Undisplaced or stable tibial fractures without significant soft tissue injury
- Shortening on initial films usually predicts final shortening
- Intact fibula is a relative contraindication because of varus malunion
- Initial long leg cast followed by Sarmiento cast once fracture is ‘sticky’
- Acceptable reduction:
  - Coronal plane <5 degrees
  - Sagittal plane <10 degrees
  - Rotation <10 degrees
  - >50% cortical contact in both AP and lateral views
- Serial wedging of cast may help correct the deformity.

Box 12.57.3 Intramedullary nailing

- Most common operative treatment
- Best for unstable diaphyseal fractures
- Reaming has biomechanical and biological advantages and reduces non-union rates
- Newer-generation nails are effective in metaphyseal fractures.

Intramedullary nailing (Box 12.57.3)

Locked intramedullary nailing has become the ‘gold standard’ treatment for most of the unstable tibial diaphyseal fractures. Interlocking intramedullary nails maintain axial alignment and provide rotational stability. The nails are either statically or dynamically locked depending on fracture configuration. The new-generation intramedullary nails that allow placement of distal locking screws near the end of the nail have helped extend the indications for nailing to metaphyseal fractures even with intra-articular extension (Figure 12.57.6). The current literature indicates high rates of fracture union in closed tibial diaphyseal fracture treated with intramedullary nailing.

Fig. 12.57.6

A) Tibial shaft fracture extending very low into the distal metaphysis. B) Fixed with a newer-generation nail with the distally placed screws. C) Healed fracture with no complications.

Intramedullary nail insertion has traditionally involved the use of a fracture table to effect reduction. The time necessary for a fracture table set-up and correct positioning of the patient may be prohibitive when treating a multiply injured patient. In addition, complications such as nerve palsy and compartment syndrome have been related to the use of excessive traction.

Techniques have been developed to achieve and maintain reduction during intramedullary nailing when operating on a standard radiolucent orthopaedic table. Devices such as the femoral distractor or a temporary external fixator can serve this purpose. Accurate alignment without traction-related complications has been reported with the use of these reduction techniques (Figure 12.57.7).

The correct placement of the entry portal is an important technical consideration. It must be placed centrally in line with the medullary canal. Because of the wide discrepancy in tibial morphology, the centre of the tibial canal may be variable in its relationship to the patella and patellar tendon. The actual insertion site may be located lateral, medial, or directly posterior to the patellar tendon and should be verified with an image intensifier. Failure to place the entry portal centrally will result in varus or valgus malalignment. Entry portal can be placed either on the medial aspect of the patellar tendon or through a transpatellar tendon approach. Anterior knee pain is a common problem following intramedullary nailing with some reports showing an incidence of greater than 50%. In those patients whose work involves kneeling, consideration should be given to alternative methods of treatment. The relationship of the approach to postoperative anterior knee pain has been an area of controversy. However, recent randomized control studies have not demonstrated any correlation between the approach and anterior knee pain.

The major concern with operative management of tibial shaft fractures is the additional disruption of the blood supply caused by the operative procedure itself. Reaming the medullary canal desascularizes the inner two-thirds of the cortex, rendering the endosteal surface of the cortex ischaemic. Devascularization is reduced to one-third when the nail is inserted without reaming. Additional devascularization occurs through the entire cortex at the region of the fracture site. However, the relative avascularity is temporary and the medullary blood vessels regenerate after a relatively short time. Although reaming disrupts the blood flow to the cortex, reaming induces a sixfold increase in the periosteal blood flow. The periosteal blood supply compensates initially for the disruption of the intramedullary blood supply. Disruption of the intramedullary blood supply is usually not a concern for closed injuries that have a competent soft tissue envelope. However, in the treatment of open or high-energy fractures where the soft tissues including the periosteum may be completely disrupted, medullary reaming could further devascularize the fracture site.

Reaming during intramedullary nailing has biomechanical and biological advantages. Reaming allows insertion of a larger-diameter nail hence increasing its load sharing capacity. The biological effect of the increased periosteal vascularity is well known. Moreover, reaming has been shown to have faster rates of union and reduce the incidence of non-union.

Unreamed nailing has the advantage of being less time consuming offers advantages in the emergency setting for stabilizing polytrauma patients. Unreamed nails when used as a definitive method of fixation have a reduced incidence of reoperations, superficial infections, and malunions, when compared with external fixators.

Reaming allows the insertion of a bigger nail and locking bolts. Fatigue failure of small-diameter unreamed nails and/or interlocking screws has been reported in many series if union of the fracture is not achieved early. However failure of interlocking screws in some cases may facilitate fracture healing by autodynamization (Figure 12.57.8).
A recent large multicentre randomized study involving 1226 patients has compared reamed versus unreamed intramedullary nails. The study suggested that reamed nails offer a benefit in closed fractures with regard to further events (surgical intervention or autodynamization) within 1 year. Most of the difference was attributed to an excess of dynamizations (both surgical and autodynamization) in the unreamed group. A non-significant increase in number of postoperative events was noted in open fractures treated with a reamed nail. The authors note that overall the number of events for this study was less than previous randomized controlled trials. Previous grade II evidence, randomized controlled trials have shown that reamed nails have an advantage over unreamed nails with regard to rate of union and non-union.

Compartment syndrome has been reported following intramedullary nailing of the tibia. It is thought to be multifactorial and could be associated with excessive traction on the limb, limb tourniquet, and extravasation of the reamings. The type of anaesthesia and the postoperative analgesic regimen has been attributed to a delay in diagnosis of compartment syndrome.

The indications for intramedullary nailing have been extended to include very proximal and distal metaphyseal fractures. Nailing of proximal one-third tibial metaphyseal fractures are fraught with potential complications, primarily valgus malunion, anterior translation, and apex anterior deformities of the proximal segment. Review of proximal shaft fractures treated with intramedullary nailing found that 84% of these patients had residual angulation of more than 5 degrees and that 25% lost proximal fixation primarily related to the placement of a single proximal locking screw. Non-union rates have been reported as high as 26%.

Surgical errors consisting of a medialized nail entry portal and a posterior and laterally directed nail insertion angle, all contribute to the malalignment. Suggested techniques for the successful nailing of proximal shaft fractures include a lateral entry portal, use of Poller’s ‘blocking screws’ and adjunctive antiglide plates located at the level of the fracture apex. This small plate serves to prevent translation and apex anterior angulation of the proximal fragment (Figure 12.57.9).

Contiguous ipsilateral distal intra-articular fracture extension and non-contiguous ipsilateral ankle fractures in concert with diaphyseal injuries can be successfully treated with intramedullary nailing techniques. Distal articular extension displaced less than 5mm, may be treated with mini open reduction and internal fixation of the articular component followed by intramedullary nailing. Non-contiguous ipsilateral ankle fractures may be treated with fixation of the ankle prior to or after insertion of the intramedullary nail. Technically, it is important to keep the articular lag screws in subchondral bone to allow room for nail insertion. It is also important to secure alignment of the entire fracture construct prior to nail insertion using a two-pin fixator, a femoral distractor, or calcaneal pin fraction (Fig. 10).
Plate fixation (Box 12.57.4)

The traditional open reduction and internal fixation with plates and screws is not a preferred option for high-energy tibial shaft fractures. This method of fixation requires extensive exposure and additional soft tissue stripping resulting in secondary devascularization of the soft tissues and fracture fragments. Reports in the literature quote high rates of complications such as wound break down, infection, aseptic and septic non-union of the fracture.

With the advent of minimally invasive plate osteosynthesis (MIPO) using locking plates, plating has regained its popularity. This technique utilizes the principles of biological fixation. The fracture is realigned in all planes utilizing indirect reduction techniques. The adequacy of reduction and the plate position are confirmed by image intensifier. Depending upon the personality of the fracture the definitive fixation is planned. In simpler fracture configuration (AO/OTA 32A and B) primary fracture fixation is carried out by using lag screws through small incisions. A precontoured plate is then tunnelled extraperiostally along the medial aspect of the tibia through a small skin incision, distant from the zone of injury. This plate is then fixed with locking screws percutaneously through stab incisions and acts as a neutralization device. In complex fractures (AO/OTA 32C) only MIPO plating is performed without any attempt at direct reduction of the fracture fragments. Here the plate acts as a bridge bypassing the area of comminution whilst stabilizing the fracture (Figure 12.57.11). The MIPO technique can also be carried out with usage of low-profile standard plates in non-osteoporotic bones. The main advantage of MIPO is that the fracture haematoma and the soft tissue envelope around the fracture are not disturbed. This method of fixation results in secondary bone healing by callus response. Review of recent literature confirms the efficacy of this fixation method and encourages its usage. A recent comparative study has shown the that plate fixation in distal tibial shaft fractures (4–11cm above the plafond) produced better rate of union as compared to intramedullary nails. Complications such as delayed union, malunion, and secondary procedures were more frequent after nailing.

Fig. 12.57.11
A) Comminuted distal third tibial fracture. B) Fixed wth MIPO technique. C) Leg with healed incision wounds resulting from MIPO technique.

Indications for plate osteosynthesis has also extended to proximal tibial shaft fractures with or without intra-articular extension with the advent of angular stable device such as less invasive stabilization system (LISS).

External fixation (Box 12.57.5)

External fixation is carried out for both emergent and definitive management of tibial shaft fractures. In the initial management of open tibial fractures and in tibial fractures associated with polytrauma, skeletal stabilization is achieved in a rapid manner by using an external fixator assembly. This temporizing device is assembled with use of multiple Schanz pins inserted into the major fragments preferably outside the zone of injury. Such fixation allows wound care and subsequent reconstruction of the soft tissue envelope in open fractures. External fixation in multiply injured patients allows early mobilization and better nursing care and shown to have reduced mortality and morbidity. These devices can be exchanged to intramedullary nails within 2 weeks of index operation (Figure 12.57.12).

Fig. 12.57.12
A) Clinical photograph showing monolateral external fixator used for distal third tibial shaft fracture. Note the ‘near- far’ pin placement. B) Clinical photograph showing the hybrid external fixator used for open tibial shaft fracture.

The use of an intramedullary nail following failed external fixation has demonstrated variable results. In general, if the external fixator is in place for less than 1–2 weeks, conversion to an intramedullary nail appears to have a low rate of associated infection. However, as the time period of external fixation increases, the risk of infection with immediate exchange to an intramedullary nail increases dramatically. Infection rates as high as 50% have been reported for patients who have had this immediate exchange. If this type of treatment is contemplated, patients who have a latency period of more than 1 month following removal of the external fixator should be considered.
fixator and prior to intramedullary nailing have a marked decrease in their rates of infection as well as increased rates of union. Although a delay of several weeks or months between fixator removal and nailing may decrease the risk of infection, there remains some elevated risk. Deep infection rates of 17% have been demonstrated in open tibial fractures treated with secondary intramedullary nailing (IMN) after external fixation (EF). All deep infections occurred in Gustilo type III fractures (22.6%, 7/31). They concluded that early skin closure within 1 week is the most important factor in preventing deep infections when treating open tibial fractures with secondary IMN after EF.

The external fixation techniques have been successfully used for definitive management of closed tibial fractures. External fixation does not cause additional disruption of the soft tissue envelope or the vascularity of the fracture fragments or other osseous structures. Axial and rotational stability can be achieved by using ring fixators, monoplanar or multiplanar external fixator constructs. In high-energy fractures, particularly with fractures associated with bone loss, an external fixator is used not only to acutely stabilize the fracture but also to aid in fracture union and bone transportation in restoring bone loss (Figure 12.57.13).

Fig. 12.57.10
A) Distal third shaft fracture with intra-articular extension and fracture through the posterior malleolus. B) CT scan through the distal tibial region reveals the posterior malleolus fracture. C) Lag screws are placed in a subchondral location prior to nail insertion in order to prevent displacement of these fracture lines during eventual nail seating. D), E) Initial postoperative radiographs reveal excellent position of the rod with no displacement of the intra-articular fracture lines.

Fig. 12.57.13
A) Complex open tibia fracture with segmental bone loss. B), C) A circular small-wire external fixator facilitates stabilization and eventual bone transport through a proximal tibial corticotomy. Following distal docking, this region underwent a small bone graft to facilitate consolidation in this region. D) After frame removal, the segmental deficit has been bridged and leg length discrepancy resolved.

With other fracture fixation methods, additional bracing or casting is often necessary to maintain a stable construct. With rigid internal fixation, primary bone healing demands that weight-bearing be delayed until full reconstitution of the cortex has been completed. Weight-bearing stimulates fracture healing. A major advantage of using adjustable external fixators is the ability to load the limb actively. Even in the most comminuted fractures, patients can begin at least partial weight bearing immediately after surgery without any supplementary casts or braces. Most frames allow for dynamization restoring cortical contact, achieving a more stable fracture construct, and decreasing the pinbone stresses. By subsequently disassembling external fixation frames, progressive dynamization leads to a less stiff frame, which facilitates secondary callus formation and bone healing.

Box 12.57.4 Plating
- Regained popularity with advent of MIPO
- Indicated for some metaphyseal fractures without severe soft tissue injury
- Good results in translated non-unions (not amenable to nailing) and after failed external fixation
- Good results in distal tibial metaphyseal fractures with MIPO.
Box 12.57.5 External fixation

- Indicated in severe open fractures
- Temporary or definitive management
- Advantage of no additional soft tissue damage
- Pin track infection is the most common complication
- Can be exchanged to nail within 2 weeks
- Ring or hybrid fixator used in septic/aseptic non-union, malunion, and for bone transportation in case of bone loss.

In general, closed fractures heal with external fixation on average within 4 months. The rates of non-union have been reported as high as 5% for closed fractures. In most series, it was felt that early dynamization or gradual frame disassembly should be performed in an effort to load the fracture and promote secondary callus formation. The most common complication was minor pin tract infection, which is seen in the majority of patients. Major pin-site infections requiring secondary surgical procedures were noted to be less than 5% in most series and none appeared to have led to any serious sequelae. Most authors agree that although external fixation requires closer patient monitoring and pin care, external fixation is a safe and reliable device for treating tibial shaft fractures.

Open tibial shaft fractures (Box 12.57.6)

The tibial shaft is the most common site for open fractures of the long bones. Most of the open tibial shaft fractures occur in young and active population as a result of high-energy injury and are particularly associated with road traffic collisions. The standard treatment consists of: early debridement of the open wound; thorough surgical toilet; antibiotics; stabilization of the fracture; adequate and early soft tissue coverage; successful reconstruction of the limb and subsequent fracture healing (see Chapter 12.7).

It has been shown that definitive stabilization by reamed intramedullary nail for low-grade open fractures produces satisfactory outcomes. The infection rate has been shown to be less than 3% for grade I open fractures. However, when reamed intramedullary nailing was performed on severe open fractures (grade IIIb), the rate of infection has previously been reported as high as 23%. Open tibial fractures stabilized with unreamed interlocking nails have reported rates of union greater than 96%, a low rate of malunion, and rates of infection in the range of 4–8% for grade IIIb fractures. More recent studies have shown that results of reamed nailing for grade IIIb fractures are comparable to unreamed nails in terms of union rates and complications.

Box 12.57.6 Open fractures

- Early debridement, skeletal fixation, and soft tissue cover
- Adequacy rather than time of debridement influences infection rates
- Primary closure is debatable. Closure within 1 week reduce infection rates
- Contraindications to primary closure:
  - Skin loss primarily or during debridement
  - Gross contamination with faeces, dirt, stagnant water
  - Farm-related injuries, fresh water-related accidents
  - Delay in antibiotic initiation >12h
  - Extensive tissue necrosis at debridement
- Secondary procedures frequently necessary.

Randomized prospective studies have been performed comparing the results of unreamed interlocking nails with external fixation for the treatment of open fractures. All of these studies demonstrated similar rates of infection and non-union for both treatment modalities, but a significantly higher prevalence of malunion with external fixation. The major advantage to intramedullary nailing is that it facilitates soft-tissue procedures, and delayed bone and skin grafting without the hindrance of an external fixation device. Recent evidence supports the usage of unreamed solid nails in stabilizing open grade IIIb and IIIc fractures.

External fixation is still considered a good choice for highly contaminated open fractures or fractures associated with prolonged delay prior to operative intervention (Figure 12.57.14). Rates of infection with external fixation for grade III injuries has ranged from 4 –7%. This relatively low rate of infection has been offset by the increased rate of malunion that has been reported when treating open tibial shaft fractures to completion with an external fixator.
When the tibial shaft fractures are treated conservatively, early weight bearing is encouraged. As soon as the patient is comfortable in the long leg cast and the swelling has subsided, conversion to a patellar tendon bearing cast is usually indicated. This will occur at 3–6 weeks. Following a short period of patellar tendon-bearing cast immobilization, the patient should be converted to a total-contact orthoses and full weight bearing encouraged.

The management of fractures treated with intramedullary nails can be varied depending on the fracture pattern, and configuration and morphology of the nail used. In general, reamed medullary nails are larger diameter and have bigger locking screws. When large locking screws are used the patient may be considered for early weight bearing. Regardless of the size of the nail and screws, if the fracture pattern is axially stable, the patient is allowed to progress to, at least, 50% weight bearing immediately after surgery. For fracture patterns with comminution or segmental injuries, which are axially unstable, then non-weight bearing should be maintained for at least 6 weeks. For the axially stable fracture patterns, full weight bearing can be initiated once progressive callus is seen on radiograph. For the axially unstable injuries, delaying full weight bearing for at least 3 months may need to be considered. Throughout the course of treatment, fracture healing should be monitored in order to avoid fatigue failure of the nail or locking bolts, especially for small nails. Early intervention is necessary to avoid these complications.

For tibial fractures treated with plate fixation, patients are usually immobilized either in a removable splint or cast until the incision heals. Soft tissue concerns are paramount in the early postoperative period to ensure that the wound heals without complications. Because the plate is a load-bearing device, weight bearing must be delayed. For the first 6–8 weeks, patients should be maintained as strict non-weight bearing, and if patient compliance is an issue, then long leg casting should be maintained with the knee flexed in order to prevent unrestricted weight-bearing. If the patient is reliable, then toe-touch non-weight bearing can be initiated immediately. In approximately 6–8 weeks when early cortical bridging and diminution of the fracture line is seen on radiograph, the patient can be advanced to 50% partial weight bearing. This may sometimes need to be augmented with a patellar tendon bearing orthosis or short-leg walking cast. When recorticalization is complete, the patient may progress to full unrestricted weight-bearing at approximately 4–6 months.

Postoperative management of external fixation is often problematic with respect to the management of the pin sites. In the case of circular small-wire external fixators for extra-articular injuries, full weight bearing may be initiated immediately after surgery. For most monolateral frames with dynamization capabilities, once early callus formation is noted the frames can be dynamized or sequentially disassembled to transfer more of the load to the fracture site itself and promote axial micromotion to facilitate healing. Following the removal of the external fixation device, a short period of orthotic management is required.

Regardless of the methodology of fracture fixation utilized, physical therapy should be initiated immediately to maintain knee and ankle range of motion. In cases of severe soft tissue injury and open fractures treated with external fixation, the foot should often be included in the fixation frame to avoid progressive equinus contracture due to the long period of non-weight bearing status necessary. Physical therapy should concentrate on maintaining a plantigrade foot. This is best established by allowing the patient to place the foot on the ground. This allows the foot to be placed in a plantigrade position while still avoiding full loading activities.

Complications (Box 12.57.7)

Complications of tibial shaft fractures include compartment syndrome, non-union, malunion, and infection. Arrest of the bony repair process with the formation of interweaving fibrous or cartilaginous tissue is defined as a non-union. The usual time frame for this diagnosis is 6–8 months. Non-union most commonly occurs following open tibial shaft fractures, which have been treated with external fixation.
Secondary procedures have been advocated to promote union and avoid hardware failure in cases where delayed healing is likely. Nail dynamization, exchanged reamed nailing, open bone grafting, and fibular osteotomy all have been used alone or in combination to promote union (Figure 12.57.15).

Fig. 12.57.15

A) This open fracture progressed to a nonunion after being treated with a statically locked unreamed nail. B) Following exchange nailing with a reamed nail of a larger diameter and a fibular osteotomy, complete healing occurred.

Exchange nailing is a standard method of treatment for aseptic non-union. Progressive reaming until bone is seen on the flute of the reamer and exchange to a larger-diameter nail is recommended. Such nailing offers the unique biomechanical advantages of an intramedullary device, together with the osteoinductive stimulus of the by-products of reaming. A larger diameter nail also allows early weight-bearing and active rehabilitation. Following intervention it can be expected that 90% of non-unions will be united at an average of 3.5 months.

There is no consensus about the definition of malunion. The accepted arbitrary values for tibial shaft malunion are more than 10 degrees of angulation in sagittal plane, more than 5 degrees in coronal plane, and greater than 10 degrees of rotational malalignment. However, long-term follow-up studies have failed to establish any correlation between malunion and development of subsequent arthritis of ankle or subtalar joints. Established malunion is treated by corrective osteotomy along with refixation either by intramedullary or extramedullary devices.

Post-traumatic osteomyelitis occurs either after open fractures or surgically treated closed fractures. Treatment of an infected fracture utilizes a staged reconstruction protocol. If there is wound breakdown along with superficial infection, implants should be left in place in order to provide a stable fracture configuration. If the implant provides no stability at the time of debridement, all hardware should be removed. Furthermore, at debridement, all necrotic bone should be excised. Stabilization is necessary and is usually provided by external fixation. Serial debridements may be necessary to obtain a biologically sound wound. Dead-space is managed by using antibiotic beads or open-wound packing. Eventual soft tissue closure may be achieved with rotational flap or free-flap or coverage. Antibiotics directed at deep culture specimens should be administered for 4–6 weeks. Following resolution of the infection and healing of the soft tissues, delayed skeletal reconstruction is performed.

**Overview**

There are several well-accepted methods of treatment of tibial fractures. Orthopaedic surgeons tend to be preoccupied with the mechanics of fracture management and specifically with the implants to be utilized. However, there is no substitute for a thorough understanding of the so-called ‘personality’ of the fracture to help determine the best choice in treatment. Conservative management utilizing casts and functional orthoses is indicated for minimally displaced and axially stable fractures. Prospective studies indicate that intramedullary nailing with and without reaming both produce excellent results with high rates of union and low rates of occult infection. Reamed nailing has been shown to have shorter times to union and lower non union rates. Unstable closed fractures and open grades I, II, and IIIA fractures can be safely treated with reamed nails. External fixation, reamed and unreamed nails can be considered in grade IIIB fractures.

**Box 12.57.7 Compartment syndrome**

- Maintain high index of suspicion
- Increased incidence associated with traction and reaming
- Extra vigilance in unconscious and unresponsive patients
- Look for serial rise in pressure
- Avoid postoperative patient-controlled analgesia to prevent delays in diagnosis
Use long two-incision approach for release.

High-energy tibial shaft fractures pose a therapeutic challenge to the treating health-care professionals. These injuries are often seen in the context of polytrauma. Astute decision-making, collaboration with plastic surgeons, timely surgical intervention, and respect for soft tissue envelope of the leg will result in successful functional outcome. The recent development of minimally invasive fracture surgery will no doubt have a positive impact on the management of the tibial shaft fractures.

**Further reading**

Tibial plafond fractures

Summary points

- Tibial plafond fractures demand respect, largely due to the fragile soft tissue envelope that surrounds the distal tibia
- Careful preoperative planning followed by meticulous operative handling of the soft tissues is required to avoid devastating complications.

Incidence

Fractures of the tibial plafond or pilon fractures involve the distal tibial articular surface. They are caused at least in part by axial loading. Tibial plafond fractures account for 1–10% of all lower extremity fractures and are more commonly seen in males than females. They occur over a broad age range, but are uncommon in children and the elderly. The average age is 35–40 years.

Anatomy

The distal tibial articular surface is rectangular in shape and forms the ceiling or plafond of the ankle joint. The cancellous bone of the distal tibial metaphysis is organized in dense trabeculae that are oriented at right angles to the articular surface (Figure 12.58.1).

Fig. 12.58.1
The trabeculae of the distal tibia are very dense within 2 to 3 cm of the articular surface. They run vertically from the articular surface before blending into thicker cortical bone. This arrangement allows the distal tibia to withstand great loads in daily activities and can affect fixation of fractures of the distal tibia.

The distal tibia soft tissue sleeve is tenuous. The anteromedial aspect is covered by only periosteum, a thin layer of subcutaneous tissue, and skin. The anterolateral aspect is covered by the tendons of the anterior compartment musculature and the anterior neurovascular bundle (Figure 12.58.2). The anterior tibial artery supplies the anterior aspect of the lower leg, but because of the lack of underlying muscle there are few perforating arteries to supply the skin. The artery’s subcutaneous position makes it prone to injury, which can further compromise perfusion of the skin. ‘Watershed’ areas between the anterior tibial, posterior tibial and peroneal arteries add to the delicate nature of this soft tissue envelope.

Fig. 12.58.2
A cross-sectional diagram of the distal leg at a level just proximal to the ankle joint reveals the thin soft tissue envelope around...
the anterior aspect of the distal tibia.

The ligaments of the ankle joint affect the way the distal tibia breaks in plafond fractures. The anterior and posterior tibiofibular ligaments are stout ligaments and typically retain their attachments to both the distal fibula and tibial articular surface despite fractures to either one or both of these bones. The fracture lines through the distal tibial articular surface may result in a large anterolateral fragment, also known as the Chaput fragment, and/or a posterolateral fragment either of which can be attached to the distal fibula via intact ligaments (Figure 12.58.3). Therefore, if the fibula is intact, the fragments connected by the tibiofibular ligaments provide a cornerstone to which the rest of the tibial articular surface can be reconstructed. Conversely, if the fibula is fractured, fibular reduction will yield a provisional reduction of the lateral side of the distal tibia via ligamentotaxis. Unfortunately these fragments may be relatively small and of little use.

Fig. 12.58.3
Anteroposterior and axial diagrams depicting the ligamentous attachments between the distal fibula and tibia.

**Associated injuries**

Associated injuries are common because of the high-energy nature of these fractures. Concomitant fractures occur in 15–52% of cases. A high percentage of these fractures are caused by compression or axial load including contralateral calcaneus or tibial plafond fractures, tibial plateau, lumbar vertebrae, and acetabular and pelvic fractures. Chondral abrasions are very common. Injuries to other systems are not uncommon, occurring in up to 25% of cases, and include head, chest, and abdominal injuries.

Approximately 20% of fractures of the tibial plafond are associated with an open soft tissue injury. Closed tibial plafond fractures also have a significant soft tissue injury; fracture blisters are commonly seen (25% incidence in one series). Neurovascular compromise and compartment syndrome although rare, can occur.

**Mechanism (Box 12.58.1)**

Tibial plafond fractures have a different mechanism of injury than malleolar fractures. At least some component of axial loading fractures the distal tibial articular surface, producing comminution or impaction. The vast majority of tibial plafond fractures occur in motor vehicle accidents, falls from a height, direct trauma, and water or snow skiing accidents. The advent of airbags in motor vehicles protects occupants from deadly chest and abdominal trauma so that they survive accidents which produce high-energy lower-extremity trauma, leading to an increase in the incidence of tibial plafond fractures.

Axial compression fractures shatter all or part of the articular surface depending on the position of the foot at the time of impact. A dorsiflexed foot may result in fracture of only the anterior portion of the plafond, whereas in plantar flexion the posterior portion will fracture. The entire plafond may be injured if the foot is in neutral position (Figure 12.58.4).

**Box 12.58.1 Mechanism of tibial plafond fractures**

- Motor vehicle accidents and falls from a height account for the majority
- The mechanism dictates injury severity, which increases with the percentage of axial load
- Axial loading fractures have severe associated soft tissue injury and fracture comminution.
Low-energy fractures which are primarily rotational may extend into the tibial articular surface. These fractures are radiographically more similar to malleolar fractures and are differentiated by the presence of articular comminution or impaction of the plafond produced by a component of axial compression. More severe axial compressive fractures may be associated with a degree of rotation causing a dislocation of the talus medially, laterally, or posteriorly that typically occurs with rotational injuries. High-energy fractures which occur after a rapid loading rate result in marked comminution of bone and open wounds or closed fractures with severe soft tissue injury. The distal tibia literally explodes (Figure 12.58.5).

Fig. 12.58.5
Schematic stress–strain diagrams illustrate that the viscoelastic nature of bone leads to greater energy release after rapid axial load than slow rotational load.

Classification

The AO/Orthopaedic Trauma Association (OTA) classification 2007 is the most complete and extensive classification of different subtypes of fractures of the plafond. This classification divides fractures of the distal tibia into groups A, B, and C, and then further subdivides them based on the amount of comminution (Figure 12.58.6). Group A consists of extra-articular fractures, group B of fractures involving part of the articular surface, and group C of fractures involving the entire articular surface. It is primarily the B3, C2, and C3 fracture types that are high-energy axial loading fractures and satisfy all definitions of a plafond fracture. B1, B2, and C1 fractures associated with marginal impaction can be considered to be plafond fractures. When combined with an assessment of the soft tissue injury, this classification may prove to be an aid to prognosis and allow comparison between patient groups.
The AO/OTA classification of distal tibia fractures. Type A fractures are extra-articular fractures of the distal tibia and are therefore not plafond fractures. Type B fractures involve only a portion of the articular surface, while the remaining articular surface has continuity with the tibial shaft. Type C fractures involve the entire articular surface and have increasing severity from group C1 to C3. http://www.ota.org/compendium/compendium.html

Unfortunately, both this classification system and the Rüedi–Allgower system have been shown to have poor interobserver reliability and intraobserver reproducibility.

Treating these injuries requires accurate assessment of the soft tissue injury which is even more difficult to categorize accurately and reproducibly. Open fractures are classified based on the size of the wound using the criteria of Gustilo and Anderson, which do not address other components of the soft tissue injury or the majority of the fractures which are closed. The Tscherne–Goetzen classification assesses the grade and severity of the soft tissue injury in closed fractures. Although it is frequently cited in the literature, due to difficulties of clinical application, it has rarely been implemented in studies of plafond fractures. In addition, the full extent of swelling and local contusion can only be appreciated after several hours to days.

Clinical evaluation

History

The mechanism of injury provides insight into the amount of energy imparted to the bone and soft tissue at the time of fracture, which is crucial for surgical planning and for advising the patient on prognosis. In open fractures, assessing the environment in which the injury occurred will guide antibiotic treatment.

Examination

The neurological and vascular status of the foot must be evaluated. Absent pulses should be managed by realignment of the extremity and reassessment. Provisional splinting with the extremity aligned prevents further soft tissue trauma. Open wounds are inspected to determine their extent and evaluated for gross contamination. The condition of the skin, amount of swelling, and the presence of fracture blisters must be noted at initial evaluation as well as prior to surgical intervention.

Fracture blisters are common and can be divided into two types: clear-fluid filled and blood-filled. Histologically, both types are disruptions at the dermoepidermal junction, but the blood-filled blisters signify greater injury and have been associated with wound-healing complications when incisions are made through them (Figure 12.58.7).

Investigation

Fracture blisters are indicative of the severe soft tissue injury incurred in many tibial plafond fractures. There are blood-filled and clear-fluid-filled types. A) A single clear fluid-filled blister. B) Two blood-filled blisters and a single clear-fluid-filled blister.
Standard imaging includes anteroposterior, lateral, and mortise views of the ankle. Repeat radiographs with the limb provisionally reduced provide useful information and should routinely be obtained if the initial radiographs show the talus to be widely displaced. Proximal extension of the fracture or suspicion of more proximal injury mandates that full-length tibia and fibula radiographs be obtained. Some surgeons find views of the contralateral ankle helpful as a template for preoperative planning. Axial computed tomography (CT) scanning helps to define the severity of the injury and aids with surgical planning. The axial plane of the CT scan delineates the size and orientation of the articular fragments. This knowledge is crucial, especially for the less invasive approaches to articular reduction, where limited incisions are placed directly over fracture lines and implants are often applied percutaneously to limit the amount of soft tissue stripping. Coronal and sagittal reconstructions further delineate the fracture anatomy and assist in preoperative planning (Figure 12.58.8).

A CT scan accurately depicts the major fracture lines and is an invaluable aid in preoperative planning as illustrated in this single coronal cut.

| Management (Box 12.58.2) |

**Initial**

Tibial plafond fractures are initially managed by provisional reduction, splinting, and elevation to minimize further soft tissue injury. A spanning external fixator with or without fibular fixation is used to maintain length and provisional reduction, and has been used as a means of portable traction prior to definitive treatment. This has the advantage of permitting mobilization. In patients with multiple injuries, open wounds, or compartment syndrome, application of a provisional spanning external fixator should always be part of the initial management.

**Non-operative**

Casting or splinting has generally been reserved for non-displaced fractures or as a treatment of default, when associated injuries or the severity of the fracture and soft tissue injury precluded any type of operative intervention.

| Box 12.58.2 Treatment of tibial plafond fractures |

- Soft tissues are the most important
- The complications of treatment are frequent and may be severe
- Optimal current treatment is controversial
- Internal and external fixation techniques are both utilized
- External fixation techniques decrease complication rate
- Temporary spanning external fixation allows soft tissue recovery
- Plating through limited approaches for some fracture patterns.

**Open reduction and internal fixation**

Current fixation of tibial plafond fractures by open reduction and internal fixation can be traced to the AO–ASIF group and their philosophy of obtaining anatomical reduction through wide operative approaches followed by rigid internal fixation to allow for early mobilization. Rüedi and Allgower reported good results with this technique and their method was widely adopted as the ideal form of treatment for this fracture type. A four-step protocol for open reduction and internal fixation was described (Figure 12.58.9):
- Reconstruct the fibula to restore length and to reduce articular fragments still attached to the distal fibula by intact ligaments
- Reconstruct the joint surface and obtain provisional fixation
- Apply cancellous bone graft to the metaphyseal defect
- Use a medial or anterior buttress plate on the distal tibia for definitive fixation.

Since the publication of Rüedi and Allgower’s work, the technique for open reduction has been modified, but the four basic steps or tenets have remained unchanged. The modifications have centred around atraumatic soft tissue technique to avoid skin slough and wound breakdown. Delaying surgery for 7–21 days avoids the time period where interstitial oedema, tense swelling, and tissue ischaemia are most likely to lead to difficult wound closures and subsequent breakdown and infection. This may be the single most important principal that has decreased what was an unacceptably high complication rate. Fracture blisters are unroofed and sterile dressings used, and definitive surgery is delayed until it is clear that swelling is receding. Length and alignment are maintained with temporary joint spanning external fixation. This allows patient mobilization and facilitates subsequent joint reconstruction. The classic surgical approach is through two incisions, one lateral incision paralleling the posterior aspect of the fibula, and an anterior incision over the tibia that curves medially in its distal aspect. Flaps in the subcutaneous layer should not be elevated. If the paratenon of the anterior tibial tendon can be preserved a skin graft can be used, preventing a tight closure. Incisions directly over the anteromedial tibia are through poorly vascularized and damaged skin and may be directly over a location chosen for implant placement. A minimum of 7–12cm between the medial and lateral incisions has been recommended to retain the vascularity of the skin flap. Intraoperative use of a femoral distractor and indirect reduction techniques decrease the amount of stripping required to obtain reduction. The use of a precontoured plate assists in both reducing and internally fixing the fracture through more limited approaches. The wound closes more easily if small, low-profile implants are used.

Alternate approaches have been described and are now frequently used. The best approach is based on the fracture pattern and surgeon preference. The anterolateral tibia can be accessed through a lateral or anterolateral approach and specially contoured plates are now available which have been designed for the anterolateral tibia. A posterolateral approach has been described and may have particular utility for posterior fracture patterns. This approach has a significant complication rate including infections and non-unions and it is recommended that it is not used for all fracture patterns. Percutaneous plating has been reported for pilon fractures. The easiest access to the tibia for percutaneous plating is the anteromedial surface. Through a small incision over the medial malleolus the plate is slid subcutaneously and fixed with proximal screws placed through stab wounds. A high secondary intervention rate has been reported indicated that limited approach plating does not guarantee healing in all these fractures.
External fixation

Several methods of definitive external fixation have been advocated to decrease the complications associated with plates. These techniques all use one or more of three methods to reduce wound complications: limited surgical approaches to the injured area; limiting bulky internal implants; or stabilization that bridges the area of soft tissue injury. There are a variety of different frames and application techniques.

A fixator body spanning the ankle may be constructed using any of several different components and frame constructs including medial monolateral frames, delta frames, and small pin circular fixators. One technique spans the ankle but preserves ankle motion through an articulated hinge. These frames are applied as the first step in the procedure, distracted and the provisional reduction is assessed with fluoroscopic image intensification. The articular surface is reduced using percutaneous and indirect techniques. The fracture fragments are stabilized with small fragment or cannulated screws, often placed percutaneously. Plates are never used; the fixator provides axial stability. Grafting is rarely utilized.

Postoperatively the hinge is initially locked, but can be released during the postoperative course so the ankle moves with the fixator still in place. One study showed no advantage of early movement through the hinge over a rigidly locked hinge for 8 weeks. Partial weight bearing usually begins by 4-6 weeks postinjury. The average time until the frame is removed is 3 months.

External fixation which does not cross the ankle must obtain purchase in the bottom of the tibia. A variety of frame constructs have been utilized, most of which use tensioned wires attached to a ring for distal fixation. The ankle is free which preserves the possibility for ankle movements. The fibula, if broken, is stabilized with a one-third tubular plate and lag screws through a posterolateral incision. Through an incision over the major fracture line the articular surface is reduced and secured with lag screws. The tensioned wire and ring construct is connected to a fixator body which spans the fracture and connects to the diaphysis with standard 5.0-mm half pins. A similar technique has been described utilizing pin fixators. The Ilizarov technique has frame modularity that allows the foot to be immobilized with a foot ring that can be removed at a time post injury dictated by the injury and other factors. Satisfactory results have been reported by many authors.

The most comminuted fractures and partial articular fractures are not amenable to this technique, since stable fixation of the distal tibia is not possible.

Postoperative management

The ankle should be splinted in the neutral position. The length of time for non-weight bearing must be tailored to the individual, the type of fixation, the characteristics of the fracture, and the personality of the patient.

Results (Box 12.58.3)

Interpreting the results of treatment of tibial plafond fractures is difficult at best. Recent studies incorporate patient perception of their outcome and have utilized validated outcome measuring tools. These studies have shown that these injuries have a profound effect on patient’s general health status and result in long-term ankle pain and dysfunction. These results have been found in patients treated with plates, external fixators, and with both plates and fixators. Patients in the second 5 years after their injury still have decreased general health status. Better outcomes have been found in patients with college education and poorer outcomes in work related injuries.

Box 12.58.3 Outcome of tibial plafond fractures

♦ Arthrodesis is unusual (<5%) in the absence of infection
♦ Significant residual impairment 2 years after injury
♦ Factors that produce optimal outcome are largely unknown
♦ Complications of wound breakdown and infection must be avoided
♦ Post-traumatic osteoarthritis common regardless of treatment technique.

Open reduction and internal fixation

Beginning in the late 1960s and early 1970s good results with open reduction and internal fixation were reported with 75–90% good or excellent clinical results and few complications. In contrast with these good results, there were a number of series which reported dismal results with open reduction and internal fixation. Most authors attributed their bad results, at least in part, to the higher number of 'high-energy' injuries in their patient groups. The high complication rates have led to modifications of techniques and in particular the practice of delays to definitive surgery to allow soft tissue recovery and the use of temporary spanning external fixation. Recent evidence indicates that the safety profile for treating these fractures with plates has improved significantly and current techniques are as safe as external fixation.

External fixation
Several authors have reported the results of treating open and severely comminuted plafond fractures with external fixators that spanned the ankle and in general, the results have been acceptable with 30–50% good or excellent and 10–25% poor outcomes. More importantly, in these injuries which were selected for their severity, all major complications were avoided. There were no infections or skin sloughs and only occasional minor pin or wire tract problems. Similar results have been reported when hybrid external fixators were used to treat selected tibial plafond fractures. Good or excellent results were obtained in 50–70% of cases treated. Complications were few and primarily related to pin sites, although each series had at least one deep infection or osteomyelitis.

In a prospective study of 49 displaced fractures of the tibial plafond managed using an articulated hinge fixator there was no tibial wound infections or osteomyelitis. At 2-year follow-up, 60% of the patients rated their result as excellent or satisfactory, 30% fair, and 10% were unsatisfied with the result.

In the most severe injuries, a substantial percentage (25–50%) of patients will continue to have pain or impaired function.

Comparative trials

There have been several comparative trials between external and internal fixation techniques. Higher rates of complication have been observed in patients treated with open reduction and internal fixation when compared to those treated with external fixation and limited open reduction and internal fixation. On the other hand, better outcomes have been identified in patients treated with plate fixation. It has been recommended that treatment should be based on the severity of the soft tissue injury with more severe injuries favouring external fixation.

Summary

The conclusions that can most readily be drawn from these studies are that both external fixation and open reduction and internal fixation can yield reasonable outcomes. Complications must be avoided. Regardless of the treatment method there is a subset of patients with severe injuries who have a poor outcome despite proper treatment that avoids complications and most patients continue to have some ankle symptoms. Table 12.58.1 summarizes the relative advantages and disadvantages of the current techniques that are most commonly utilized.

Complications

Postoperative complications may be divided into early and late by time of onset. Wound breakdown leading to osteomyelitis is the most troublesome, and an all too common early complication of tibial plafond fractures treated operatively. The incidence is quite variable ranging from none to 55%. The evidence indicates that the rate correlates with the severity of the injury and the operative technique (Table 12.58.2).
The high rate of infection is related to the tenuous soft tissue envelope about the distal tibia, which has inherent poor vascularity. Severe soft tissue damage results from the energy released by the fracture. This causes swelling and interstitial oedema resulting in relative tissue ischaemia. Surgical dissection, soft tissue stripping, and the use of large implants often tips the scales, resulting in the progression to skin slough, wound breakdown, and osteomyelitis. The best treatment is prevention which can be accomplished by delaying surgery until the initial swelling and oedema have diminished, using small implants, performing indirect reduction techniques and stabilizing with external fixation at least temporarily.

Once faced with wound breakdown and infection, treatment must be aggressive. All nonviable tissue must be debrided, loose hardware removed, and the fracture stabilized with an external fixator. A prolonged course of intravenous antibiotics is required. Free tissue transfer for soft tissue coverage is routinely necessary. Despite these aggressive measures, a long difficult treatment course may still result in arthrodesis or amputation.

The primary late complications are non-union, malunion, and post-traumatic arthrosis. The incidence of non-union and malunion has been reported to be as high as 18% and 42% respectively. Some authors have concluded that non-unions are not complications, but rather an expected outcome in a certain percentage of fractures. Aseptic non-unions may be treated with bone grafts and/or skeletal stabilization with a high degree of success. Non-unions complicated by infection pose a much greater problem. Treatment is prolonged and expensive often requiring multiple procedures with technically demanding techniques. Amputation may be required.

Post-traumatic arthrosis is a frequent sequelae of these severe injuries (54%). One study at 5–11 years of follow-up had fairly high-grade arthrosis in 26 out of 36 ankles studied. The relative role of the damage inflicted at the time of injury versus incomplete reduction is unclear. Radiographic arthrosis, or its absence, does not correlate well with clinical measures of outcome or patient satisfaction.

Treatment of arthrosis centres around symptomatic relief with non-steroidal anti-inflammatory drugs, braces, and shoe modifications. Once conservative treatment has been exhausted, arthrodesis is a reliable option for pain relief. Ankle fusion may become exceedingly difficult if early postoperative complications have resulted in infection, nonunion, or bone loss.

### Future directions

The shortcomings seen in the current literature point out where future investigation and advancement is warranted. The inability to classify these fractures reliably and reproducibly makes comparison between any two series of patients extremely difficult. Comparison is further hampered by the multitude of scales used to measure outcome parameters. In order to become better at predicting the factors that are responsible for patient outcome, there needs to be some consensus on how to measure outcome. This problem is magnified by the relative rarity of this fracture, which ensures that no single surgeon or facility treats enough of these injuries to perform multiarmed studies comparing different treatment options. A goal of the future is to aim to decrease the incidence of complications and late sequelae of these injuries. Further advances in imaging such as intraoperative three-dimensional imaging may increase the use and utility of limited approaches.

### Further reading

Ankle fractures

**Summary points**

- Ankle fracture management is dependent on the patient, stability and congruence
- Comparative studies of treatment options should be interpreted with caution.

**Introduction**

Ankle fractures are often the first fractures treated operatively by trainees. Many principles of fracture fixation can be applied in the management of these fractures. The authors have developed an algorithm to apply to their management where possible. Otherwise, treatment decisions can be based on fundamental principles.

**Normal and pathological anatomy of the ankle**

It has probably been stated rather too readily that the aim of the treatment of ankle injuries is the restoration of normal anatomy and early function. Accepting this aim drives one toward operative intervention. The bulk of ankle injuries, including fractures, are treated non-operatively with good functional results. Therefore it is necessary to look critically at which anatomical features require restoration for satisfactory function and avoid unnecessary intervention.

The ankle is composed of joints between the tibia and fibula, the talus and tibia, and the talus and fibula, and their associated soft tissue structures. These joints have load-bearing surfaces to transmit the compressive forces. The bony contours and the soft tissue configuration of the joint maintain the load-bearing surfaces in the correct apposition to transmit the load without damage. Therefore skeletal injuries to the ankle region can be divided into two groups: those which directly affect the load-bearing surface, and those which damage the stability and alignment of the joints. The Comprehensive Classification of Fractures reflects this division by separating the load-bearing tibial plafond fractures or pilon-type fractures (AO/OTA 43) from a special group of malleolar segment fractures (AO/OTA 44). Tibial plafond fractures are discussed in Chapter 12.58.

The bony mortise of the ankle is formed from the distal tibia and fibula. The fibula sits posterolaterally in the incisura of the distal tibia. They are bound together by the five ligamentous components of the inferior tibiofibular joint. The strongest of these is the posterior tibiofibular ligament, which runs from the posterior fibula to the area of Volkman’s triangle on the posterior aspect of the tibia. The anterior tibiofibular ligament is not as strong and runs from the fibula to the tubercle of Chaput. The talus fits snugly into this mortise. The collateral ligaments secure the talus in the mortise. The medial collateral ligament (deltoid ligament) comprises a superficial and a deep layer. The deep fibres are especially noteworthy for their short direct path and are said to be the most important component of this ligament. Their deep position, behind the anterior colliculus of the medial malleolus, renders them inaccessible to surgical repair.

**Diagnosis (Box 12.59.1)**

A careful assessment is necessary to avoid premature labelling as an ‘ankle injury’. This will obscure diagnosis of one of the many other problems that can present around this region. The history must include the mechanism of the injury and the general features which may influence the choice of treatment, e.g. previous injury, mobility, anticoagulation, and diabetes. A history of weight bearing after the injury suggests a stable injury except in the neuropathic patient.

Dressings or splints should be removed to allow a full assessment by the person who will control management. Inspection will allow an assessment of swelling, wounds, or impending breakdown of skin. Palpation must be performed systematically to determine the precise location of tenderness. The examiner must have a mental picture of the structures being palpated and this should include the whole length of the fibula and the anterior tibiofibular syndesmosis. Random ‘prodding’ medially and laterally will lead to errors. The joint should be moved and note made of the range and confidence of the movement and the feel of the endpoint to help assess stability.

There are many pressures to order special investigations, particularly radiographs. Many departments have guidelines for the use of radiographs. Implementation of the Ottawa ankle rules can reduce the requests for ankle films and minimize the risk of missing injuries. A mortise and a lateral view are usually required in the first instance. To obtain the mortise view the ankle needs to be internally rotated by 15 degrees; the anteroposterior view has little additional value. Indiscriminate use of ankle radiographs for all problems vaguerly in that anatomical area with cursory scrutiny of the malleoli alone may lead to overlooking of subtalar dislocations, tarsometatarsal dislocations, talar fractures, and calcaneal fractures (Figure 12.59.1). A group of patients who require particular attention are those who have an emergency reduction of a clinically diagnosed ankle dislocation but then subsequent radiographs appear normal. In this group there may be occult subtalar dislocations, calcaneal and talar fractures. In our opinion they merit computed tomography (CT) examination.
History:
- Mechanism
- Postinjury weight bearing
- Previous injury
- Comorbidities

Examination:
- Assessment of the skin is important
- Find the sites of maximal tenderness
- Assess ankle stability

Imaging:
- Radiography only if clinically indicated
- CT scan when indicated.

Fig. 12.59.1
A) and B) This ankle was originally described as normal, but closer scrutiny revealed a subtalar fracture dislocation. C) and D) Further imaging showed the true nature of the injury.

The limitations of plain radiographs should be remembered and when the radiograph does not fit the clinical findings, think again. The radiograph in Figure 12.59.2 shows an apparently normal ankle in a patient with significant symptoms and local tenderness anterolaterally. Symptoms persisted and about 6 weeks later a scan demonstrated an intra-articular Tillaux fracture. In this instance, even if a scan had not been available oblique views may well have demonstrated the injury. In fact, on closer inspection a depressed segment of the joint surface can be seen on the original lateral view. It may be helpful to look for a joint effusion analogous to the fat-pad sign at the elbow. The appearance of a joint effusion of more than 15mm on the lateral film indicates the presence of an occult fracture in 83% of cases and is an indication for further investigation.
Whilst soft tissue signs may prompt the diagnosis of a bony injury, the converse is also true. The soft tissue significance of bony abnormality should also be remembered. A vertically orientated fragment may be the marker of an avulsion of the peroneal sheath with dislocated or dislocatable peroneal tendons (Figure 12.59.3).

A two-dimensional picture of a three-dimensional structure can lead to confusion when estimating the shape and size of the posterior malleolar fragment. Plain radiograph measurements lead to very poor inter- and intra-examiner reliability. When compared with the CT scan measurement, 54% of the plain radiographic readings revealed more than 25% error. A further limitation of plain radiograph is the inability to demonstrate rotational abnormalities and relationships clearly. At other sites, rotational abnormalities of clinical importance can be assessed clinically however this is not possible when assessing fibular rotation.

**Description and classification of injuries (Box 12.59.2)**

Once the characteristics of an injury have been identified, it must be described and classified.

The Lauge-Hansen system is based on mechanism of injury. This system, which was introduced in the 1940s, has stood the test of time and is used in many papers on ankle injuries. For this reason alone, familiarity is required. However, as the terminology is difficult to remember and it is unusual for two people to both understand it adequately it is not very helpful in day-to-day communication.

Weber and Danis are credited with the basic classification of fibula fractures as A, B, or C depending on the relationship of the fracture to the inferior tibiofibular syndesmosis. It is easily remembered and understood, to the extent that it is used in plain speech. It is very limited in the other goals of a classification system, such as guiding treatment, prognosis, etc. However, it does provide the foundation to the malleolar segment injuries group in the Comprehensive Classification of Fractures. This more comprehensive system with its alphanumeric format is suited to use on computer-based systems for storage and retrieval. A comparison of the AO/OTA and Lauge-Hansen systems is shown in Figure 12.59.4.
Stability may be assessed in three ways.

1) Knowledge of the various injury patterns and their effects on the stabilizing structures of the ankle will allow an estimate of stability.
2) Direct observation may show the ankle to be displaced already.
3) Stressing the ankle to observe for abnormal movements.

Assessment of the injury pattern is an attractive way of estimating stability as it would allow treatment decisions to be made on basis of fracture classification. Experimental destabilization of the ankle gives some insight into the importance of various components. Posterior malleolar fragments of up to 50% as seen on a lateral view are not necessarily associated with instability. Resection of the lateral malleolus causes greater instability than sectioning of the deltoid ligament. In clinical studies accurate reduction of the lateral malleolus has produced a satisfactory reduction of talus. In an experimental model of supination–external-rotation (type B) fractures, a significant increase in external rotation of the talus at maximum planar flexion was seen with transection of the deep deltoid fibres. This was corrected incompletely by insertion of an anatomical fibular plate. Pronation–external-rotation (type C) fractures investigated in a similar fashion also noted the importance of an intact deep portion of the deltoid ligament.

These findings beg the question how to assess the integrity of the deep portion of the deltoid ligament. Demonstration of a medial diastasis of 4mm or more confirms rupture of the deltoid ligament. The finding of localized medial tenderness is less consistent and may suggest deltoid ligament rupture but can be present in the presence of incomplete disruption. In the presence of medial tenderness but no diastasis at rest, there may be an indication for a stress test under anaesthesia. Alternatively the consequences of physiological stresses may be monitored. Serial radiographic observation may be used to ensure bony alignment is maintained during the healing process.

The other aspect of stability which is often discussed relates to injuries of the tibiotalar syndesmosis and the need for placement of a diastasis screw. Not all fibular fractures above the syndesmosis require formal stabilization of the syndesmosis. Bimalleolar lesions where both fractures are fixed do not require a syndesmosis screw. It has been suggested that a syndesmosis screw is unnecessary in a type C fracture when the fibula break is within 3.5cm of the top of the syndesmosis with a medial ligamentous injury and within 15cm if a medial malleolar fragment was fixed. These recommendations are best confirmed by intraoperative assessment of the syndesmosis after the other bony injuries have been fixed. This is best achieved by taking a mortise view whilst the tibia is pushed with a screwdriver and the fibula is pulled with a bone hook (Figure 12.59.5). As most of the instability is in the sagittal plane it has been suggested that the fibula should be pulled in an anteroposterior direction.

Research has suggested that a 1-mm lateral shift in the talus caused a 42% decrease in contact area in the tibiotalar joint makes one wary of accepting any possibility of talar shift. In these experiments, talar shift was obtained by placing spacers of the appropriate width in the medial joint space. In this experiment, and others, the talus is noted to adopt its position of maximal congruence on loading, unless restrained. Mortise widening alone, with or without deltoid rupture, has not been seen to significantly affect contact area, centroid position, or joint contact pressure. Other experiments have suggested that lateral displacements of the talus and fibula up to 4mm have not shown an increase in peak stress. It has been suggested that factors other than the magnitude of normal contact stresses are of greater importance in the pathogenesis of post-traumatic arthritis.

In the isolated Weber type B fibula fracture there is often the clear appearance of displacement of the lateral malleolar fragment on a plain radiograph. CT scans have been used for further delineation of the nature of this injury and the apparent external rotation of the lateral malleolus is relative only to the proximal fibula and is not associated with derangement of the talofibular articulation.

If the posterior malleolar fragment is sufficiently large and displaced, it will clearly affect the contact area and stability. As noted above, estimating the size of the fragment from plain films is inaccurate but it is usually all that is available. Experimentally produced posterior malleolar fracture fragments of 25%, 33%, and 50%, as visualized on lateral radiographs, lead to a corresponding decrease of 4%, 13%, and 22% in tibiotalar contact area.

Congruence and stability (Box 12.59.3)

Congruence

The articular surfaces of a normal ankle are congruent. The articular surface of the talus is not uniform and therefore to maintain full contact during the normal movements of flexion and extension the shape of the mortise must change, i.e. the fibula and tibia move relative to each other. Abnormal movements or displacements are likely to cause loss of congruence such that the load across the joint is spread unevenly, and the articular cartilage may be exposed to forces sufficient to cause it to fail. This potential cause of late degenerative arthritis following a displaced fracture has been recognized for a long time but attempts to quantify the forces and estimate their effects have given variable results. Interpreting clinical results is difficult because late degenerative changes may be the inevitable consequence of damage to the articular surfaces at the time of the original injury rather than any subsequent damage consequent upon instability or malunion. The difficulty in interpreting the results may lead one to the conclusion when treating ankle fractures: 'if you don't understand it, just put it back where it came from'.
Injury classifications

- The Lauge-Hansen system is based on the mechanism of injury
- The Weber–Danis system is easy to remember and understand but is limited in guiding treatment
- The AO/OTA classification is useful for research.

![Fig. 12.59.5](image)

Testing stability of a type C fracture intraoperatively using a screwdriver and bone hook.

General considerations in the treatment of ankle fractures

Initial treatment

The initial treatment of an ankle fracture is aimed at preventing further injury and keeping the patient comfortable. A grossly displaced fracture may compromise the overlying skin as well as deeper structures; prompt reduction and splintage is indicated. This is a clinical decision, and the procedure is generally carried out under sedation or with Entonox prior to any radiological examination. In these grossly unstable cases radiographs are taken with the splint in place. In other cases higher-quality images are obtained out of the splint.

Box 12.59.3 Congruence and stability

- In a type B fracture the talofibular relationship may be normal and any displacement may be of the proximal fragment
- Lateral displacement of the talus, up to 4mm, may not markedly affect peak joint stress
- Stability assessment:
  - Recognition of injury pattern
  - >4mm of static displacement
  - Stress test may displace the talus to an unacceptable position.

Definitive treatment

Closed treatment

An injury deemed stable and in a satisfactory position does not require a fixed period of immobilization, multiple follow-up radiographs, or an operation. They may be treated symptomatically. The function of the injured part and the whole patient is important. Thus an identical physical injury may be treated with a Tubigrip bandage and crutches in one patient, but a mother with small children may require a short period in a cast or splint to allow her hands to be kept free.

Closed treatment of an unstable injury is not the simple option. More judgement is required over a greater period of time. A percentage of cases in which non-operative treatment is planned will at some stage need to be changed to operative management. Closed methods of treatment require the constructive use of the remaining intact soft tissue. Understanding the mechanism of the injury is helpful and allows the reversal of that mechanism to be employed in fracture reduction. Image intensifiers are of great benefit in facilitating reduction and determining how it will be maintained i.e. moulding and the need for an above- or below-knee
cast. Managing an unstable fracture in cast requires skill (Figure 12.59.6), and a clear post-manipulative regimen must be prescribed by the surgeon dictating weight bearing and x-rays.

**Box 12.59.4 General treatment of ankle fractures**

- Reduce fracture-dislocations urgently
- Operate early on fractures which have been dislocated
- Stable fractures require little more than symptomatic treatment
- Control symptoms and maintain function
- Unstable fractures require close supervision.

![Fig. 12.59.6](https://example.com/image)

A) Cast applied for symptomatic relief. B) Cast applied to control an unstable fracture. Note the difference in the closeness of fit and moulding of the casts.

**Operative treatment**

**Intraoperative management**

Embarking on operative surgery exposes the patient to a wider spectrum of complications, and so methods of minimizing these have to be considered. The operative treatment of a fracture should not be an exploration. When it is not possible to make a clear plan of the proposed surgery on the basis of the available information, then obtain more information. The soft tissues around the ankle pose special problems. There is a relatively poor blood supply to the skin and a tendency to postoperative swelling. There is little in the way of redundant skin so any loss or underlying swelling can lead to great difficulty in closing a wound. When a wound cannot be closed, the exposed underlying tissues are very frequently unsuitable for split-skin grafting. Therefore great care must be taken with soft tissue envelope.

The surgeon can control a number of factors which may affect the soft tissue outcome. The first is the timing of surgery. The actual manipulation and fixation of the fracture fragments is easier the sooner after the injury it is attempted. However, there are often pressures to delay surgery. The most common problem is the difficulty or inconvenience of gaining access to an operating room soon enough after the injury without the surgeon clearly designating it as an emergency. When there has been a fracture-dislocation there is good evidence to support emergency treatment. Major complications have been reported in 44% when surgery was delayed greater than 24h in comparison to 5.3% in those operated upon as emergencies.

**Box 12.59.5 Considerations in operative treatment of ankle fracture**

- Local cutaneous blood supply may be poor and may be compromised further by swelling
- Urgent fixation of fracture-dislocations reduces complications
- Do not use a tourniquet as routine but for a specific purpose
- Check radiographs before closure
- No conclusive evidence to support early mobilization.
Many surgeons routinely use a tourniquet when operating on ankle fractures. However, it is not always necessary and the period of tissue hypoxia and venous stasis caused by the use of a tourniquet has been shown to increase the incidence of soft tissue complications. It would seem appropriate to position a tourniquet but only inflate if required.

The patient should be positioned according to the planned procedure to facilitate access and instrumentation. It is recommended that the image intensifier and not the limb is moved to obtain the lateral view; this is particularly important when taking provisional views as the contortions required may displace a hard-won reduction.

The skin and soft tissues should be handled with care. To avoid damaging the skin’s blood supply it should not be separated from the deep fascia. Straight incisions are easier to close and have less tension than curved incisions. Self retainers can be damaging and if they are used, do not over-tension them and move them from time to time.

The position of the fracture and the implant should be checked radiographically before closure so that any necessary alterations can be carried out easily.

Postoperative management

Postoperative management will naturally be tailored to the individual injury. In general the hours following operative treatment should be aimed primarily at making the patient comfortable. A backslab and elevation should provide such comfort and prevent the ankle resting in an equinus position.

When early range of motion is considered it is essential that stable fixation has been achieved and this needs to be assessed intraoperatively. As the deltoid ligament has been shown to be a significant component of stability, a lateral fracture associated with a major injury of the deltoid ligament may not be stable when treated with anatomical lateral fixation and may require a period of immobilization. Three quasi-randomized controlled studies have looked into the merits of early mobilization of surgically fixed ankles. All three have shown no difference in clinical scores at 12 weeks compared with immobilized ankles and only one demonstrated an earlier return to work if mobilized early. With regard to complication rates, the studies were too small to show any significant difference but infection rates appeared higher in the early mobilization group. The decision to mobilize early should therefore be made on an individual basis. Factors such as patient compliance, comorbidities that affect healing, occupation and the surgeon’s confidence in the resulting construct should all be taken into account.

Fixation of specific bony injuries

Fibula

Type A fractures (Box 12.59.6)

Infrasyndesmotic fibula fractures tend to be transverse in orientation representing a failure in tension of the lateral malleolus. The majority will be suitable for non-operative treatment. When fixation is required it must be stable to tension loading, either using a third tubular plate placed or a tension band wire (Figure 12.59.7). When a wire construct is used, care should be taken to bury the longitudinal K-wires carefully under the lateral ligament. If soft tissues are caught in the crook of these wires, they will loosen, back out, and cause early problems. Furthermore, consideration should be given to the possibility that the wires will have to be removed and twists should be placed where they can be easily found.

Fig. 12.59.7
A) Type A fracture; B) radiograph showing a tension band wire; C) schematic drawing of the K-wire position.

Type B fractures (Box 12.59.7)

The most common fracture configuration is a spiral or long oblique with the apex of the distal fragment lying posteriorly. Soft tissue stripping including the peristemeum should be kept to a minimum. Only the fracture site needs exposed. Reduction may be obtained directly by using reduction forceps; a small degree of shortening can be corrected by judicious rotation as shown in Figure 12.59.8. Excessive local force may lead to fragmentation and the creation of a more difficult fracture. When it is difficult to obtain length, traction may be applied indirectly via a sharp towel clip embedded in the cancellous bone of the distal fragment. The two common methods of fixation are a lag screw with a lateral plate or a posterolateral antiglide plate (Figure 12.59.9). When the bone is of good quality, either method can be used. The antiglide construct does not rely on screw fixation in the softer bone of the distal fragment. In addition it facilitates indirect reduction by a combination of longitudinal traction and tightening of the plate to the proximal fragment. The metalware is not placed laterally and so is more easily covered and less likely to require removal. The authors strongly favours the antiglide construct when there is any doubt about the bone quality.
Box 12.59.6 Type A fractures

- Usually transverse
- Fixation should use a tension band principle.

Fig. 12.59.8
Use of pointed reduction forceps to obtain a direct reduction of an oblique shortened fibula fracture. This direct technique is only suitable in good-quality bone as fracture propagation is a risk.

Fig. 12.59.9
Two methods of fixation of a type B malleolar fracture: A) lag screw and neutralization plate; B) antiglide plate. The direction in which the distal fragment will displace is shown by the arrows. The antiglide plate relies on the ‘key’ screws which are in the better cortical bone. The hold in the softer cancellous bone is not needed to maintain reduction. This is the preferred technique in poor-quality bone.

Type C fractures (Box 12.59.8)

With simple fractures a direct method should achieve an anatomical reduction, which is then often fixed with a lag screw neutralized with a one-third tubular plate. When the fracture is relatively distal the position of the plate should allow any diastasis screw which may be required to pass through the plate or at least not to be obstructed by it.

When there is fragmentation at the fracture site or there is a segmental injury judging reduction is much more difficult. It may help to key in small fragment, so long as this does not involve the sacrifice of soft tissues. When this cannot be done it is quite possible to greatly misjudge the adequacy of reduction, particularly the rotation of the fragments. Figure 12.59.10 shows the malrotation of a fixed fibula as is used as it does not take into account the normal spiral arrangement of the fibulas lateral surface. The image intensifier can be used to compare the length and contour of the fibula with the uninjured leg. It may be necessary to expose the inferior tibiofibular joint to see whether the fibula is sitting in the incisura and, if not, whether it is blocked by debris in the joint or proximal malreduction. Even when it can be assessed, achieving a reduction may be awkward.
Fig. 12.59.10
A) Single-cut CT scans through the ankle after fixation of a type C fracture. The metalware in the medial malleolus is evident on the injured side. B) The malrotation of the poorly fixed fibula is clear when compared with the normal side.

Where there is fragmentation it is preferable to bridge the damaged area, avoiding the temptation to fix the fragments. This requires the use of a plate stronger than the one-third tubular and a 3.5 mm reconstruction plate is usually sufficient. A precontoured plate can be used as a push plate. It is applied to one fragment and length is then obtained by using a small laminar spreader between the other end of the plate and a separate screw (Figure 12.59.11).

Box 12.59.7 Type B fractures

- Usually spiral with distal spike posteriorly
- Reduce with care and do not complicate the task by further fragmentation
- Consider bone quality when deciding on fixation technique: when poor bone quality use antiglide principle

Box 12.59.8 Type C fractures

- Be prepared to use indirect reduction methods
- Simple fracture patterns—direct anatomical reduction
- Fragmented fracture patterns—consider indirect reduction and bridging the fragments.

If operative treatment is decided, reduction of the medial malleolar fragment is usually under direct vision, and the fixation is most often placed from distal to proximal. This needs to be recalled when placing the incision, which frequently has a redundant proximal portion and needs distal extension.
During reduction there is a risk of fragmentation and it is safer to manipulate the fragment with a sharp instrument such as a dental pick. When cleaning the fracture site of soft bone avoid removing bone with instruments such as curettes and picks. Temporary reduction can be achieved with K-wires or a clamp. Drilling a location hole in the proximal fragment will help with clamp application.

Medial malleolar fractures have been classified by Herscovici and the method of fixation will depend on the fracture pattern (Figure 12.59.12). Type A is an avulsion of the tip of the anterior colliculus, thus leaving the deep deltoid ligament intact. Fixation of these would therefore not offer any benefit to stability. Types B and C are transverse fractures of the malleolus at the mid-portion and at the level of the plafond, respectively. These have usually failed in tension. Type D fractures are vertically orientated above the plafond.

The most common pattern is type C, where the bone has failed in tension. These together with type B fractures are often fixed with two partially threaded screws. The length of the screw required is determined by the length of shank needed to ensure that the threads are passed fully across the fracture line. Unnecessarily long screws will result in the threads being in poorer-quality bone. Careful consideration should be made when placing the screws in order to avoid abutment of the posterior tibialis tendon.

Biomechanical tests demonstrated a fourfold increase in stiffness with tension band wiring compared to two cancellous screws. If a tension band is used, great care should be taken in burying the wires. Again, it is important to bury the K-wire ends into the deltoid ligament.

When the fracture is oblique (Type D), it is assumed that the failure was in compression. This compressive load may lead to impaction of the medial side of the tibial plafond thus obstructing any attempts at reducing the malleolus. A preoperative CT scan can thus prove very valuable if there is any suspicion of such an injury. If there is compression, the joint surface can be elevated and bone grafted. The malleolus itself may be fixed with partially threaded screws placed perpendicular to the fracture line. With larger fragments this is supplemented by using an antiglide plate at the apex of the fracture. Extending the plate all the way to the tip of the malleolus is not necessary.

When there is fragmentation of the medial malleolus, fixation with screws alone is not usually possible. A useful manoeuvre is to contour a mini fragment quarter tubular plate around the malleolus and pass the partially threaded 4.0-mm screws though it (Figure 12.59.13). The plate acts as a washer or artificial cortex binding the fragments together. Tension band wires are a useful alternative in these situations.
Posterior malleolar fragment (Box 12.59.10)

As discussed earlier, it often unnecessary to fix a posterior malleolar fracture. When fixation is required the first step is to have a mental image of where the fragment that needs fixing is located. It is usually posterolateral. Screws fixing the fragment need to run perpendicular to the fracture plane. The fixation may be placed from the front or the back. There are advantages to operating with the patient prone. Direct visualization of the fragment should allow a good reduction. When using a screw to fix a small to a large fragment, it is technically easier to pass through the smaller into the larger fragment. If compression screw fixation alone is inadequate it can be supplemented with an antiglide plate.

When the screw is placed from the front it is important that the threads only engage the posterior fragment to ensure both maximum hold and compression. In order to drill the two 3.5-mm gliding holes to the correct depth it is recommended to perform this step before reducing the fracture.

Diastasis fixation (Box 12.59.11)

A great deal has been written about the use of diastasis screws. Their indications have been discussed earlier.

Once again the treatment of an injured diastasis has two components: reduction and fixation. The objective is to hold the distal fibula in its correct position relative to the tibia, with the mortise neither too wide nor too narrow. The author uses a pelvic reduction clamp across the fibula to the medial aspect of the tibia applied at the level of the syndesmosis. The joint is viewed on an image intensifier. When compression is applied, the fibula should reduce into the incisura. If this does not happen the block to reduction should be sought, if necessary by opening the joint. If it looks ‘odd’ in some way, compare it with the normal side on image. Once reduction has been obtained, the foot is dorsiflexed during drilling and tapping as the talus is wider anteriorly. This is the conventional teaching to prevent overtightening of the syndesmosis. One study has suggested the position of the ankle during screw tightening does not affect maximal dorsiflexion. It is important to note that the study was performed on cadaveric models and so only passive and not active motion was evaluated.

Box 12.59.10 Posterior malleolar fragment

- Consider whether it is necessary to fix the fragment
- If fixation is likely to be difficult, place the patient in the prone position
- If screws are placed from the front, be careful that the length is correct and threads are not across the fracture line.

Box 12.59.11 Diastasis screw

- Ensure that reduction is adequate
- Use one screw if the fibula is fixed
- Use two screws if the fibula is not fixed.

If a screw is to be used, it should also be placed 1 cm proximal to the syndesmosis (4cm proximal to and parallel to the horizontal...
joint line). Placement distal to this may interfere with the interosseous ligament causing painful calcification. Too proximal placement can result in the lateral malleolus toeing outwards. The screw also needs to be angled anteriorly 25-30 degrees in order to obtain a good purchase of both fibular cortices and the tibia (Figure 12.59.14).

The diastasis stabilization has been an area of considerable debate. No biomechanical advantage has been demonstrated with 4.5 mm screws over 3.5mm screws and three cortex fixation has been shown to be as good as four. Many surgeons now feel that the need for planned screw removal is unnecessary as it rarely poses a clinical problem. The use of bio-absorbable screws also obviates the need for elective screw removal and some small studies have demonstrated no difference in terms of biomechanical and clinical outcomes. Another alternative is the use of a suture-button system passed through a 3.5mm drill hole placed 1.5cm proximal to and parallel to the horizontal joint line from fibula to tibia (Figure 12.59.15). Although biomechanical cadaveric studies have demonstrated inferior suture button strengths compared to tricortical screw pull-out strengths, some short-term clinical results have been promising.

Where possible the author places a diastasis screw through the fibula plate. When its placement is not associated with the operative fixation of a fibula fracture, for example, in a high fibular fracture (Masonneuve), it is sensible to place two screws for more adequate control of the fibula.

Outcome of ankle fractures (Box 12.59.12)

Some ankle fractures probably require nothing but symptomatic treatment. Lateral malleolar fractures with no medial injury (Type B, Lauge-Hansen SE stage II) managed by support in a cast without reduction demonstrate good long-term results. These injuries have also been successfully managed in just functional splints. Regardless of treatment, it is clear that anatomical reduction of the fibula fracture, in these injuries, is not required for good results.

What displacement is of clinical importance? A variety of radiographic markers have been said to be of importance in predicting outcome. Abnormal medial clear space, the presence of a large (>20%) posterior malleolar fracture, and an abnormal talocrural angle have been reported as the most predictive of a poor outcome. Many studies comment that in effect better results are associated with the fractures which heal in a good position. Thus, with the exception of the isolated lateral malleolar fracture, it would seem that a key aim of treatment should be a good reduction.

How to achieve and maintain the adequate reduction of a displaced fracture is more debatable. When closed methods clearly fail to achieve a reduction, the need for an open procedure is agreed. However, assessing the adequacy of a closed reduction may not be easy, requiring judgment and good images. There are few prospective randomized studies to guide us in this field. There is some research to support both operative and non-operative treatment. The impact of age is becoming increasingly important. Data from the National Health Service in the United Kingdom (2005-6) show that 25% of ankle fractures occur in adults over 60. It has been noted that there is a high incidence of early complication in operated fractures of women over the age of 55 years. The problems are, mainly, twofold. Firstly, the fractures tend to occur in poor bone quality, often with large degrees of fragmentation, leaving the final bone-implant construct up to 10 times less effective than in younger patients. Secondly, this population often have comorbidities such as late onset diabetes, oedema from congestive cardiac failure, chronic venous insufficiency, and peripheral vascular disease that render the soft tissues less tolerant to wounds. Figure 12.59.16 illustrates the nature of the dilemma which
may occur. Thus, if operative fixation is chosen, the mechanical construct should be considered even more carefully than usual. If the resulting construct is likely to be so fragile that the ankle requires protection from motion as well as weight bearing, the benefits of fixation allowing early ankle motion no longer apply. Indeed, the insult to the soft tissues may be the greater evil compared to a poorer functioning ankle joint.

Fig. 12.59.16
Poor decision-making in an A-type fracture in osteoporotic bone. Because of problems with the skin, a minimally invasive approach was adopted. The construct asked too much of the screws on the medial side. A) Type A fracture in osteoporotic bone with medial impaction. B) Intraoperative view of fixation. C) Failure of the fixation. D) Thus, if surgery was required for protection of the skin, the surgeon could have chosen a small plate as a buttress, rebated it to avoid prominence, and augmented with bone graft. Alternative option for the medial side; the other option is a cast.

The failed ankle fracture

Periodically a surgeon is confronted with a ‘failed’ ankle fracture. This may be the result of poor initial treatment, poor bone stock, infection, or comorbidities. A theme of all the treatments discussed earlier in this chapter is that most ankle fractures, when reduced, require little force to hold them in place. Thus stabilization can generally be achieved with casting or metalware with a relatively low strength. When the fracture has demonstrated a tendency to fail then holding it becomes much more difficult. Three illustrative cases can be used to demonstrate this, see Figures 12.59.17–19). Whilst some failures are inevitable the clear message is to strive to succeed at the first attempt.

Box 12.59.12 Outcomes
- Anatomical fibula reduction not necessary
- Poor outcome if:
  - Large medial space
  - Large posterior malleolar fracture
- Best outcomes with reduced ankle displacement
- No definitive advantage to internal fixation
- Elderly females have less satisfactory results.

Fig. 12.59.17
A) Young adult with malunion evident at delayed presentation. B) The fracture was mobilized and the high-quality bone was harnessed using long screws, C), that were sufficient force to allow ankle joint mobilization.
Fig. 12.59.19
A) and B) Failure of non-operative treatment of elderly ankle fracture. C) Revised to standard limited internal fixation which similarly failed. In this instance the tibial plafond was preserved and stabilization was temporarily achieved with a ring fixator to hold adequate alignment until union. The original metalware was left in situ.

**Treatment algorithm**

The algorithm shown in Figure 12.59.20 summarizes the authors’ treatment preferences. The major concern is to establish whether the fracture is stable or not. When the fracture is unstable, in the younger patient (<60 years) we prefer to offer operative fixation as we believe that this gives a greater chance of achieving and maintaining a satisfactory position. In the over sixties it remains unclear whether operative fixation is advantageous. The position at union seems to be the best predictor of a good result. The cost of achieving this improved position is the possibility of operative complications. Thus every effort must be made to minimize the risks. This involves the timing of the surgery, care of soft tissues, avoidance of tourniquets, and accommodation in the technique for poor-quality bone.

Fig. 12.59.18
A) and B) Elderly patient with unstable fracture noted at the time of the original operation. Poorer quality bone lead to failure of the fixation. C) The loss of reduction had damaged the lateral side of the tibial plafond and therefore stable and useful movement of the ankle joint was unlikely to be regained. D) Salvage was obtained using a retrograde intramedullary nail arthrodesing the ankle and subtalar joint.

Fig. 12.59.20
Management of ankle fractures.
Summary

Despite all the discussion of congruence and stability, there are two basic surgical backgrounds from which ankle fractures are approached—those who believe that unless proven beneficial no surgical intervention should be made, and those who believe that the anatomy should be restored precisely unless it can be shown to be unnecessary. Depending on which of these beliefs is held, the results of the same studies will be interpreted quite differently and different treatments pursued.

Further reading

Fractures of the talus and peritalar dislocations

Summary points

- Talar fractures are uncommon injuries and the outcome is very dependent on the tenuous blood supply
- Fixation with absolute stability must be achieved
- Osteochondral and process fractures are sometimes difficult to appreciate on plain x-rays. Clinical examination and a high degree of suspicion will help to identify these problems early.

Introduction

The talus is also known as the astragalus (see aviator’s astragalus, discussed later). The ancient Grecian game of knuckle bones uses five taluses in which one is thrown up and the others are swept up in the hand in different combinations and the thrown talus is then caught before it hits the ground, in the same hand. Talus is the Latin name for the Greek Talos, the bronze giant portrayed in Jason and the Argonauts who was defeated by opening the porthole in his ankle and letting the liquor flow out.

The talus is a remarkable bone. Think of its small size in the context of its function. It has to transmit forces of 4g at heel strike at ordinary walking pace. Consider the forces it transmits when running and jumping. It is surprising that fractures are therefore rare accounting for between 3.4% of all fractures of the foot and only 0.32% of all fractures.

The talus articulates superiorly with the mortise joint of the ankle, inferiorly with the calcaneum, and anteriorly with the navicular. Posteriorly the talus has a posterior process comprised of the medial and lateral tubercles, between which runs the flexor hallucis longus tendon. Laterally the prominence of the lateral part of the posterior facet is called the lateral process (Figures 12.60.1–3.).

The talus has 60% of its surface area covered by articular cartilage and has limited soft tissue attachments and blood supply. An appreciation of the tenuous blood supply is important in understanding the disruption that occurs both at the time of injury and
during surgical intervention (Figure 12.60.4). The head and neck of the talus are supplied by periosteal branches from the dorsalis pedis and peroneal arteries. Two-thirds of the body is supplied by the tarsal sinus and tarsal canal arteries. Laterally, the tarsal sinus artery arises from the perforating peroneal artery and dorsalis pedis artery. Medially, the tarsal canal artery arises from the posterior tibial artery within the deltoid below the medial malleolus. Deltoid (ligament) and posterior tubercle branches from the posterior tibial artery also supply the body of the talus. In fractures/subluxations these branches within the deltoid may be the only viable blood supply that remains. Therefore if a medial approach needs to be extended, a medial malleolar osteotomy should be used.

In 60% of cases there is a complete intraosseous anastomosis between all regions of the talus. As a result of its unique anatomy, fractures of the talus have great potential for morbidity.

Investigations for talar and peritalar injuries are documented in Box 12.60.1.

**Box 12.60.1 Investigation of fractures of the talus and peritalar dislocations**

- Radiographs:
  - Standard ankle and hindfoot views
  - Oblique views for posterior process fractures
  - Canale view to visualize talar neck (Figure 12.60.5)
- CT scan for talar body, neck, and head fractures
- MRI:
  - Osteochondral fractures
  - AVN.

Fractures of the talar neck are well described; however, the talus is prone to a number of other less well recognized fractures (Box 12.60.2).
Box 12.60.2 Fractures of the talus

- Neck fractures—the commonest
- Osteochondral fractures of the dome
- Body fractures
- Lateral process fracture (snowboarder’s fracture)
- Fractures of the posterior process
- Head fractures
- Avulsion fractures of the neck (sprained ankles).

Talar neck fractures

Aviator’s astroagalus (an anachronistic name for the talus) was a term used to describe talar neck fractures sustained by military glider pilots in crash landings. The Crawford-Adams arthrodesis, which he called the RAF arthrodesis, was developed as a consequence. It was postulated that hyperdorsiflexion of the ankle with impaction of the neck into the anterior lip of the tibia was a likely mechanism. Cadaveric work has demonstrated the role of focal loading of the talar neck and pre-impact bracing in the generation of these fractures.

Half of talar fractures appear in the neck and are basicervical. They usually have an oblique orientation and can be associated with disruption of the subtalar, tibiotalar, and talonavicular joints. Talar neck fractures are commonly described using the Hawkins classification (Table 12.60.1 and Figure 12.60.6). Not only does displacement increase the risk of avascular necrosis (AVN) but malunion will affect hindfoot function due to the complex relationship between subtalar, talonavicular, and calcaneocuboid function. Surgical reduction should be anatomical as malunion is associated with uniformly poor results.

Hawkins type I fractures are undisplaced (confirmed with computed tomography, CT) and can be treated non-operatively in a below-knee non-weight-bearing cast for 6 weeks. Fifty per cent of these injuries are not visible on presenting radiographs so the clinician must have a high level of suspicion. Full weight bearing is permitted when radiological union is achieved (trabeculation crossing fracture site), usually 8–10 weeks.

In closed Hawkins type II fractures, closed reduction of the subtalar joint should be performed as a matter of urgency. If the surgeon waits until the swelling settles, reduction will be very difficult.

Surgery is indicated for all displaced fractures as it is associated with malunion and non-union. Malalignment of the talar neck has significant mechanical consequences and is associated with poor outcome. The approach must not further compromise vascularity and therefore the vascular anatomy must be clearly understood. The options involve anteromedial, anterolateral or posterolateral approaches. CT is mandatory and three-dimensional CT reconstruction can be very useful to determine the fracture plane and fragmentation. The anteromedial incision allows insertion of anterior to posterior longitudinal screws and can be extended to include a medial malleolus osteotomy. Reduction may be difficult to judge due to fragmentation and an additional anterolateral incision may be required to ensure reduction. The posterolateral approach allows the insertion of posterior to anterior longitudinal screws. A plate is occasionally required, when there is comminution, to hold the neck out to the correct length and orientation.

Hawkins’s sign is a radiological subchondral zone of osteoporosis on mortise/AP views, seen at 6 weeks post-fracture and is a predictor of retained vascularity of the talus following fracture, see Box 12.60.3.

### Box 12.60.3 Avascular necrosis of the talus

- **Hawkins sign:**
  - Subchondral lucency implies intact blood supply
  - 4–5% false positive
  - Hawkins sign absent at 12 weeks—75% AVN
- **MRI allows definitive diagnosis**
- **Treatment**
  - Best managed expectantly
  - Arthroscopic debridement can help symptoms
  - Fusion should be considered for pain relief

### Osteochondral fractures

These fractures should be differentiated from osteochondritis dissecans which is referred to as an infraction (incomplete bone fracture without displacement) with a suspected avascular cause associated with abnormal repetitive loading. They tend to be located on the medial dome and may be bilateral.

Osteochondral fractures are fresh injuries as a result of a single episode of trauma. They may not be visible on initial radiographs and occur frequently in association with ankle ligament sprains. Hence, if an ankle injury fails to settle within a reasonable period of time, further investigation with x-ray and magnetic resonance imaging (MRI) is indicated (Figure 12.60.7). Lesions may occur in up to 6.5% of ankle sprains.
An osteochondral fracture is essentially a divot of bone with overlying articular cartilage. The management depends on the size, location, and symptoms as well as general state of health considerations. The commonest location is the lateral dome and is a shear injury associated with an inversion which subluxes the talus in the mortise. Healing is an issue as the fragment has lost its blood supply and may act as a loose body. The separation may be incomplete or may in fact be a transchondral injury.

An undisplaced lesion may be stable or unstable and MRI scan may help to determine if there is a zone of lucency all around the lesion implying separation. The decision to fix in situ may then depend on whether the lesion is symptomatic or not.

Stability of a fragment offers the best chance of healing be that achieved in a cast or by internal fixation. The author uses CT with three-dimensional reconstruction to evaluate the size and position of the fragment as well as planning a surgical strategy in which it is important to determine if the fragment is to be reached via an arthrotomy (open or arthroscopic) or an osteotomy. The surgical options are to fix, excise, or drill the lesion.

Fixation depends on the size and when possible, the author favours 1-mm screws from the compact hand set. Internal fixation may need to be augmented with casting and protective weight bearing but if fixation is sound then non-weight-bearing range of movement exercises with a night resting splint to prevent equinus contracture, is to be preferred. A 2-month period of non-weight bearing is appropriate and sporting activities are not recommended for 1 year.

Salvage strategies may include drilling the defect to provoke healing with fibrocartilage together with loose body removal. Alternatively the defect can be grafted.

In 1959, Berndt and Harty proposed a staging system based on radiographic findings and Anderson et al. and Ferkel et al. used MRI to classify talar osteochondral injury. Pritsch et al. graded lesions according to articular injury visualized during ankle arthroscopy. These staging systems are summarized in Table 12.60.2

* Stage 2a is a variant in which a cyst forms in the subcortical bone.
These are intra-articular fractures that will usually require anatomical reduction of the articular surface with internal fixation. The dense trabecular bone frequently allows excellent screw purchase. Again CT scanning is mandatory and the author finds three-dimensional reconstruction useful to plan the approach and determine access to the fragments and hence the need for malleolar osteotomy (Figure 12.60.8).

Fig. 12.60.8
A) Talar body fracture; B) treated with open reduction and internal fixation using medial malleolus osteotomy. C) Mortise view at 18 months.

The outcome of these fractures is generally poor with AVN rates similar to displaced neck of talus fractures. Post-traumatic arthritis is seen to occur frequently but does not always correlate with symptoms.

Snow boarder’s fracture

These are fractures of the lateral process of the talus. The lateral talocalcaneal, cervical, bifurcate, and anterior talofibular ligaments originate from tip of this process. This fracture was seen rarely following falls and motor vehicle accidents but is now increasingly recognized and the incidence is rising. It is believed to occur as a result of dorsiflexion and eversion of an axially loaded ankle. It may mimic a lateral ankle ligament sprain and the injury may not be obvious on initial radiographs. Untreated it can be the cause of long-term disability. Primary surgical treatment may improve the outcome of this injury, reducing the risk of secondary subtalar joint osteoarthritis.

Any patient presenting following a snowboarding injury with lateral ankle pain, especially just distal to the tip of the lateral malleolus needs further investigation. Clinical suspicion of this injury mandates a CT scan (Figure 12.60.9). The author again favours three-dimensional reconstruction as well. This helps visualize the size, location, displacement, and degree of fragmentation of the fracture. This helps answer the question as to whether surgery is feasible.

Fig. 12.60.9
Lateral process talar fracture.

Although these fractures may present late, the investigation and management are similar. Lateral process fractures are reported to have generally poor outcomes when treated in a cast alone. However, small (<1cm) minimally displaced (<2mm) fragments can be considered for non-weight bearing in a below-knee cast for 6–8 weeks. Large fragments should be stabilized with internal fixation unless truly undisplaced. Displaced multifragmentary fractures not amenable to fixation should be considered for excision.

Fractures of the posterior process

Fractures should not be confused with the os trigonum which is a secondary centre of ossification of the posterior process that has not fused to the body of the talus. It occurs in 7–10% of the population and is corticated and rounded. It can be fractured in its own
right and diagnostic difficulties may arise which require CT or even MRI scanning to resolve.

The posterior process is comprised of two tubercles and the undersurface of the combined tubercles articulates with 25% of the posterior facet of the subtalar joint (Figure 12.60.10). Displaced fractures are therefore a potential cause of morbidity and oblique views (30 degrees external rotation) or CT may be required to make the diagnosis.

**Fractures of the lateral tubercle** are known as Sheppard’s fracture and may present clinically like an ankle sprain but may demonstrate tenderness posterolaterally with pain on movement of the subtalar joint and passive movement of flexor hallucis longus tendon.

Displaced fractures are best excised unless so large they can be reduced and fixed with small hand set screws (1-mm diameter). Undisplaced fractures may be treated in a cast, non-weight bearing for 6–8 weeks and although non-unions are rare, persistent painful non-union is best treated by excision of the fragment. Non-union may cause pain on subtalar movement or full plantar flexion.

**Head fractures**

The literature is limited largely to case reports and fractures are frequently associated with dislocations of the talonavicular joint. They represent less than 10% of talar fractures. The experience is that late presentation is common as the fracture may not be visible on plain radiographs. The consequence of late presentation is degenerative change. Diagnosis depends on a careful physical examination for pain, swelling and tenderness of the proximal medial column of the foot and CT scanning. Pain from degenerative changes may warrant fusion.

Accurate reduction and stable fixation should give rise to satisfactory results. Undisplaced fractures may be treated in a non-weight bearing below-knee cast for 8–10 weeks.

**Avulsion fractures of the neck**

These are small fractures that may be seen on lateral radiographs and are small irregular, often triangular fragments 2–3mm in size. They represent avulsions of the anterior talofibular ligament (ATFL) and are hence radiological signs of ankle sprains as the ATFL is the commonest ligament to be injured. The treatment is aimed at rapid restoration to function with elevation and compression and ice with early weight bearing with physiotherapy in the form of long extensor and proprioceptive retraining to prevent recurrent instability.

Caution is recommended to avoid missing associated undisplaced talar neck fractures.

**Ankle dislocation**

Dislocation of the tibiotalar joint, without associated ankle fracture, occurs infrequently. In 90% of cases the talus dislocates posteromedially and in 50% of cases there is an open anterolateral wound. In open injuries in addition to the standard management of an open wound the lateral ligaments can be repaired. In closed injuries reduction and immobilization in a below-knee cast for 6 weeks has been demonstrated to produce good to excellent results.

**Subtalar dislocation**

A subtalar dislocation involves disruption of both the talocalcaneal and talonavicular joints. The calcaneus and foot dislocate medially in 59%, laterally in 23%, posteriorly in 11%, and anteriorly in 7% (Figure 12.60.11). Subtalar dislocation is frequently associated with fractures of the foot (64%) and osteochondral fractures of the talus (47%). Many of these associated injuries will have an adverse effect on the outcome and may not be readily identifiable on plain x-rays.
Subtalar dislocations should be reduced as soon as possible to avoid further compromise of the soft tissue envelope. Reduction will frequently have been performed by emergency staff prior to the first x-rays and therefore subtalar dislocation should be considered in ankle injuries with a history of gross deformity without obvious cause. Closed reduction may require a general anaesthetic and it is recommended that it is performed by applying pressure to the navicular with the knee flexed and foot plantarflexed. Traction on the heel and initial exaggeration of the deformity may be required initially to unlock the talus and calcaneum. Closed reduction may not be possible due to entrapped tendons, ligament, capsule, retinaculum, bony impactions, or neurologic and vascular structures. It is recommended that postreduction CT scan is performed as a matter of routine. The subtalar joint is inherently stable and does not usually require internal fixation. In the absence of identifiable pathology requiring operative intervention, treatment involves a below-knee cast for 4–6 weeks depending on the initial instability. K-wire stabilization should be restricted to unstable injuries and it is important to use stout K-wires and strict non-weight bearing to avoid breakage. Assessment of stability should be performed after removal of the cast and in those cases demonstrating instability a further short period of immobilization is indicated.

The majority of patients will complain of subtalar stiffness and subtalar arthritis is common in the long term. AVN of the talus is rare.

Complete talar dislocation

Complete talar dislocation occurs very rarely and is associated with an open injury in approximately 75% of cases. In addition to standard treatment for open wounds, consideration can be given to reducing the talus and stabilising with K-wires. Although acceptable results have been reported, infection and AVN are common complications requiring secondary operative intervention. Alternatively, primary talectomy can be considered. Results of treatment for this injury are anecdotal.

Further reading

Fractures of the calcaneum

Summary points

- Surgical management of displaced fractures is becoming the norm
- Fixation and soft tissue procedures should allow early mobilization
- Subtalar fusion should not be used at the time of primary surgery
- In children minimal intervention indicated
- Abnormal hindfoot biomechanics frequent cause of long term disability.

Introduction

Calcaneal fractures account for 2% of fractures and 60% of tarsal bone injuries. Since the fracture usually occurs in the working population the economic cost is considerable.

Normal anatomy

Bone

The calcaneum is a box-like structure, squashed from superior to inferior anterior to posterior facet of subtalar joint (PFSTJ) by the sharp crucial angle of Gissane. Posteriorly, the superior surface is bare up to PFSTJ. This is quadrilateral in shape and orientated posteromedial to anterolateral. The bone behind and beneath PFSTJ is termed the tuberosity or body of the calcaneum. (Figure 12.61.1A).

Anterior to PFSTJ, the bone is extended anteromedially as the sustentaculum tali (ST), which consists of two thick sheets of cortical bone with the middle facet of subtalar joint (STJ) on its superior surface. Anterior to ST a deep groove, the inter-osseous sulcus, passes laterally terminating as the crucial angle of Gissane, a sharp edge of thick cortical bone into which fits the anterolateral process of talus. The interosseous sulcus forms the inferior surface of the sinus tarsi which gives rise to the interosseous talocalcanean ligament and contains the artery of the sinus tarsi.

In front of the sinus tarsi, the calcaneum narrows. Medially, the superior surface contains the anterior facet of STJ (which may be confluent with the middle facet). It gives origin to three structures from medial to lateral, the bifurcate ligament, which inserts into the adjacent cuboid and navicular bones, the extensor digitorum brevis, and the inferior extensor retinaculum.

The lateral wall of the calcaneum is flat and is mainly thin cortical bone. Immediately anterior to the crucial angle of Gissane, the inferior peroneal retinaculum, through which run the peroneal tendons, is attached to the peroneal tubercle. The posterior calcaneofibular ligament arises from the lateral wall behind and below PFSTJ and immediately anterosuperior to this the capsule of STJ inserts, leaving a bare area posteroinferior to the lateral edge of the joint.

The medial wall is thicker than the lateral and is arched from posteroinferior to anterosuperior with its apex lateral from
subcutaneous sustentaculum tali to the medial process inferiorly. The thick cortical sheets of ST are continued anteriorly as a strong anteromedial buttress and fuse with the medial aspect of the calcaneocuboid joint (CCJ).

The medial wall gives origin to the intrinsic muscles of the foot, which separate it from the posterior tibial neurovascular structures. Superiorly, the medial wall is grooved by the flexor hallucis tendon passing beneath ST.

The anterosuperior corner of the medial wall is intimately related to the talus and navicular.

The anterior wall of the calcaneum is the CCJ which is shield shaped with its point inferiously (Figure 12.61.1B). The superior part of the joint is orientated in an oblique plane from posterolateral to anteromedial, while inferiorly the orientation is anterolateral to posteromedial. In addition, the superior edge lies anterior to the inferior. This complicated geometry makes reduction and fixation of the joint difficult.

The plantar surface of the calcaneum contains the medial and lateral processes, which give origin to the plantar fascia and the small muscles of the plantar aspect of the foot.

The posterior surface of the calcaneum contains the tendo Achilles (TA) insertion.

**Soft tissues**

Laterally, the calcaneum is subcutaneous and the sural nerve runs obliquely within the subcutaneous fat passing posterosuperior to anteroinferior with a variable course. It supplies the lateral border of the foot and is easily damaged in direct incisions over this area which may cause neuromas.

Laterally above the calcaneum the soft tissues consist of superficial and deep triangles. The superficial triangle lies in the sagittal plane. Its boundaries are the superior border of the calcaneum inferiory, anteriorly the peroneal muscles and tendons and posteriorly the TA. In the anterior wall of the superficial triangle, in the coronal plane is the deep triangle. It is bounded laterally by the peroneal tendons, inferiory by the superior border of the calcaneum, just behind PFSTJ and medially by the flexor hallucis muscle covered by fascia. The floor from inferior to superior is PFSTJ, STJ capsule, talus, ankle joint capsule, and tibia. Surgical dissection of these triangles by the extended lateral approach gives massive access to the hindfoot.

The posterior peroneal artery is the artery of supply of the skin of the lateral aspect of the heel. It is usually the terminal branch of the peroneal artery and enters the deep triangle at its apex. It transits both triangles, anastomosing with the periarticular vascular ring around the ankle and crosses the superior border of the calcaneum behind PFSTJ in close proximity to the sural nerve, becoming an end artery. There are poor anastomoses between the posterior peroneal artery cutaneous angiosome and the posterior foot or the sole. Therefore a surgical approach to the lateral side of the hindfoot must dissect the angiosome or the wound is at high risk of breakdown.

Medially, the short abductor of the foot and flexor accessorius muscle separate the bone form the posterior tibial neurovascular bundle, which is in danger from medial incisions, lateral drills or instruments placed through the primary fracture line to reduce the body fragment (BF). It may also be damaged by the inferior spike of the sustentacular fragment (SF) which pierces the skin in an open fracture.

### Anatomy of the fracture

Fractures of the calcaneum occur according to a series of readily definable patterns knowledge of which permits a logical approach to treatment.

**The normal intra-articular fracture**

This constitutes approximately 75% of cases and is usually caused by a fall from 6–12 feet (1.8–3.6m). It involves three fracture lines, the primary fracture line (1#L) and the coronal (C2#L) and longitudinal secondary fracture lines (L2#L) (Figure 12.61.2), modified from the original description of Essex-Lopresti.
The anatomy of the usual calcaneus fracture: A) lateral oblique view; B) medial oblique view. ALF, anterolateral fragment; AMF, anteromedial fragment; BF, body fragment; LJF (t) tongue type lateral joint fragment; LJF (jd), central joint depression type lateral joint fragment; SF, sustentacular fragment. Solid line, primary fracture line; dashed lines, coronal secondary fracture line; transverse dashes, lateral part; longitudinal dashes, medial part; small dots: longitudinal secondary fracture line forming a central joint depression type lateral joint fragment; large dots: longitudinal secondary fracture line where it separates to form a tongue type lateral joint fragment.

1#L is the result of shearing forces between the heelstrike point and the mechanical axis of STJ (Figure 12.61.2). It splits the bone from posteromedial to anterolateral, crossing PFSTJ and usually CCJ creating a two-part fracture. The lateral fragment contains the lateral part of PFSTJ, the tuberosity or body of the calcaneum and the lateral part of CCJ while the medial fragment contains ST and the medial part of the subtalar and CCJ.

The two-part fracture is usually undisplaced, however the posterolateral fragment may dislocate lateral to the talus, either in a high-energy injury, or in middle aged females after a minor trip. As the lateral fragment is forced upwards, it escapes lateral to the talus and continues superiorly until stopped by the lateral malleolus, which sustains a small posterior fracture. The lateral fragment rebounds and pulls the lateral edge of the talus inferiorly, subluxing the ankle joint. This rare fracture is often missed and non-operative treatment leads to painful ankle and midfoot dysfunction which is difficult to salvage. Primary operative treatment through an extended lateral approach is straightforward.

Usually secondary fracture lines occur. C2#L runs along the sinus tarsi splitting the anterolateral fragment (ALF) from the posterolateral. Crossing 1#L in the majority of cases, it exits at the middle facet, splitting the medial fragment into an anteromedial fragment (AMF) and a posterior SF. L2#L arises on the lateral wall of the calcaneum and passes posteriorly splitting the residual posterolateral fragment into a lateral joint fragment (LJF) and a body fragment (BF). Usually it skirts PFSTJ creating a small semilunar, central joint depression LJF. Less frequently it passes directly posteriorly to the posterior aspect of the bone, creating a large, tongue type LJF.

Thus a four- or five-part fracture is created, depending on whether the coronal secondary line stops medially at 1#L.

Fragment description

- Body fragment (BF). Lateral to 1#L and below L2#L. It includes the heelstrike point, calcaneal tuberosities and TA insertion
- Sustentacular fragment (SF). Medial to 1#L and posterior to C2#L if this line crosses 1#L. It includes the medial part of PFSTJ, ST, and the superior part of medial wall of calcaneum. In a four-part fracture, where C2#L does not extend medial to 1#L, it also includes STJ middle and anterior facets and medial CCJ
- Lateral joint fragment (LJF). Lateral to 1#L, posterior to C2#L, and above L2#L. It includes lateral PFSTJ
- Anterolateral fragment (ALF). Lateral to 1#L and anterior to C2#L. It includes the crucial angle of Gissane and lateral CCJ
- Anteromedial fragment (AMF). Medial to 1#L and anterior to C2#L. It contains the STJ middle and anterior facets and medial CCJ.

In a four-part fracture, where C2#L does not cross 1#L (approximately 30%), AMF remains part of SF. Open reduction and internal fixation (ORIF) is simple since the combined SF and AMF provides a large area for screw insertion. Occasionally, a four-part fracture is created by 1#L failing to pass anterior to C2#L. This leads to a combined ALF and AMF.

Fragment movement

The interaction of 1#L and C2#L usually produces a BF which has a sharp, wedge-shaped superior edge (Figure 12.61.3). The injury forces BF superiorly and anteriorly, in a variable direction, sliding laterally on the oblique lateral surface of SF and tips into varus and internal rotation (Figure 12.61.3). The triangular upper surface of BF splits apart LJF and SF, tipping LJF into valgus and SF into varus. With increasing fragment displacement, the sharp inferior spike of SF becomes more medial, until it penetrates the skin causing an open fracture.
Fig. 12.61.3
Semicoronal reconstruction of an axial CT scan of a calcaneus fracture. This scan has been taken at the level of the lateral malleolus and posterior facet of subtalar joint. The posterior facet is disrupted into two main fragments with a primary fracture line in the middle of the posterior facet (a Sanders 2b fracture). The fractured lateral wall is comprised of the body fragment inferiorly and the lateral joint fragment superiorly (an Atkins type 2 fracture).

1. Lateral malleolus.

2. Body of talus.

3. Medial malleolus.

4. Sustentacular fragment and sustentaculum tali. Note that the fragment is rotated so that its inferior tip comes to lie more medial and that the tip of the sustentaculum is relatively undisplaced.

5. Lateral joint fragment and the lateral part of the posterior facet.

6. The lateral wall of the calcaneus which is pushed outwards and upwards broadening the heel and impinging on the lateral malleolus and the peroneal tendons.

7. The tuberosity of the calcaneus and the body fragment. The fragment is tipped into varus bringing the heel-strike point medially. The body fragment is also pushed upwards so that its superomedial corner moves up the medial oblique face of the sustentacular fragment and so causes the body fragment to move laterally. This broadens that heel.

8. The peroneal tendons which are closely applied to the displaced lateral wall.

Occasionally, in high energy or osteoporotic fractures, the usual sharp triangular upper border of BF is absent. LJF is crushed into BF and may be captured within it causing true lateral joint fragment depression (Atkins type 3 fracture).

Displacements of AMF and ALF are less marked. AMF is undisplaced or shifted upwards. ALF rotates outward and upward filling in the crucial angle of Gissane. These displacements must be addressed in ORIF to prevent painful STJ impingement.

Fracture classification

A number of complementary fracture classifications are useful:

- Essex-Lopresti distinguished between central joint depression fractures and tongue-type fractures based on the course of L2#L
- Sanders classification depends on the number and position of fracture lines within PFSTJ
- The Zwipp and Tscherne system concentrates on the number of major fracture fragments (2 to 5) and the number of joints involved.
- The Atkins system is based on the composition of the residual lateral wall. In a type 1 fracture, the lateral wall is made up of LJF, in a type 2 it is formed of LJF above and BF below and in a type 3 fracture, LJF is captured within BF and the latter forms the entire lateral wall.

Tuberosity fractures

The classical tuberosity fracture is a TA avulsion in an osteoporotic bone.

The medial process fracture of the body of the calcaneum was originally described by Watson-Jones, as due to a fall with the foot in severe valgus and by Bohler, who considered it to be an avulsion of the plantar fascia.

We have identified a fracture of the calcaneal tuberosity that occurs in young adults (Figure 12.61.4). #L is replaced by a semicoronal fracture line, which separates the posterosuperior part of the calcaneum. This fracture line may cross PFSTJ or pass posteriorly. The fracture line exits on the posterior wall of the calcaneum. The displaced fragment includes TA insertion and rotates upwards causing a heel boss.
Anterior process fracture

There are two different types, avulsion and compression.

The more common bony avulsion of the calcaneal origin either of the bifurcate ligament or of the extensor digitorum brevis is caused by forced inversion. There is tenderness on the lateral side of the hindfoot and the injury is usually obvious on the lateral x-ray. Non-operative treatment which may require cast immobilization gives good results although recovery may be slow.

The rare high violence compression fracture is caused by forced abduction of the foot with compression of the anterior part of the calcaneum, classically either in motorcycle racing or waterskiing. The displaced fragment is larger than in the compression fracture and involves a significant portion of CCJ. Swelling is often considerable and CT scanning may demonstrate associated fractures of the calcaneum. Non-operative treatment gives poor results. Surgery is difficult and requires often involves stabilization of PFSTJ.

Sustentacular fracture

ST is small and fractures may be missed radiographically. ST is firmly attached to talus and medial malleolus, so fractures are rarely isolated and are associated with severe ligamentous and bony damage elsewhere and treatment is a part of treatment of the overall hindfoot injury. ST fractures are often associated with gross instability of PFSTJ.

Fractures in children

These are rare but easily missed. The usual mechanism is a jump or fall; however lawnmower accidents may directly involve the calcaneum. In younger children undisplaced extra-articular fractures predominate, with a high incidence of anterior process fractures. The prognosis is good with non-operative treatment. Adolescent fractures are rare, similar to adult fractures but simpler although occurring following greater falls (Figure 12.61.5).

Intra-articular calcaneal fracture in a mature child. The fracture is an Essex Lopresti central joint depression fracture. It is a Sanders 2b or 2c fracture, the exact place at which the primary fracture line crosses the posterior facet cannot be judged on these views. The posterior facet of the sub-talar joint is involved and probably the middle facet but the calcaneo-cuboid joint is intact. The primary fracture line does not extend anterior to the interosseous sulcus so that there is one large anterior fragment. It is therefore a Zwipp and Tscherne four part, two joint fracture.

A) Lateral radiograph. Bohler's angle is flattened indicating significant fracture displacement.

B) Axial CT scan. There is a large but incomplete lateral wall segment of bone suggesting an Atkins type 2 fracture, although this cannot be absolutely stated on these views. There is significant anterior movement of the body fragment on the sustentacular fragment. This would possibly remodel with time. A crack in the sustentaculum is visible.

C) This sagittal reconstruction CT scan shows severe derangement of the posterior facet of sub-talar joint which is unlikely to remodel.

D) Postoperative lateral radiograph. Bohler's angle is restored.
Open fractures

Two types are seen. Type 1 is a standard highly displaced intra-articular fracture where the inferior border of SF penetrates the skin on the medial side of the foot beneath the medial malleolus.

A type 2 injury occurs in a high violence atypical fracture where random fracture fragments penetrate the skin. The open injury varies but is typically on the sole of the foot.

Clinical history (Box 12.61.1)

The majority of fractures occur in a fall from a height, usually more than 6 feet (1.8m). A two part fracture dislocation in a middle aged women or the avulsion fracture of the tuberosity in the elderly occur after a simple trip. Both open and bilateral fractures are associated with greater violence injuries and give poorer results. The other common cause for calcaneal fractures is a road traffic accident and in these cases atypical fractures, sometimes with dislocations are seen.

The patient experiences immediate hindfoot pain and cannot walk. Swelling soon follows. Initial clinical examination usually demonstrates swelling and tenderness of the heel. Very rarely, a calcaneal fracture with a dislocation will cause vascular compromise in the foot. Swelling increases over several days and bruising of the lateral side of the heel becomes obvious (the Battle sign). As the swelling subsides, the characteristic short, wide heel and poorly defined lateral malleolus become obvious.

The two part fracture dislocation of the body of the calcaneum presents a clinical trap. The x-ray may look deceptively normal and, because the calcaneum is impacted against the lateral malleolus, the patient may be able to walk with ease.

Radiographic assessment

Plain radiographs

Lateral and axial views of the heel will show most clinically significant fractures. Ankle and foot radiographs may also be performed. On the lateral radiograph assessment of Bohler’s angle will give some indication of fracture displacement (Figure 12.61.6). The fracture may also be classified according to Essex-Lopresti into a tongue or central joint depression fracture. The axial view will demonstrate 1#L separating BF from SF and may give some indication of heel widening (Figure 12.61.7). Ankle radiographs will demonstrate subluxation with a dislocated calcaneal tuberosity in the case of a two-part fracture dislocation. Oblique radiographs of the foot demonstrate fractures of the anterior part of the calcaneum.

Fig. 12.61.6
Lateral view of a calcaneus showing an Essex–Lopresti tongue type fracture. Bohler’s angle is outlined by the white line. Reversal of the angle, as here, suggests significant fracture fragment displacement and a poor prognosis following non-operative treatment. 1—the exit point of the longitudinal secondary fracture line on the posterior aspect of the bone. 2—the inferior part of the coronal splitting the bone into anterior and posterior parts. 3—the anterior corner of the posterior facet of the sub-talar joint on the lateral joint fragment. (Figures 12.61.6-8 show the same fracture.)
Fig. 12.61.7  
Axial view of a fractured calcaneus.

1. The inferior tip of the sustentacular fragment.
2. The bulging lateral wall.
3. The tuberosity of the calcaneus, forming the body fragment, tipped into varus.
4. The sustentaculum tali.
5. The lateral malleolus.

Computed tomography scanning

Fractures may easily be missed on plain radiographs and in case of doubt a computed tomography (CT) scan should be performed. CT scanning is essential to demonstrate fracture anatomy and displacement and for surgical planning. Using a spiral scanner, axial, sagittal and semi-coronal (normal to PFSTJ) views are obtained.

Semi-coronal scan (see Figure 12.61.3) shows the disposition of the fracture in the posterior part of the bone. PFSTJ is well demonstrated and BF displacement can be assessed. The composition of the fractured lateral wall can be determined. In the context of reconstruction of mal-union, impingement between displaced fracture fragments and the fibula can be assessed.

Axial scan (Figure 12.61.8) shows the fracture as it effects the anterior part of the bone well. Involvement of CCJ is clearly seen and fracture lines passing just anterior to ST can be visualized. In the posterior part of the bone, rotation of BF in the axial plane can be estimated. The scan will also show whether the fracture is an Essex-Lopresti tongue or central joint depression fracture, although this is normally readily seen on the lateral radiograph.
2. The medial extension of the coronal secondary fracture line passing into the sustentaculum tali. This fracture line usually passes just anterior to the sustentaculum.

3. The anterior part of the calcaneus is in one piece in this fracture and the calcaneocuboid joint is not involved. This fracture is therefore a Zwipp and Tscherne 4 part 2 joint fracture. The fracture fragments are sustentacular, lateral joint, body and anterior. The two involved joints are the posterior and middle facets of the sub-talar joint.

4. The lateral joint fragment

5. The posterior extension of the longitudinal secondary fracture line. Since this exits the posterior rather than the superior aspect of the bone, the fracture is an Essex–Lopresti tongue type.

6. The posterior limit of the primary fracture line separating the sustentacular fragment antero-medially from the body fragment posterolaterally. The body fragment is displaced anteriorly compared to the sustentacular fragment.

---

**Treatment**

Treatment remains controversial; however, with improved surgical understanding, anatomical approaches and implant technology, operative treatment is becoming the norm.

**Non-operative treatment without reduction**

**Background**

This should be reserved for undisplaced fractures or for cases unfit for operative treatment. After elevation to resolve swelling, the patient is mobilized non-weight bearing with physiotherapy. If this is too uncomfortable, a short period of initial immobilization is used. An elastic stocking aids resolution of swelling. The patient should be fully weight bearing by 12 weeks in a solid shoe with a permanent insole.

**Open reduction and internal fixation**

**Background**

There are four goals to calcaneal fracture fixation

1) Restoration of PFSTJ
2) Restoration of hindfoot biomechanics by reduction of the medial wall fracture line and realignment of BF
3) Reduction of the anterior part of the calcaneum in order to release STJ and reduce CCJ
4) Fixation and soft tissue procedures which allow early mobilization.

The surgical approach is crucial and develops a fasciocutaneous flap based on the terminal branch of the peroneal artery. The incision heals well and allows early mobilization. The medial wall fracture line can be addressed through this lateral incision obviating the need for a medial approach.

**Current surgical techniques (Fig. 12.61.9)**

**The usual intra-articular fracture**

**Preamble and positioning**

Surgery is performed after the swelling has begun to subside and under general anaesthetic and antibiotic cover. The patient is placed in the lateral position and the foot prepared and draped free from the mid-calf.

**Extended lateral approach to the hindfoot**

The incision is in two parts joined at the posterior corner of the heel. The superior limb begins in the midline approximately 15cm above the sole and passes inferiorly and anteriorly ending approximately 2cm anterior to the lateral corner of the heel. The inferior limb begins distally at the level of the base of the fifth metatarsal bone at the junction of the lateral side of the foot and the sole. It is below the bruised skin and separated from it by approximately 1cm. The two limbs meet at an angle of greater than 100 degrees in a gentle curve. The skin incision allows development of the cutaneous angiosome of the posterior peroneal artery. Flap elevation begins at the apex with dissection directly onto the calcaneum. Anteriorly, abductor digiti minimi is split and the entire lateral wall of the calcaneum is exposed subperiosteally as far as PFSTJ. The inferior peroneal retinaculum is dissected intact to expose of the crucial angle of Gissane and ALF. The lateral wall fragment is now removed and preserved for later reposition. This may require formal osteotomy.

  - Varus/valgus
  - Width

Investigations

- Lateral and axial hindfoot x-rays ± ankle and foot x-rays
- CT.

Disimpaction of LJF and removal from STJ

LJF is rotated out of STJ. In a tongue type fracture the posterior soft tissues should be retained. In a central joint depression type fracture, the fragment will usually have been denuded of soft tissues and is removed. Exposure of the posterior aspect of STJ is improved by cutting directly through the superficial and deep triangles, avoiding damage to the peroneal tendons and flexor hallucis muscle.

Transcalcaneal reduction of BF and medial wall

This exposes the medial wall fracture line, between the apex of BF inferiorly and the lateral surface of SF medially and superiorly. A Steinman pin may be used for manipulative reduction of BF. I have not found this to be necessary.

A periosteal elevator is inserted gently between the visible apex of BF and the lateral edge of SF. Care is taken to avoid damage to the posterior tibial neurovascular bundle. The periosteal elevator is now rotated, levering BF downwards and medially, reducing the medial wall. The reduction may be held temporarily with a K-wire.

Reconstruction of PFSTJ

The PFSTJ is now reconstructed anatomically and LJF is replaced. Fixation of intermediate fragments may require K-wires or Herbert screws. Temporary K-wire fixation is checked visually and radiographically. Definitive fixation is with a small fragment cortical lag screw into ST with a washer.

Reconstruction of the anterior part of the calcaneum

Subperiosteal dissection within the sinus tarsi allows reduction of ALF and AMF, which are stabilized with temporary K-wires. The lateral wall fragment is now replaced. If a good reduction has been obtained it fits well into the remaining lateral bone defect.

Plate fixation

The majority of standard calcaneal fractures do not require a locking plate. Once BF has been reduced beneath SF and PFSTJ stabilized by repositioning of LJF, the fracture is longitudinally stable and the plate serves to buttress BF against SF and to hold the anterior part of the bone in place. Union occurs rapidly possibly with a minor, irrelevant loss of height. Where significant bone crushing, comminution or osteoporosis renders the fracture longitudinally unstable, a locking plate is required. In these cases bone grafting may be advisable in order to enhance bone healing and prevent collapse.

Postoperatively ankle and subtalar joint exercises are begun immediately and the patient remains non-weight bearing until union is well advanced, usually at 6–8 weeks. Weight bearing is then gradually introduced.

Tuberosity fractures

Isolated medial process fractures are invariably managed conservatively.

Tuberosity fractures involving the upper part of the calcaneum fare poorly non-operatively. Healing is slow with a heel bump and...
Tuberosity fractures involving the upper part of the calcaneum fare poorly non-operatively. Healing is slow with a heel bump and weakened plantarflexion. An extended lateral approach is used to compress the fracture line using a posterolateral tension band. A short period of cast immobilization may be necessary; however, the patient can usually mobilize weight bearing and union is rapid.

**Comminuted atypical cases**

Comminuted fractures of the calcaneum fare poorly non-operatively but they are a daunting surgical prospect and will not be suitable for standard fixation. There is invariably at least one large fragment of bone, which usually contains the majority of PFSTJ and BF. ORIF using an extended lateral approach reduces the large fragment into its anatomic position beneath the talus and fixes it with K-wires into the talus. The remainder of the calcaneum is then fixed to this fragment. Non-weight-bearing cast immobilization is maintained until fracture healing is established, usually 6–8 weeks. The K-wires are removed and the patient mobilizes freely in a new cast until union is complete, after approximately a further 6–8 weeks. Treated thus, patients complain of few symptoms and revision to subtalar fusion is rare.

We do not advocate a subtalar fusion at the time of primary reduction. Subtalar fusion without prior reduction gives poor results.
5. The apex of the body fragment.
6. The periosteal elevator is placed through the medial wall fracture line in order to reduce it.
7. The tendo Achilles.
8. The lateral surface of the body fragment.
9. The inferior fibres of the abductor digiti minimi, which has been split during the approach.
10. The lower arm of the superior flap of the extended lateral approach.

E) Final fixation
1. K-wire through the lateral malleolus keeping the superior limb of the flap out of the operative field.
2. Bone lever over the superior aspect of the calcaneocuboid joint.
3. Calcaneal fracture fixation plate.
4. Cortical lag screw through the lateral joint fragment into the sustentaculum tali part of the sustentacular fragment.
5. Neutralization screws through the lateral joint fragment and the sustentacular fragment.
6. Cancellous screws into the body fragment.
7. Cortical screw into the anterior aspect of the sustentaculum tali. Passing through the anterolateral fragment.
8. Abductor digiti minimi, split in the line of its fibres.
10. Lateral joint fragment.
12. Lateral process of the talus.
13. Just below this, the lateral part of the posterior facet of the sub-talar joint can be seen.

F) Preoperative lateral radiograph.
G) Axial CT scan.
1. Lateral joint fragment
2. Articular cartilage of the lateral joint fragment
3. Sustentaculum tali, which is part of the sustentacular fragment. Note that in this case the coronal secondary fracture line does not pass medial to the primary fracture line so that there is no separate anteromedial fragment. The medial part of the calcaneo-cuboid joint is therefore part of the sustentacular fragment.
4. Anterolateral fragment containing the lateral part of the calcaneo-cuboid joint
5. Lateral wall
6. Navicular bone
7. Cuboid bone

H) Postoperative lateral image intensification radiograph at the time of surgery. Compare to (F). Bohler’s angle has been restored.
1. Temporary K wire passing into the fibula (compare to (E)).
2. Lag screw passing through the lateral joint fragment into the sustentacular fragment.
3. Two neutralization screws passing through the lateral joint fragment and the sustentacular fragment.
4. Cancellous screws passing into the body fragment.
5. Cancellous screw passing into the posterior aspect of the lateral joint fragment.
6. Cortical screw passing through the anterolateral fragment into the anterior part of the combined sustentacular and anteromedial fragment.

Sometimes, a comminuted fracture combines features of a standard intra-articular fracture with those of a tuberosity fracture. In these cases, reduction is maintained by a combination of plates and screws and a tension band wire.
Open fractures

Type 1: the fracture is more displaced than the average and therefore untreated the outcome is poor. The open wound is debrided primarily and the foot elevated. By the time that the soft tissues have settled sufficiently to allow internal fixation, the open wound is usually healed and reduction and internal fixation are performed as outlined previously. Alternatively, ORIF may be performed at the time of initial wound debridement.

Type 2: these are among the most challenging hindfoot injuries to manage. Treated conservatively, the severe displacement leads to major disability and the combination of open wounds and unstable fracture fragments predisposes to chronic infection so that there is a high chance of late amputation. Operative treatment is very difficult and plastic surgical cover may be necessary. Surgical treatment may precipitate amputation but on balance it is the better option.

In all open cases and particularly where the open wound is more serious, the risks of ORIF must be carefully weighed against the likely outcome of non-operative management in order to determine whether operative management is indicated.

ST fractures

Treatment is determined by the associated injuries. ORIF may be with a lateral to medial lag screw through an extended lateral approach or from medial to lateral using a direct medial incision. However, the importance of the ST fracture is the instability which it confers on PFSTJ. It is often better to reduce PFSTJ under direct vision and stabilize it with a 2mm K-wire. The patient is then mobilized non-weight bearing for 6 weeks in a cast and the wire is then removed.

Fractures in children

Calcaneal fractures in very young children heal uneventfully and treatment consists of immobilization until healing in a few weeks. In older children (see Figure 12.61.5), there is significant scope for remodelling of the hindfoot even after a displaced fracture. The aim of treatment is to provide a fully functional hindfoot with the minimum intervention possible. Minor joint and hindfoot malalignments even out with time but large displacements should be treated by operative reduction. Owing to the simple fracture pattern in adolescents, ORIF is straightforward and gives excellent results without damage to the calcaneal apophysis (Figure 12.61.5).

Compartment syndrome

Toe clawing is common after calcaneal fracture and while this may be due to a missed compartment syndrome, it is more likely to be the result of damage to the intrinsic muscles of the foot at the time of fracture. Foot compartment syndrome does occur and may be common after calcaneal fracture. This suggests that if the patient has clinical features of a compartment syndrome with excessive pain, sensory abnormalities, and raised compartment pressures, decompression should be performed if the patient has been evaluated within 24h. However, the open wounds of compartmental decompression may preclude subsequent ORIF because of the risk of infection. Therefore, either ORIF should be undertaken at the time of decompression or the morbidity of an unreduced calcaneal fracture will need to be traded against the disability of untreated compartment syndrome.

Techniques which avoid open surgery

In an attempt to avoid the massive exposure and consequent morbidity of the extended lateral approach, a number of different percutaneous methods of reduction and fixation have been devised. In some techniques an external fixator is used. They are applicable to a limited range of fractures and must be undertaken at an early stage. Perfect reduction is not obtained but the avoidance of the morbidity of open surgery may compensate for this. Early reports of these techniques are encouraging. It is important to note that the techniques all require a thorough knowledge of fracture anatomy and are generally undertaken by surgeons skilled in calcaneal fracture surgery.

Results

The results in some individual groups are outlined earlier. Despite a bewildering array of papers, the evidence base for calcaneal fracture treatment is unsatisfactory in that ‘level 1 evidence’ is not available as with much of orthopaedic surgery. The historic literature is difficult to interpret because it is impossible to know the exact nature of the fracture described and more modern studies are small or scientifically flawed or employ outmoded fixation techniques.

In general terms the evidence base for calcaneal fracture outcomes may be summarized as follows.

- Fractures which are initially undisplaced and unite in an undisplaced position fare well
- Displaced fractures give poor outcomes treated non-operatively. The more displaced the fracture the worse the outcome
- Modern operative treatment is safe but technically highly demanding
- An anatomical surgical reduction with stable internal fixation gives a better result than non-anatomical reduction
- The eventual disability may be predicted from the nature and displacement of the fracture.

Disability after fracture (Box 12.61.2)

Introduction
In deciding whether to treat a calcaneal fracture by ORIF, knowledge of the expected disability and management of a conservatively treated fracture is essential. The problem is that there are multiple causes of symptoms and overlapping disability syndromes. The patient will complain of a combination of pain, limitation of walking ability and derangement of their lifestyle and a superficial history and examination may give little indication of the true cause of the problem. In the past, excessive concentration on PFSTJ as the major cause of symptoms has clouded the issue. In a calcaneal malunion, careful assessment will usually reveal one or more of the following:

Subtalar joint derangement

Angular malalignment

Angular PFSTJ malalignment is invariable in a standard intra-articular calcaneal fracture. It may cause minimal early symptoms. The more severe the malalignment and the greater STJ comminution, the more likely is the development of painful arthritis later. This causes pain on walking particularly on uneven ground. Rest pain is a late feature.

In the presence of normal hindfoot biomechanics, subtalar joint symptoms are not usually a significant problem unless the patient in a heavy manual worker or regular rough ground walker. Therefore, isolated angular PFSTJ malalignment is not a strong indication for ORIF and symptoms may be treated with fusion. However, angular PFSTJ malalignment is usually associated with abnormalities of hindfoot biomechanics.

Subtalar joint depression

True lateral joint fragment depression invariably causes serious disability. There is a sense of insecurity and giving way within the foot with lateral pain on taking a step. With time rest pain occurs. Examination reveals tenderness laterally and a valgus hindfoot. This severe disability is an inevitable consequence of subtalar depression and this feature is a strong indication for ORIF.

Abnormal hindfoot biomechanics

This is due principally to BF displacement; this is a common cause of severe disability. Three syndromes occur: heelstrike medial, heelstrike lateral, and short heel.

Heelstrike medial

BF displacement has carried the heelstrike point medial to the axis of the hindfoot, the unloaded hindfoot lies in varus, accentuated on weight bearing. These patients complain of severe difficulty in walking or standing. There is a cavus midfoot and the medial ray is unloaded. At toe-off, the varus is accentuated because of TA medialization. Supination instability is common and the patient may walk on the outer border of the foot. FHL is often trapped in the fracture. Degenerative changes of the ankle and midfoot occur rapidly with increasing pain.

Conservative treatment of these feet is of little use. The only satisfactory solution is surgical reconstruction of the heel and this is made particularly difficult by the varus position of the hindfoot. Therefore, BF varus and internal rotation position, which will produce a heelstrike medial syndrome is a strong indication for ORIF.

Heelstrike lateral

This is more benign than heelstrike medial but less common. There is a valgus heel with fibular impingement and a planus midfoot, accentuated and painful on load bearing. Compensatory overactivity of tibialis posterior causes calf pain. However, resection of the lateral bony boss will make matters worse by allowing the heel to collapse further into valgus. Likewise, in situ fusion of STJ will destroy the compensatory effect of subtalar inversion and may make matters worse.

Treatment by a medial shoe-raise and supporting insole is often extremely effective in these cases. Operative treatment to reconstruct the hindfoot biomechanics and fuse STJ is easier than in the case of heelstrike medial.
Short heel

Following a calcaneal fracture, the heel is always shortened and broadened in relation to the extent of the displacement. However, when the heelstrike is displaced medially or laterally, the symptoms from this shortening are usually masked by those more intrusive problems.

The short broad heel causes problems with shoeware and sometimes the broadening is sufficient to cause lateral pain beneath the fibula. The major problem is, however, weakness of plantarflexion due to reduction of the moment arm of the gastrocnemius-soleus complex. In order to compensate for the short heel, the ankle is held in dorsiflexion and if the problem is severe, there may be an overall apparent equinus deformity of the foot. The abnormal posture of the ankle may lead to secondary arthritis. The patients characteristically complain of weakness of the foot and limping, while in a severe case, the equinus may lead to catching the foot. Later ankle arthritis pain becomes a feature.

Treatment is by a heel raise to restore the ankle to neutral and protect it; however, the patient often finds that this makes them symptomatically worse by exaggerating the weakness of the plantarflexors. Operative treatment is by hindfoot reconstruction. If treatment is delayed until ankle arthritis supervenes, the situation is difficult to recover.

Anterior calcaneal syndromes

Owing to its attachment to the bifurcate ligament, the anterior part of AMF is rarely displaced following a fracture. The posterior part is attached to the talus and may ride upwards compared to PFSTJ. The displacement is seldom great, however even this small malalignment may contribute to blocking subtalar joint movement. In contrast, ALF will often tip upwards because of its attachment to the inferior peroneal retinaculum. As it does so its posterosuperior border fills in the crucial angle of Gissane preventing evasion of heel and in severe cases causing a fixed inversion deformity. When this is combined with a medial translation of the heel due to BF movement, the resulting disability is severe.

ALF syndrome is seen in untreated isolated compression fractures or in inadequately treated fractures where the crucial angle of Gissane has not been correctly addressed. The patient complains of pain, initially only on attempted eversion. Gradually the pain becomes more intrusive, occurring first on walking on rough ground, then on any walking, on standing and finally as arthritic changes occur at rest. Rarely a late spontaneous fusion will occur. In my experience excision of the displaced fragment at a late stage does not relieve symptoms and fusion combined with reconstruction of the hindfoot is necessary.

These symptoms are an inevitable result of the displacement of LJF and I regard displacement of this fragment as a strong indication for ORIF of the fracture.

Heelpad syndrome

The specialized weight-bearing tissues of the heelpad are not permanently damaged in a calcaneal fracture and heelpad pain is rare after ORIF. However, in a displaced calcaneal fracture, shards of bone may penetrate the deep structures of the sole of the foot. If the fracture is treated conservatively, these pieces unite in their displaced position. These patients are always severely disabled clinically. They walk with a severe limp and great pain, although rest pain is rare. Treatment is very difficult. Thick insoles are of some help but reconstructive surgery is usually required and it is difficult to remove all the bone at this stage. Even a radical removal of the protruding bone combined with reconstruction does not relieve the heelpad pain. In contrast, acute fracture reduction removes the shards from the sole and heelpad pain does not occur. Therefore I regard bony protrusion in the heelpad as a strong indication for operative treatment of a fracture in the acute stage.

Fibular impingement (peroneal tendon impingement)

During a calcaneal fracture, lateral wall expansion closes the space between it and the fibula and compresses or even dislocates the peroneal tendons. In a severe case, the laterally displaced calcaneum will articulate with the lateral malleolus, defunctioning the ankle joint. Isolated lateral wall protrusion is effectively treated by simple resection. However, fibular impingement is usually associated with abnormal hindfoot biomechanics due to BF displacement. Simple lateral wall resection in these cases may cause further valgus collapse of the heel, worsening symptoms.

Late surgery in operated cases

After ORIF, metalwork removal is frequently necessary, which may be combined with arthrolysis of PFSTJ. This will often improve symptoms of apparent subtalar arthritis. It is therefore reasonable to do this surgery and defer fusion in a marginal case. In situ subtalar arthrodesis may be required for degenerative change but usually this is deferred to 2 years, since symptoms may settle for this period. It is performed either through the extended lateral incision or a sinus tarsi approach.

Reconstruction of calcaneal malunion

Calcaneal malunion surgery is technically highly demanding surgery. The case is analysed by careful clinical examination, plain radiology, and CT scanning. I do not find gait analysis or pedobarography of use. Non-operative treatment consists of modification of shoe ware, the use of supportive and cushioning insoles and even a caliper, and change of lifestyle to cope with the disability. Some care must be exercised in pursuing a conservative course. Calcaneal malunion surgery is a major undertaking. There may well be morbidity from the bone graft donor site and if deep infection occurs, amputation is likely. However, a significantly misaligned calcaneum will cause a dorsiflexed talus leading in time to ankle arthritis, while bone beneath the lateral malleolus will eventually cause peroneal tendon dislocation or rupture. In addition, the hindfoot malalignment strains Chopart’s joint causing arthritis. In these circumstances reconstruction needs to be performed early for optimal results. The problems that will be
encountered include lateral impingement, peroneal tendon dislocation, PFSTJ arthritis, hindfoot malalignment, and bone in the sole of the foot.

The aim of surgical reconstruction is to restore the biomechanics and fuse degenerate joints. *In situ* subtalar fusion is ineffectual except rarely where there is symptomatic PFSTJ degeneration with normal hindfoot biomechanics.

Surgery is invariably performed through an extended lateral approach and proceeds stepwise, correcting only the necessary problems. The protruding lateral wall is resected. Dislocated peroneal tendons are located. PFSTJ is entered and laminar spreaders used to derotate the talus into correct orientation. PFSTJ is prepared and the talus held in its corrected position with a bone block from the iliac crest. An extra-articular calcaneal osteotomy is undertaken and used to place the heelstrike point in the correct place. If necessary, a bone block is used to hold the correction. The peroneal tendons are relocated in a new groove behind the lateral malleolus. The wound is sutured in three layers beginning with the periosteum.

In a two-part fracture dislocation, the reconstructive surgery is different. Through the extended lateral approach, the primary fracture line is found inferomedial to the talus. It is re-opened and the dislocated calcaneal body relocated. A PFSTJ fusion is undertaken if necessary.

Midfoot and forefoot fractures and dislocations

Summary points

- Mid- and forefoot injuries are common
- Minimally displaced and stable injuries allow early weight-bearing rehabilitation and lead to a good functional outcome
- Displaced and unstable injuries require restoration of the length, alignment, and joint congruency followed by stable fixation
- Respect the soft tissue element of the foot injury.

Introduction

Injuries to the mid- and forefoot are common. Many of these injuries are relatively benign. Fractures that are minimally displaced without significant soft tissue injury may be expected to give satisfactory clinical results with minimal intervention. However, a significant proportion of mid- and forefoot injuries can give rise to long-term impairment and disability, and require more careful attention.

Successful management of these injuries depends on recognizing the important distinction between the benign fracture and more significant fractures and dislocations that disrupt the normal form and function of the mid- and forefoot. Early functional rehabilitation is possible for minor fractures. More significant injuries require restoration of length and alignment of the columns of the mid- and forefoot, restoration of joint congruity, followed by stable fixation to achieve the best possible results. Even with optimum treatment of severe injuries, recovery may be incomplete. However, as close a restoration of normal anatomy as is possible is more likely to yield a more favourable outcome.

Functional anatomy

The foot may be considered as a tripod. The limbs are formed by the heel, with a medial column running from the talus through the cuneiforms, medial metatarsals, and toes and a lateral column running through the cuboid and lateral two metatarsals. Maintaining the relative length and alignment of these columns is a key element in treating mid- and forefoot injuries successfully.

It is convenient to consider the foot and ankle as units—ankle, hind-, mid-, and forefoot. Functionally, these units are integrated. Disruption of one unit may affect function throughout, and injuries commonly extend across more than one ‘unit’.

The midfoot spans the area between Chopart’s joint and Lisfranc’s joint. It is formed by the navicular, three cuneiforms, and cuboid bones. Chopart’s joint is formed by the talonavicular and calcaneocuboid articulations. With the hindfoot everted, the axis of these joints lie parallel, allowing maximum flexibility through the midfoot. With the hindfoot inverted, the joint axes converge thus locking the transverse tarsal joint and providing a more rigid lever for propulsion. Restricting movement at either joint limits movement at the other, as well as limiting movement at the subtalar joint by up to 50%.

Tibialis posterior provides the power to invert the subtalar joint and adduct the forefoot through its broad insertion on the navicular tuberosity and plantar aspect of the mid- and forefoot. It is opposed by the action of peroneus brevis that inserts on the base of the fifth metatarsal. Tibialis anterior inserts plantar medially on the medial cuneiform and base of the first metatarsal. Peroneus longus provides the antagonist.

There is little movement between the bones of the midfoot. Loss of motion between these joints is well tolerated.

Lisfranc’s joint is formed between the base of the metatarsal bones distally and the three cuneiforms medially and cuboid laterally. In cross-section they resemble the form of a Roman arch, providing some inherent stability. They are held in place by strong plantar ligaments and weaker dorsal ligaments that are little more than the condensation of the joint capsule. Medially, the joint is relatively stable. The fourth and fifth tarsometatarsal joints permit significant motion, which allows the foot to adapt to uneven surfaces.

The base of the second metatarsal is recessed between the medial and lateral cuneiforms. Lisfranc’s ligament extends between the plantar aspects of medial cuneiform and the base of the second metatarsal. Strong ligaments connect the second to fifth metatarsals, but there is no corresponding connection between the first and second metatarsal bases.

The first metatarsal is shorter and wider than the lesser metatarsals. The first metatarsal head bears twice the weight of each of the lesser metatarsals through the two subjacent hallucal sesamoids.

The lesser metatarsals demonstrate increasing sagittal mobility from medial to lateral. The only extrinsic attachments on the lesser metatarsals are the peroneus brevis and tertius muscles as they insert on the base and shaft of the fifth metatarsal, respectively.

An extension of the plantar aponeurosis, the deep transverse metatarsal ligament, serves as a transverse ‘tether’ between the metatarsal heads, except between the first and the second. This structure also limits excessive mobility in the sagittal plane.
The hallux has two phalanges, each with the insertion of a flexor and extensor tendon. The three phalanges of each lesser toe are similar. Flexor digitorum brevis attaches to each intermediate phalanx by way of two separate slips on either side of the flexor digitorum longus tendon. The distal phalanges are small and serve as attachments for the extensor digitorum longus and flexor digitorum longus.

The plantar aponeurosis runs from the tubercle of the calcaneum to the base of each proximal phalanx. It provides static support for the medial longitudinal arch of the foot. On dorsiflexion of the toes, the effective length of the aponeurosis shortens—the windlass effect—and further stabilizes the longitudinal arch.

**Clinical evaluation**

The majority of mid- and forefoot fractures occur in isolation. They are the result of low and medium energy trauma. Careful clinical examination for localizing tenderness will usually identify the anatomical location of the injury. Swelling and bruising develop rapidly, and may mask rather than reveal the exact site of injury.

The evaluation of high-energy injuries is more of a challenge. There may be other injuries that require immediate attention or distract from the ‘minor’ foot injury. In addition to identifying any fracture or dislocation, the soft tissue element must be considered. The presence of open injuries or devitalized skin from crush or degloving must be noted. Compartment syndrome should be excluded, although this can be more difficult to assess in the foot than the leg. The neurovascular status must be carefully evaluated and documented, especially after any manipulations.

Once assessed, the foot can be elevated and rested in a well-padded splint. A pneumatic compression device may be used in the case of severe, closed soft tissue injuries if tolerated by the patient.

**Investigations**

The majority of mid- and forefoot injuries can be diagnosed and managed on the basis of plain x-rays. The x-ray should be centred on the area of clinical concern. Standard dorsoplantar, lateral, and oblique views should be requested. Additional specific views, e.g. for the sesamoids or Lisfranc’s joint, will be required on the basis of clinical examination.

When initial x-rays are normal or inconclusive, further imaging is required. Stress x-rays may be taken with the patient anaesthetized or with a more cooperative patient weight bearing after severe pain has resolved. However, computed tomography (CT) scan is the most useful additional investigation for diagnosing subtle injuries or defining the nature of complex injuries in greater detail. Appropriately directed requests and discussions with the radiologist are more likely to be fruitful than undirected scans.

**Specific injuries**

**Navicular**

The navicular is the keystone of the medial longitudinal arch of the foot—being wider dorsally than plantarwards. It is also wider medially than laterally. The proximal surface is concave and articulates with the head of the talus. This joint allows significant inversion and eversion as part of the subtalar–transverse tarsal articulation. Distally, it is relatively flat where it articulates with the cuneiforms. Little motion occurs at these joints.

Short dorsal and plantar ligaments support the naviculocuneiform joints. Proximally, the navicular is supported by the spring ligament and tendon of tibialis posterior. The dorsal and plantar talonavicular ligaments receive some reinforcement from the anterior deltoid ligament. Laterally, there is a variable articulation with the cuboid.

The central third of the navicular is relatively avascular. This may predispose to stress fractures of the central navicular and the risk of delayed healing or avascular collapse in acute injuries.

An accessory ossicle, the os tibiale externum, is present in up to 25% of the population. It lies in the insertion of the tibialis posterior to the navicular. It is bilateral 90% of the time. It is possible for adults to fracture the synchondrosis that exists between the ossicle and the navicular tuberosity.

**Classification**

Fractures of the navicular can be divided into fractures of the tuberosity, dorsal lip fractures, fractures of the body and stress fractures. Body fractures are subdivided into displaced and undisplaced. Displaced fractures may be further classified into Type I (coronal plane with large dorsal fragment), Type II (oblique dorsal plantar fragment with large medial fragment and Type III (comminuted). There may be associated injuries to the rest of the mid- and forefoot.

**Management (Box 12.62.1)**

Dorsal lip fractures are avulsion injuries resulting from forced plantar flexion. Other ligament injuries to the midfoot, subtalar and ankle joints should be excluded. They are stable injuries. They can be treated symptomatically with cast immobilization or bracing as required for 3–4 weeks. Prominent fragments that remain symptomatic may be excised.

Navicular tuberosity fractures are caused by forced abduction or eversion of the midfoot on the hindfoot. They should be differentiated from disruption of the synchondrosis of the accessory navicular. Associated fractures of the cuboid or forefoot may
occur in association and so should be considered (Figure 12.62.1). Displacement is uncommon, and may require open reduction and internal fixation with lag screws. The majority of tuberosity fractures can be managed in a supporting below-knee weight-bearing cast for 6–8 weeks. Occasionally, fibrous union occurs. If symptomatic, internal fixation should be considered. Where the fragment is too small, excision of the fragment and advancement and reattachment of the tibialis posterior tendon can be performed.

**Box 12.62.1 Management of navicular fractures**

- Dorsal chip fractures and non-displaced tuberosity and body fractures are treated conservatively (6–8 weeks, below knee weight bearing cast)
- Undisplaced body fractures (6–8 weeks below knee non-weight bearing cast)
- Displaced body fractures are treated with open reduction and screw fixation
- Repetitive trauma (6–8 weeks below knee non-weight bearing cast).

Fractures of the body are often the result of high-energy injuries. They may be isolated, but in all cases associated mid- and forefoot disruption should be considered and managed appropriately. Treatment is aimed at restoring the length, alignment, and stability of the medial column. Reconstruction of joint congruency, especially the talonavicular joint, should be achieved when possible. Specific complications of post-traumatic arthritis, deformity, and avascular necrosis may still occur.

Undisplaced navicular body fractures may be treated in a short-leg non-weight-bearing cast until radiographic healing is complete. This is usually 6–8 weeks. An orthotic device may be used thereafter to support the arch.

Displaced body fractures should be managed by open reduction and fixation when the soft tissues allow. Lag screw fixation is suitable for simple fracture patterns when anatomical reduction has been achieved. When comminution precludes this, the larger fragments may be reduced and fixed to the adjacent cuneiforms (Figure 12.62.2). Bridging the fracture with a plate or external fixator can maintain length and alignment while bone and ligament healing occurs. Any such bridging fixation will require removal before unprotected weight bearing is allowed, usually at 8–12 weeks. Bone graft is used when defects exist after reduction. Primary arthrodesis may be considered in cases where there is extensive destruction of the articular surfaces, taking care to maintain the length and alignment of the medial column.
Stress fractures of the navicular may occur following repetitive trauma, typically running. Symptoms of pain in the midfoot, aggravated by activity and relieved with rest, should raise suspicion of a stress fracture. Plain x-rays may be difficult to interpret, and CT or magnetic resonance imaging (MRI) scan may be required to make the diagnosis. Non-displaced (complete or incomplete) stress fractures should be treated in a short-leg non-weight-bearing cast for 6–8 weeks. Displaced injuries or fractures which did not unite with appropriate non-operative treatment should be treated with open reduction and lag screw fixation and bone grafting. This is followed by immobilization in a non-weight-bearing short-leg cast until union is complete.

Results

The more severe the injury, the worse the outcome. In one study, satisfactory reduction (defined as restoration of 60% of the joint surface) was achieved in all Type I fractures. In 67% of Type II fractures, satisfactory reduction was achieved, and only 50% of Type III injuries were reduced satisfactorily. A satisfactory reduction was associated with a good clinical result (no restriction of daily living but pain associated with vigorous activities).

The majority of undisplaced stress fractures will heal when managed in a non-weight-bearing cast. However, displaced fractures treated by limited activity but persistent weight bearing are liable to result in pain associated with delayed union, non-union, or fracture recurrence. Therefore, operative treatment of navicular stress fractures is advised if radiographs show a wide fracture gap, cyst formation, delayed healing, or extension of an incomplete fracture. Recovery may take up to 12 months.

Complications

Avascular necrosis may follow either traumatic or stress fractures of the navicular body. If avascular necrosis involves only a small portion of the navicular, the patient may still have a satisfactory result. Larger areas of avascular necrosis often lead to collapse, arthrosis, and pain.

Malreduced or unreduced body fractures typically result in painful arthrosis. Persistent pain may accompany non-union of either body or tuberosity fractures (Figure 12.62.3).
CT scan demonstrates the origin of chronic midfoot pain in this runner to be both non-union of a navicular stress fracture and subsequent talonavicular and naviculocuneiform arthritis.

Cuboid fractures

The cuboid occupies an important position in the lateral column of the foot. It articulates with the calcaneus, lateral cuneiform, fourth and fifth metatarsals, and sometimes the navicular. Injuries to this bone may alter articular relationships, which result in long-term deformity and disability.

Fortunately, most cuboid fractures are minimally displaced capsular avulsion fractures associated with inversion injuries and are treated symptomatically. Compressive forces typically produce higher-energy injuries resulting in more serious problems. The mechanism of injury involves forefoot abduction causing compression of the cuboid between the lateral two metatarsals and the calcaneus. Because of this mechanism, the cuboid body fracture has been called 'the nutcracker fracture'. Cuboid fractures often accompany other midfoot injuries, particularly tarsometatarsal joint injuries and navicular fractures.

Cuboid fractures may be difficult to image. Plain radiograph evaluations should include an oblique view. While plain films usually demonstrate this injury, the amount of intra-articular displacement and collapse is often underestimated. CT scan provides more accurate information about the magnitude of displacement and intra-articular incongruity as well as any associated medial column injury that may accompany cuboid fractures (Figure 12.62.4).

Classification

No meaningful classification system currently exists because of their infrequent occurrence. Cuboid fractures are typically referred to as capsular avulsion injuries, displaced or undisplaced body fractures.

Management

Avulsion and undisplaced fractures may be treated in a short-leg weight-bearing cast with progressive weight bearing.

Treatment goals for displaced injuries should be those of any displaced intra-articular fracture: accurate anatomic reduction and stable fixation. A longitudinal dorsolateral incision is recommended. The extensor brevis is reflected medially and the peroneal tendons are protected. This approach provides exposure of both calcaneocuboid and cuboid-metatarsal joints. Impaction of the cuboid articular surface is frequently seen. A small distractor placed between the fifth metatarsal base and the calcaneus may be helpful in restoring cuboid length. Articular surfaces should be elevated and buttressed, with bone graft or substitutes. A plate spanning the cuboid from proximal to distal can be applied (Figure 12.62.5). If comminution of the fracture precludes stable fixation, a plate or external fixator may be applied as temporary bridging fixation of the calcaneocuboid or tarsometatarsal joints.
Results

Cuboid fractures are uncommon and so no large series have been reported. However, displaced fractures treated non-operatively tend to fare badly, often requiring late salvage by arthrodesis. In series where fractures have been reduced and fixed adequately, results tend to be better. Therefore, open reduction and stable fixation is recommended for displaced fractures.

Complications

Articular incongruity may result in degenerative arthritis and pain. Cuboid collapse will shorten the lateral column, and may result in medial or lateral foot pain.

Salvage

Fractures of the cuboid that result in post-traumatic arthritis of the calcaneocuboid joint or symptomatic shortening of the lateral column of the foot can be managed by arthrodesis. A tricortical iliac crest bone graft may be used to correct significant shortening.

Degenerative changes at the cuboid-fourth and fifth metatarsal articulation is a more difficult problem. Loss of motion in these joints is more debilitating than on the medial side of the foot. Interposition arthroplasty has been described as a treatment for this difficult problem.

Tarsometatarsal (Lisfranc) injuries (Box 12.62.2)

Lisfranc injuries refers to any bony or ligamentous disruption of the tarsometatarsal complex. This covers a broad spectrum of injuries. A high proportion of injuries are overlooked, especially in multiply injured patients or in low-energy injuries. Associated midfoot injuries are common. Neglected injuries often result in long-term pain, deformity, and disability. Early recognition and appropriate management can reduce the risk of such complications.

Lisfranc injuries may be caused by direct or transmitted forces. Direct trauma may be applied as a dorsal crush or on the plantar aspect, for example through a car pedal (although it is difficult to determine whether an indirect load from the intruding foot well is the more likely mechanism). Longitudinal compressive forces applied to a plantar-flexed foot, as occurs in sport or even from simple falls down a step can be sufficient to disrupt a normal tarsometatarsal joint.

A high index of clinical suspicion is the key to avoid missing Lisfranc injuries. Significant midfoot pain, swelling and bruising, and an inability to weight bear merit active exclusion of a Lisfranc injury. Associated injuries should also be considered (e.g. intercuneiform disruption and cuboid fractures and calcaneocuboid joint injuries). Gentle manipulation of the distal metatarsals may provoke significant tarsometatarsal pain in individuals who have sustained this injury. The foot is usually too swollen at acute presentation to detect subtle instability, but this may become apparent after several days.

X-ray examination should focus on the tarsometatarsal joint. In subtle injuries, weight-bearing views taken after the acute pain has settled or after the administration of local nerve blocks can unmask an occult injury. A 20-degree sagittal oblique anteroposterior (AP) view, 45-degree coronal oblique view, and lateral view should be requested. On the AP view, the medial border of the base of the second metatarsal and the medial border of the medial cuneiform should be an unbroken line (Figure 12.62.6). Avulsion of the insertion of Lisfranc’s ligament, the ‘fleck sign’, may be the only indication of a significant injury. Variants of the Lisfranc joint injury may also involve disruption of the cuneiforms, (Figure 12.62.7). On the oblique projection, the medial base of the fourth metatarsal should line up with the medial border of the cuboid. Normal variations of 2–3mm have been described at this articulation. On the sagittal view, dorsal displacement of the metatarsal bases may be evident. On the lateral view, angular and/or translational abnormalities are often seen (Figure 12.62.8).
Subtle lateral displacement of the base of the second metatarsal relative to the middle cuneiform. Equally, subtle lateral shift of first metatarsal base is also present.

Disruption between the medial and middle cuneiform represents a variant of the Lisfranc’s joint injury. Note the navicular tuberosity fracture, often associated with this injury.

Lateral radiograph demonstrates the first metatarsal to be dorsally translated and plantar widening of the joint. CT scanning is useful to pick up some occult injuries and to evaluate more complex injury patterns to aid in preoperative planning (Figure 12.62.9).

Significant displacement of the base of the second metatarsal is easily seen on CT scans when plain radiographic interpretation is unclear.

Classification

There are a number of classifications for tarsometatarsal injuries. None of these are comprehensive due to the diverse spectrum of injuries. Interobserver agreement is moderate at best. None of the classification systems have been shown to be prognostic. The outline of a popular system is reproduced in Figure 12.62.10.
Fig. 12.62.10  
Simplified classification of Lisfranc’s fracture–dislocation: type A, complete homolateral dislocation; type B, partial dislocation (can be medial or lateral); type C, divergent dislocation. This system does not account for intercuneiform variations.  
(Reproduced from Hansen and Swiontkowski (1993).)

Management

The goals of management of Lisfranc injuries are early recognition, anatomical reduction, and stable fixation. Closed reduction of grossly displaced injuries should be undertaken to reduce further soft tissue compromise. Temporary splintage, elevation, and the use of a foot pump aid the soft tissue management. Open reduction and internal fixation (ORIF) should be performed as soon as the soft tissues allow.

Urgent fixation may be required in the presence of open fractures, compartment syndrome, or vascular injuries together with appropriate soft tissue management. In complex injuries, it is reasonable to stabilize the injury with temporary bridging fixation until the patient’s general condition and soft tissue allow, and a suitably experienced team is available to perform definitive surgery.

ORIF is recommended for displaced tarsometatarsal joint injuries. Even if closed reduction can be accomplished, instability persists. Incisions must be planned to allow exposure of the relevant joints to confirm reduction. Fixation with a single positional screw of 3.5mm diameter is usually sufficient for the first to third tarsometatarsal joints (Figure 12.62.11). More complex fractures may require bridging with plates or external fixation.

More recently, it has been proposed that in patients with purely ligamentous injuries that fusion of the first to third tarsometatarsal joints is associated with a better outcome than open reduction and fixation alone. This has yet to receive acceptance across the board, but it has been my practice to consider arthrodesis in the older, low-demand patients with isolated Lisfranc’s joint injuries.

Reduction and fixation of the fourth and fifth tarsometatarsal joints should be performed if displacement persists here after medial tarsometatarsal joint stabilization.

Protected weight bearing in a brace or cast may start at 8 weeks along with an active range of motion exercise programme for the hindfoot, ankle, and metatarsophalangeal joints. Hardware removal may be considered after 4 months. If the more mobile fourth and fifth tarsometatarsal joints have been stabilized, the lateral hardware should be removed before weight bearing.

Results

Better results are achieved when better reduction is achieved and maintained. Patients treated by open reduction and internal fixation do better than those treated by closed reduction and percutaneous pinning or closed reduction and plaster immobilization.
Quality and maintenance of the initial reduction correlate with better clinical results. However, patients defined as having good or excellent result often complain of residual symptoms. Those who do significant amounts of standing or walking are often not able to return to their pre-injury level of activity.

In patients with unrecognized or inadequately treated injuries pain and swelling and deformity often lead to significant impairment and disability.

Complications

Compartment syndromes may accompany Lisfranc joint injuries. This is discussed later.

Wound slough, particularly when using a two-incision technique, has been described. This problem can be minimized by waiting until the soft tissues are showing signs of wrinkling, no undermining of skin incisions and maintaining a skin bridge of at least 3cm.

Nerve injury, particularly the deep peroneal nerve and medial branches of the superficial peroneal nerve, can be minimized by careful dissection.

Hardware problems including screw breakage may also occur if the patient prematurely bears weight. Reflex sympathetic dystrophy may be the result of either the injury or surgical treatment. Early recognition and aggressive treatment can minimize any functional disability.

Salvage

Tarsometatarsal arthrodesis is indicated for patients with intractable pain following a Lisfranc's joint injury. Restoration of normal midfoot alignment should be the goal in addition to bony union of the affected joints.

Good pain relief may be expected, although a significant minority of patients may continue to complain of disabling pain despite successful fusion.

Midfoot sprains

The diagnosis of midfoot sprain should be one of exclusion. It may be applied to midfoot injuries when significant bony or ligament injury has been ruled out by appropriate clinical and radiological examination. As described earlier, midfoot fractures and dislocations may be subtle. Until these have been excluded, this diagnosis should not be used.

Radiographic evaluation

These injuries should be investigated as for suspected unstable injuries. Good quality plain x-rays are the mainstay. Weight bearing or stress views may be required to confirm stability. CT or MRI scans may be indicated if the diagnosis remains unclear.

Box 12.62.2 Tarsometatarsal injuries

- May be difficult to diagnose:
  - Routine x-rays
    - 20-degree sagittal oblique AP view
    - 45-degree coronal oblique view
    - Lateral view
  - Weight bearing or stress x-rays
  - CT
- Displaced and unstable injuries: ORIF ± arthrodesis
- Quality of reduction may relate to functional results
- Tarsometatarsal arthrodesis for salvage.

Management

Stable injuries may be managed by early functional rehabilitation. A failure to improve rapidly should prompt a review of the initial diagnosis, with repeat investigations if appropriate.

Results

With accurate diagnosis to exclude unstable injuries, the majority of patients make a good recovery. This may be prolonged, with return to sports taking up to 3 months.

Fractures of the medial four metatarsals
Fractures of the metatarsals are relatively common. Most authorities agree on early weight bearing for undisplaced fractures, although specific thresholds for reduction and fixation of displaced fractures are not established. However, relatively minor displacement and angulation can alter the distribution of weight across the forefoot, leading to intractable plantar keratosis or transfer metatarsalgia.

**Classification**

No specific classification system exists for all metatarsal fractures. Fifth metatarsal fracture classification and management are discussed separately.

**Management**

Undisplaced fractures may be treated by protected weight bearing in a cast or rigid soled shoe. The patient is allowed to weight bear once the acute pain has settled, and this may take 3–4 weeks.

The amount of displacement that can be accepted is not defined. However, most authorities suggest that more than 3mm of displacement or 10 degrees of angulation is likely to compromise forefoot function. In these cases, particularly in the more active patients, reduction and fixation may be required.

Closed reduction using Chinese finger traps can be attempted in cases of significant displacement. If a stable reduction is achieved, a short-leg cast is applied and progressive weight bearing initiated. If it is not possible to achieve a satisfactory and stable reduction, open reduction and internal fixation is required. First metatarsal fractures may require plate fixation, and there are many implants designed for use in the foot specifically. An external fixator may be used to reduce the fracture and maintain length and alignment as a definitive treatment (Figure 12.62.12). In the case of lesser metatarsal fractures, K-wire fixation may be sufficient, but for more unstable fracture patterns, plate fixation may be required (Figures 12.62.13 and 12.62.14).

Fig. 12.62.12
A) Comminuted short first metatarsal fracture associated with other forefoot trauma. B) The first metatarsal has been brought out to length and stabilized by an external fixator. Second metatarsal neck fracture and tarsometatarsal injury are also stabilized, restoring bony forefoot relationships.

Fig. 12.62.13
Schematic diagram of fracture fixation options in the forefoot.
Metatarsal fractures are more likely to angulate than shaft fractures. Therefore, ORIF is more likely to be required to achieve healing in a satisfactory position.

Displaced intra-articular metatarsal head fractures are uncommon. Displaced injuries should be reduced, with small fragments debrided. Fixation can be achieved with intramedullary K-wire fixation for about 3 weeks, or lag screw fixation of larger fragments. Avascular necrosis of smaller fragments does not appear to be a significant problem.

**Complications**

Malunion is the most common complication. Shortening or elevation of a metatarsal, particularly the first, may lead to transfer metatarsalgia. Plantar displacement or angulation may cause an intractable plantar keratosis. Post-traumatic interdigital neuroma may accompany malalignment in the transverse plane. Non-union is rare.

**Salvage**

Orthotic management often provides satisfactory relief of transfer metatarsalgia in the majority of cases. If non-operative measures have failed, surgery can be considered. The aim should be to restore relative length and alignment of the metatarsal heads. Osteotomy, with interposition structural grafting can be effective in more severe cases. However, this may exacerbate pain and stiffness in the distal metatarsophalangeal joint. Where overload of a single metatarsal exists, osteotomy to shorten or elevate the metatarsal head can be undertaken. The patient should be warned that this might transfer load to an adjacent metatarsal. Diaphyseal shortening or dorsiflexion osteotomy of the overloaded metatarsal may be considered, but can result in subsequent overload of the adjacent metatarsal.

**Box 12.62.3 Medial four metatarsals**

- Non-operative treatment with protective below knee splint weight bearing as tolerated if:
  - <10 degrees angulation
  - <3-4mm of shortening
- Otherwise consider closed/open reduction and internal fixation
- First metatarsal may require a plate or external fixator to maintain length
- Most common complication is malunion and subsequent abnormal load distribution.

**Fractures of the fifth metatarsal (Box 12.62.4)**

Fractures of the fifth metatarsal are the most common fracture in the forefoot. Fractures of the shaft should be evaluated and treated in the same manner as described for the medial four metatarsals. The mobility of the lateral tarsometatarsal joints does allow greater tolerance of malalignment. However, prominence of a lateral spike may require resection once the shaft fracture has united. Fractures of the proximal fifth metatarsal are considered separately.

**Classification**

Fractures of the base of the fifth metatarsal can be subdivided into fractures of the metaphyseal/diaphyseal junction (Type I). These may be minimally displaced (Type IA) (Figure 12.62.15) or multifragmentary or displaced (Type IB). Stress fractures (Type II)
may be more distal, and associated with a suggestive history including prodromal pain. X-rays may reveal sclerosis and or lucency around the fracture line, and a periosteal reaction. Type III fractures are those of the tuberosity or so-called ‘avulsion’ fractures. Type IIIA fractures are extra-articular and IIIB fractures extend into the fifth tarsometatarsal base.

**Box 12.62.4 Fractures of the fifth metatarsal**

- Mid-diaphyseal and distal fractures are treated similar to the medial metatarsals
- Non-operative treatment can be considered in undisplaced fractures:
  - Metaphyseal-diaphyseal fractures—non-weight bearing until evidence of radiological union
  - Undisplaced tuberosity fractures
- Operative treatment should be considered in:
  - Stress fractures
  - High demand
  - Recurrent fractures
  - Tuberosity fractures displaced >2mm.

**Fig. 12.62.15**
A) Acute type IA fracture. The patient refused treatment. B) The patient presented with persistent pain 3 years later. Non-union with significant intramedullary sclerosis is present.

**Management**

Acute Type I fractures are most commonly treated in a below-knee non-weight-bearing cast until signs of clinical and radiological union are well advanced. This may be up to 6 weeks. Premature weight bearing is associated with an increased risk of delayed or non-union.

Early operative treatment may be considered for patients with higher demand, recurrent fractures, or stress fractures. Surgery usually allows a more rapid functional recovery and return to pre injury activities. The majority of such injuries can be treated with intramedullary lag screw fixation alone (Figure 12.62.16). A 4.0-mm screw is often used, although depending on the size and contour of the fifth metatarsal, a 3.5- or 4.5-mm cortical screw may be appropriate. Protected weight bearing is allowed once symptoms allow. Occasionally, bone graft may be required.
Treatment of Type III tuberosity fractures is symptomatic. A cast is not required routinely. The threshold for open reduction and fixation of displaced intra-articular fractures has not been determined. Some authorities have suggested that fractures with more than 2 mm displacement should be considered for reduction and lag screw fixation.

Results
The majority of proximal fifth metatarsal fractures will heal when managed non-operatively and with good functional results. More rapid and reliable union has been reported in surgically treated zone II and zone III injuries.

Complications
Non-union and delayed union are well described complications of type I and II injuries (Figure 12.62.16). This may reflect the vascular watershed and the biomechanical stresses present at the metaphyseal-diaphyseal junction. Non-union of the tuberosity fractures are rarely symptomatic.

In surgically treated fractures, screw penetration through the distal cortex is usually asymptomatic. Screw breakage after may limit salvage options due to difficulty retrieving the distal portion of the screw. Prominent screw heads may require removal once the fracture has healed.

Salvage
Excision of small tuberosity fragments and reattachment of the peroneus brevis is recommended for the unusual case of symptomatic tuberosity non-union. Type I and II injuries that fail to unite can be treated by intramedullary screw fixation.

Sesamoid fractures
Acute fractures of the sesamoid are rare. Bipartite sesamoids are common, with variable patterns. It can be difficult to distinguish a fracture from disruption of a synchondrosis of a bipartite sesamoid. Stress fractures of the sesamoids are well recognized.

Radiographic evaluation should include a tangential view of the sesamoids. An AP, lateral, and axial view of the opposite foot may be helpful in differentiating acute fracture from congenital partition (Figure 12.62.17).
Fractures may be displaced or undisplaced.

Management

The management of minimally displaced fractures is symptomatic. A well-padded cast with a recess for the sesamoids allows early mobilization. Patients with acute sesamoid fractures should be warned that symptoms might persist for months. Surgery should be considered for patients with persistent pain after appropriate non-operative treatment or if the fracture is markedly displaced. Open reduction and lag screw fixation has been described, although excision of the smaller fragments and repair of the short flexors usually provides adequate pain relief.

Complications

Symptomatic non-union or inflammation of the sesamoid–first metatarsal joint may follow appropriate treatment. Persistent pain, restricted dorsiflexion of the hallux metatarsophalangeal joint and plantar flexion weakness are common sequelae of sesamoidectomy. Disruption or imbalance of the short flexors may lead to a cock up toe deformity or hallux valgus or varus. Excision of both sesamoids is not recommended.

Metatarsophalangeal joint injuries

Injuries to the metatarsophalangeal joints range from mild sprains to dislocation. The majority are relatively mild injuries that follow a benign course.

Classification

Dislocation of first metatarsophalangeal joint usually forces the metatarsal head plantar wards. The metatarsal head may buttonhole through the plantar plate without disrupting the sesamoid complex (type I). Sesamoid disruption occurs by tearing of the intersesamoid ligament (type IIA) or a fracture through one or both sesamoids (type IIB).

Management

Sprains are managed symptomatically. After a period of rest, ice, elevation, and compression the patient is allowed to mobilize in a cast or rigid soled shoe. A prolonged recovery is not unusual, and it can take weeks for symptoms to resolve.

Dislocations of the first metatarsophalangeal joints should have a trial of closed reduction. However, interposition of the plantar plate will prevent reduction in Type 1 injuries. In such cases, open reduction through a dorsal approach is required. Sesamoid fractures usually reduce once the joint has been reduced. Loose fragments lying within the joint should be removed.

The first metatarsophalangeal joint is usually stable after reduction. Mobilization in a cast or rigid soled shoe can start as the patient’s symptoms allow. Protected weight bearing for several weeks is advised.

Dislocation of the lesser metatarsophalangeal joints should undergo closed reduction and buddy taping to the adjacent toe until comfortable. Percutaneous pinning can be used to achieve stability in the unlikely event of residual instability.

Results

These are rare injuries, and so large series are not reported in the literature.

Complications

Instability is uncommon following reduction. Post-traumatic pain, from arthritis, loose body formation, or osteochondral injuries may all complicate recovery. Stiffness is common after metatarsophalangeal dislocations.

Salvage

Unstable joints should be reduced, ensuring no soft tissue interposition. If instability persists, transfixion with a K-wire for 2–3 weeks should be performed.

Post-traumatic arthrosis at the first metatarsophalangeal joint is managed by orthotics, injections and fusion when these measures fail.

Fractures of the phalanges

Fractures of the toes are the most common fracture in the forefoot. Phalangeal fractures and dislocations usually occur as a result of a direct blow. They are likely to be painful for 2–3 weeks but rarely cause long-term problems.
Classification

Phalangeal fractures are described as displaced or undisplaced.

Management

Undisplaced fractures or minimally displaced fractures are treated symptomatically. Displaced fractures that result in clinical deformity should be reduced and immobilized by neighbour strapping. Open reduction and K-wire fixation should be considered if a satisfactory closed reduction cannot be maintained.

Displaced intra-articular fractures involving the metatarsophalangeal joint may require ORIF. Displaced fractures that extend into the interphalangeal joints are less troublesome but may still result in joint incongruency and subsequent arthritis.

Complications

Significant malunion can cause localized pressure symptoms. Pain from arthritis or instability resulting from intra-articular fractures is relatively uncommon.

Salvage

Arthrodesis is a predictable salvage procedure for metatarsophalangeal or interphalangeal arthritis of the great toe. Malunion can be managed by resection arthroplasty or arthrodesis in the lesser toes.

Foot compartment syndrome

Compartment syndrome is defined by raised pressure in an osseofascial space leading to localized ischaemia. Once interstitial pressure rises above capillary closing pressure, occlusion of the capillary bed causes myoneural ischaemia. This is responsible for the intense pain of compartment syndrome. If unrelieved, necrosis followed by healing with fibrosis is the end result. These events usually occur in the presence of foot pulses and a warm foot, so an apparently well perfused foot does not preclude the presence of compartment syndrome. Compartment syndrome can develop in the presence of open foot fractures.

The foot has five major compartments that are clinically significant: the medial, central, lateral, interosseous, and calcaneal compartments. Communication between the compartments of the foot and leg may be demonstrated experimentally, but probably occur only under high pressures or following traumatic disruption of fascial membranes.

The diagnosis of compartment syndrome should be considered in any patient with a significant crush injury with or without fractures and dislocations. Massive swelling is usually apparent. Pain is unremitting and out of proportion to the severity of injury. Stretching the intrinsic muscles of the foot by dorsiflexion the toes exacerbates the pain. Other signs of altered sensation, pulses and capillary refill are not reliable indicators.

Compartment pressures may be monitored by passing a needle attached to a manometer under the base of the first metatarsal (medial and central compartments) or through the dorsal intermetatarsal approach (interosseous and central). The calcaneal compartment is reached by inserting the needle approximately 5cm distal and 2cm inferior to the medial malleolus.

Fasciotomy is indicated when the clinical diagnosis of compartment syndrome has been made or pressures reach 40mmHg or is within 30mmHg of the diastolic pressure. They should be performed as soon as possible, although a dilemma exists in patients presenting more than 24h following injury. Fasciotomy may expose necrotic muscle to an increased risk of infection. If surgery is required to reduce and fix the fractures, then decompression may be undertaken at the same time.

Fig. 12.62.18

Foot compartment release can be done through (A) two dorsal incisions and/or (B) a medial approach. Exposure needed for fixation of bony injuries may dictate the most appropriate approach.
Fasciotomy technique is similar to elsewhere in the body. The skin is incised longitudinally without undermining. The muscle fascia is divided to expose the bulging muscle fibres. Dorsal or medial approaches or a combination may be used. Definitive or temporary reduction and stabilization of the skeletal injury is likely to reduce swelling and pain and should be considered if the expertise is available. Pneumatic compression devices can be used to aid swelling reduction. The wounds may be secondarily closed in 5–7 days. Split-thickness skin grafting may be required.

The sequelae of compartment syndrome can include chronic pain, stiffness, clawing or flexion deformities of the toes, and soft tissue atrophy. Chronic neuropathic pain should be distinguished from pain secondary to contractures and deformity. Release of soft tissue contractures to realign the foot and ankle fusion of proximal interphalangeal joints may help with the latter. It must be explained that normal function cannot be restored, although significant improvements in pain and function may be expected.

**Future directions**

A significant amount of foot trauma management is based upon our understanding of basic biomechanics and anatomy. Evidence based medicine in the form of clinical trials is starting to impact upon treatment. However, the evidence base remains thin with regard to tolerable degrees of malunion and optimum methods of operative treatment. In the current climate, it is difficult to see how the time and funding for such research is going to be made available.

Chapter: Osteomyelitis and septic arthritis in children

Author(s): J.S. Huntley and H. Crawford

DOI: 10.1093/med/978019555847.003.013001

Summary points

♦ Staphylococcus aureus is the commonest organism causing both septic arthritis and osteomyelitis
♦ There has been a decline in the number of infantile infections due to Haemophilus influenzae but both Kingella kingae and methicillin-resistant Staphylococcus aureus (MRSA) infections are increasing
♦ Early diagnosis and prompt treatment are key elements to the treatment of both conditions (Boxes 13.1.1 and 13.1.2).

Box 13.1.1 Unwell and feverish? Bone pain and a limp? Assume osteomyelitis

♦ Investigations:
  • Blood tests: FBC, ESR, CRP, cultures
  • X-ray
  • Consider bone aspiration
  • MRI scan
  • Bone scan

♦ Management:
  • IV antibiotics
  • Rest/elevation
  • Reassess
  • Reimage further if condition declines
  • Consider surgical drainage
  • Modify antibiotics.

Box 13.1.2 ‘Septic’ patient? Hot and swollen joint? Assume septic arthritis

♦ Investigations:
  • Blood tests: FBC, ESR, CRP, cultures
  • X-ray
  • MRI scan
  • Aspiration (must not be delayed by imaging)
    — Microscopy (include Gram stain)
    — Cell count
    — Culture

♦ Management:
  • Joint washout
  • IV antibiotics
  • Rest/splintage
  • Reassess
  • Reimage if condition deteriorates
  • Modify antibiotics.

Introduction

Although in the United Kingdom paediatric musculoskeletal infection is a diminishing problem, worldwide, bone and joint sepsis remains a common cause of morbidity. Despite improved imaging, delay to diagnosis remains common and treatment can be challenging. Nelson (1991) warns against ‘a cookbook approach of standardized management for a disease with varied
manifestations and a variable course’. With appropriate management, recurrence is unusual. Complications, however, are difficult to treat and constitute major morbidity. This chapter outlines the pathology, diagnosis, and treatment of paediatric musculoskeletal infections.

**Aetiology, pathogenesis, and pathology**

For osteomyelitis, infection usually occurs by the haematogenous route, with the metaphysis being the most common site for colonization; very rarely, osteomyelitis may involve an epiphysis. Trauma increases the likelihood of osteomyelitis subsequent to bacteremia which may explain the increased incidence in males. Initially there is an acute inflammatory response in the cancellous bone. The formation of pus may lead to perforation of the metaphyseal cortex with subperiosteal accumulation of pus which in turn may breach the periosteum to track externally. A subperiosteal collection may also deprive some cortical bone of its blood supply; the dead cortical bone forms a sequestrum.

Although most bones in the body can be a focus for osteomyelitis, the commonest are the tibia and femur. Similarly, the commonest joints affected by septic arthritis are the knee and hip. The acute inflammatory response involves the influx of neutrophils into the synovial fluid and subsequent rapid destruction of the articular cartilage. Septic arthritis is, therefore, a surgical emergency and joint washout the key treatment.

In joints that have an intra-articular metaphysis (the femoral neck, proximal humerus, proximal radius, and distal lateral tibia), metaphyseal osteomyelitis can transgress directly into the joint. For these joints, particularly, an initial negative aspirate should not provide false reassurance. If the clinical picture deteriorates, secondary infection of the joint may have occurred.

In the neonate, bone and joint infection may present late because of the lack of clinical signs. Furthermore, transphyseal blood vessels allow epiphyseal extension of a metaphyseal osteomyelitis with a subsequent septic arthritis: 60–100% of neonates with septic arthritis have a contiguous osteomyelitis.

**Osteomyelitis**

The presentation and severity of acute haematogenous osteomyelitis (AHO) can vary considerably, sometimes making it difficult to treat. Prompt diagnosis and appropriate intravenous (IV) antibiotics can lead to complete resolution with no sequelae. However multiple complications may occur, if diagnosis and treatment are delayed, or if the patient’s response is poor. Three salient factors must be considered (see Box 13.1.3).

**Box 13.1.3 Factors influencing the presentation of AHO**

- The patient
- The organism
- The bone.

**The patient**

Bone infection occurs predominantly in lower socioeconomic classes where delayed presentation is common. As a result, the infection is well established within the bone before treatment commences and the subsequent clinical course is more likely to be complicated. Other patients also present late, including the immunocompromised, those with neuromuscular disabilities (whose ‘bone pain’ has been misdiagnosed as a fracture), and the neonate with a pseudoparalysis (Figure 13.1.1). If AHO is diagnosed ‘early’ when the infective organism is causing bone pain as a result of local inflammation, then prompt appropriate IV antibiotics will usually result in complete resolution. If there are significant comorbidities, the clinical course is less predictable and patients with diabetes mellitus, haemoglobinopathies, chronic renal disease, and rheumatoid arthritis will often require IV antibiotics for 2–3 months.

**Fig. 13.1.1**

Serial (monthly) radiographs right forearm. A 15-month-old boy had a delayed presentation for forearm tenderness and pseudoparalysis. Despite treatment, he developed whole bone ulna osteomyelitis.

**The organism**
Staphylococcus aureus is the commonest infective organism in AHO but other organisms are relatively more common at specific ages and in certain patient groups. This knowledge influences antibiotic selection. Bactericidal levels of an appropriate antibiotic need to be delivered to the site of infection as swiftly as possible to halt progression (Table 13.1.1).

### Table 13.1.1 A summary of the most common pathogens and the most appropriate antibiotic

<table>

</tr>
<tr>
<td>Infant/child</td>
<td>Staphylococcus aureus</td>
</tr>
<tr>
<td>Sickle cell disease</td>
<td>Staphylococcus aureus Salmonella</td>
</tr>
</tbody>
</table>

If the patient is slow to improve, other organisms like Haemophilus influenzae and Kingella kingae need to be considered. In some areas, community-acquired meticillin resistant Staphylococcus aureus (CA-MRSA) is a significant cause of AHO.

**The bone**

The most common sites of osteomyelitis are the proximal tibial and distal femoral metaphyses. Infection in these areas is relatively straightforward to diagnose and treat. Extension of the infection along the diaphysis is uncommon if treated early, thus whole bone osteomyelitis and its sequelae are rare. Infection in the pelvis, clavicle, and calcaneus is less common, and therefore diagnosis is often delayed. These three bones are largely cancellous and eradication of the infection can take longer.

**Clinical features**

Bone pain, tenderness, and fever suggest osteomyelitis until proven otherwise. A painful limp and general malaise are also features. However, in immunocompromised and neonatal patients there may be few signs until the condition is well advanced. Pelvic osteomyelitis has a large differential diagnosis that includes psoas abscess, urinary tract infection, hip joint sepsis, appendicitis, and gynaecological conditions.

**Clinical investigation**

Blood investigations are: C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), full blood count (FBC), and blood cultures. The CRP is raised in 98% of cases on admission). A normal value does not preclude infection especially in neonates, the immunocompromised or anaemic patients, or in sickle cell disease. The ESR is higher than 20mm/h in 70–90% of cases. The white blood cell count (WCC) may be useful when the differential shows a left shift but it is an unreliable indicator of bone infection, being elevated in only 35–40% of cases. In a young child with bone pain and fever, leukaemia is a possible diagnosis. A blood film and WCC will help determine this diagnosis. Blood cultures are only positive in 30–50% of patients with AHO.

Imaging includes plain radiographs and although these are normal in the initial 7–10 days of AHO, they help with the differential diagnosis (Box 13.1.4). After this early phase there may be periosteal elevation with underlying resorption and/or new bone formation. Other imaging options include the whole body bone scan: a cold scan may indicate early disease or hypoperfusion/osteonecrosis. Magnetic resonance imaging (MRI) is the most sensitive test for osteomyelitis (97–100%) and has a specificity of 73–92%. Furthermore it allows definition of soft tissue extension, intraosseous collection, joint involvement, and aids in planning the surgical approach (Figure 13.1.2).

**Box 13.1.4 AHO: differential diagnosis**

- Septic arthritis
- Ewing’s sarcoma
- Langerhans cell hystiocytosis
- Leukaemia
- Metastatic neuroblastoma
- Sickle cell
- Fracture (e.g. in neuromuscular patient)
- Infarct
- Gaucher’s disease
- Haemarthrosis (e.g. due to haemophilia).
Bone aspiration can identify the infecting organism accurately in 75–80% but reservations concerning this technique within the overall management are outlined in the following section.

**Treatment and prognosis**

The aims of AHO treatment are to treat promptly and appropriately with IV antibiotics in order to prevent overwhelming sepsis, to cure the local disease as rapidly as possible, and to prevent the secondary sequelae of growth plate damage, pathological fracture, osteonecrosis, deep vein thrombosis, and chronic osteomyelitis.

Antibiotics should be given on the assumption that osteomyelitis is present. It is controversial whether or not the bone should be aspirated first. Some surgeons advocate aspiration before starting parenteral antibiotics. However, aspiration usually involves sedation or a general anaesthetic which delays treatment. Therefore in our institution, we do not routinely aspirate bone before starting antibiotics. Antibiotics are given as soon as the diagnosis is presumed and the child is then investigated with either MRI or bone scan. The bone scan is especially useful if multiple sites of infection are present, or if the site is hard to localize. Beware the ‘cold’ scan which may represent early disease or the coexistence of infection and osteonecrosis. If an abscess is present that requires surgical drainage, specimens are attained at that stage, acknowledging that antibiotic treatment may mean that the culture result is negative.

Conversely, in areas where AHO due to MRSA is common, bone aspiration may be useful. Initial treatment is with vancomycin, but subsequently, antibiotics can be modified if/when organisms other than MRSA are identified.

The patient needs to be monitored closely in a hospital environment and clinical improvement, in terms of vital signs, range of movement, and pain, assessed. Not all children respond well. The role of the orthopaedic surgeon is to establish why and reinvestigate. The patient may require repeat imaging, surgical debridement, or a change in antibiotics. In the situation where the infection is not resolving quickly and the child remains symptomatic, a repeat MRI is used to look for further collections (intraosseous or subperiosteal) or spread of infection. Ultrasound scans can also be useful. Infected deep vein thromboses may be visualized in vessels abutting AHO which may result in septic embolization and require anticoagulation (Figure 13.1.3).

The change in CRP values during treatment for AHO is useful in monitoring control of the infection. In conjunction with the clinical findings, a declining CRP can indicate when a change from IV to oral antibiotics is appropriate. For uncomplicated AHO, the CRP is likely to have normalized by day 9. IV antibiotics may be discontinued once the child has improved clinically and biochemically (often <5–7 days) although oral treatment should be continued for a total of at least 3–4 weeks.
The current controversies relate to duration of treatment and when to switch antibiotics to oral (Box 13.1.5). Prolonging IV therapy requires specialized ‘long lines’ that have their own inherent risks. Unless adequate home support is available the child has to remain an inpatient. Each patient with osteomyelitis is unique because of the factors outlined earlier. Therefore the clinical course must be closely monitored, with antibiotics and surgical interventions used appropriately. In resistant/intractable cases and compromised hosts, IV antibiotics should be continued until all clinical features are resolved (and total antibiotic treatment may need to be extended to 6–12 weeks).

**Box 13.1.5 Switching from IV to oral antibiotics? Factors to consider**

- The patient—immuno-compromised vs. healthy
- The bone—proximal tibia vs. pelvis, clavicle, calcaneus
- The organism—Staph aureus vs. E coli, Pseudomonas, MRSA
- The clinical response—rapid improvement vs. repeat surgical debridement.

The timing of surgical intervention is crucial to prevent secondary complications (Box 13.1.6). If pus is encountered on aspiration or an abscess localized by MRI (Figure 13.1.4), then surgical debridement is mandatory. Decisions concerning surgical approach are helped by accurate imaging. Occasionally small abscesses in difficult locations can be drained percutaneously with the help of ultrasound or computed tomography (CT) guidance. This is especially useful in pelvic osteomyelitis where, for example, a deep abscess in the iliacus muscle would otherwise require an extensive surgical approach. Rarely does the bone need to be ‘drilled’ as part of the surgical debridement, as the intraosseous collection has already decompressed itself into a subperiosteal collection. Following debridement, large drains are left in the wounds and the skin edges closed loosely with sutures. A ‘second look’, 48h later, enables a repeat washout/debridement or definitive closure to be performed. If a large amount of pus is still present, the wound is left open and a suction dressing applied.

**Box 13.1.6 Complications of osteomyelitis**

- Chronic osteomyelitis
- Deep vein thrombosis
- Septic thrombus and pulmonary septic emboli
- Overwhelming sepsis
- Growth disturbance (Figure 13.1.5)
- Chronic osteomyelitis
- Pathological fracture
- Antibiotic complications—neutropenia.

Fig. 13.1.5
AP pelvis radiograph. An 11-year-old boy with coxa vara after episode of neonatal left hip sepsis.
Fig. 13.1.4
Sagittal T2-fat saturated MRI section of distal femur. A 3-year-old girl presented with 48h of fever and distal thigh pain with focal bony tenderness. The scan shows a distal femoral subperiosteal abscess.

Depending on the clinical course, patients are seen regularly after discharge, for a clinical and radiographic review and blood tests (WCC, ESR, CRP). For patients on flucloxacillin, weekly liver function tests and neutrophil counts are advisable, as there can be a high rate of flucloxacillin-associated neutropenia (Box 13.1.7).

Box 13.1.7 Keeping out of trouble with osteomyelitis

1. Educate primary care physicians and paediatricians regarding early referral of patients with probable AHO
2. Suspect AHO in a child who is systemically unwell with associated bone pain
3. Aggressive IV antibiotic treatment appropriate to the child’s age and the presumed organism
4. Radiological investigation, especially MRI, to localize collections of pus and to aid surgical debridement
5. Continue IV antibiotics until the clinical symptoms and signs and CRP have improved.

Septic arthritis

Clinical features

A patient with septic arthritis usually presents with signs of sepsis and a hot swollen joint with restricted movement due to pain. Swelling in some joints such as the hip is difficult to detect. For pyogenic septic arthritis the onset and progress is usually rapid and severe. The joint rests in the position of maximum capsular laxity. Such a picture is indicative of a septic arthritis until proven otherwise by appropriate investigations (usually aspiration and microscopy). The picture may be less overt if the patient is on steroids or has been on antibiotics. Limb pseudoparalysis in a neonate, often without overt signs of sepsis, is a typical presentation of septic arthritis.

Clinical investigations

Aspiration is the key to diagnosis with fluid being sent for microscopy, culture, and cell count. Preoperative investigations should include FBC, CRP, ESR, blood cultures, and plain radiographs. In certain circumstances, ancillary imaging (ultrasound, MRI, and bone scan) can help localization, indicate an effusion, or define an associated osteomyelitis. However, these tests should not delay aspiration. An ultrasound can confirm the presence of an effusion but cannot distinguish between infected and sterile fluid.

Criteria for diagnosis

Microscopy of the aspirated fluid may show organisms, confirming the diagnosis. If no organisms are seen, a WCC of more than 40.0 × 10⁹/L has greater than 90% sensitivity and specificity in detecting a septic arthritis. However, WCC of greater than this value may be found in acute inflammatory arthritis. Furthermore, if the disease is detected early or has been partially treated with antibiotics, the WCC may be equivocal. If there is any doubt, proceed to immediate washout.

Differentiating between transient synovitis and septic arthritis can be difficult. Four factors are useful predictors to aid clinical judgement: history of fever, inability to weight-bear, ESR greater than 40mm/h, and WCC greater than 12.0 × 10⁹/L. The CRP rises more rapidly than the ESR in early infection and therefore, is often preferred (Box 13.1.8).

Box 13.1.8 Differential diagnosis of septic arthritis
Osteomyelitis
- Transient synovitis
- Lyme arthritis
- Juvenile rheumatoid arthritis
- Leukaemia
- Avascular necrosis—Perthes disease, haemophilia
- Appendicitis
- Psoas abscess
- Gynaecological conditions.

**Treatment**

A septic joint must be washed out urgently by arthrotomy with high volumes of fluid. For the hip, a Smith–Petersen approach is preferred so that the posterior vessels supplying the femoral head are protected. Tissue biopsy should be performed for histology as well as microbial culture. Parenteral antibiotics, usually for 3–4 weeks, should cover the most likely organisms, and are then adjusted to culture results. The CRP is a useful guide to resolution. There is a trend towards a reduced duration of IV antibiotics.

**Prognosis**

Antibiotics have good joint penetration after surgical washout. If the condition is diagnosed and treated early, the prognosis is good. Neonatal sepsis, particularly of the hip, has a worse prognosis and may be complicated by limb length discrepancy, angular deformity, avascular necrosis, and joint dislocation.

**Special cases**

**Osteomyelitis in sickle cell disease**

Patients with sickle disease have an increased risk of osteomyelitis, and are more prone to complications. It can be difficult to distinguish a sickle crisis from AHO. Fever and raised ESR are suggestive of infection. *Staphylococcus aureus* remains the most common pathogen in sickle cell disease but *Salmonella* must also be covered.

**Chronic osteomyelitis**

Osteomyelitis is considered chronic if it has been present for more than 3 months. The definition of a sequestrum, by both CT and MRI scanning, is important with the aim of aggressive surgical debridement of infected material and sequestrectomy.

**Epiphyseal osteomyelitis**

Primary osteomyelitis of the epiphysis is rare and usually subacute. It presents with mild pain, minimal decrease in function, and little in the way of systemic reaction. The differential diagnosis is large and a gadolinium-enhanced MRI scan is useful in making the diagnosis, localizing and defining the extent of infection, and planning the surgical approach if required (Figure 13.1.6).

![Click to view larger](image)

**Fig. 13.1.6**

MRI right knee. Appearances are of subacute epiphyseal osteomyelitis in a 21-month-old child. There is also a large effusion, which on aspiration was purulent, mandating knee arthrotomy and washout curettage of the epiphyseal abscess.
Gonococcal arthritis

Neisseria gonorrhoeae is a common cause of septic arthritis in the sexually active population. The major differential includes Reiter’s disease. It is usual for more than one joint to be involved. The aspirate WCC is not as high as in pyogenic arthritis. Appropriate antibiotics are IV penicillin or third-generation cephalosporins for resistant strains.

Foot puncture wounds

This injury is common in children: washout, debridement, and tetanus prophylaxis are required. Staphylococcus is the commonest infecting organism. Pseudomonas which has a predilection for cartilage may also be involved, causing a stubborn infection that requires surgical debridement and IV antibiotics.

Sacroiliac joint infection

Infection of the sacroiliac joint presents with pain, abnormal gait, and pyrexia and may be mistaken for a variety of other conditions. Flexion–abduction–external rotation test and direct sacroiliac compression (with the patient prone) are useful in localizing pathology to the sacroiliac joint. A bone scan is also helpful (Figure 13.1.7). Blood, stool, and urine cultures should be obtained. Anti-staphylococcal IV antibiotics are the treatment of choice, and surgical debridement/drainage is not usually necessary.

Fig. 13.1.7
Bone scan. Localizes pelvic pain to the right sacroiliac joint.

Other issues

Panton–Valentine leukocidin (PVL) is a virulence factor secreted by certain strains of Staphylococcus aureus. PVL is capable of destroying host neutrophils, and has also been associated with increased intravascular coagulopathy. PVL is thought by some authorities to be responsible for increased severity of sepsis. In practice, PVL status has not yet been proven to be a useful guide to treatment.

Further reading

Summary points

- Juvenile idiopathic arthritis is defined as an arthritis persisting for at least 6 weeks
- The cause may relate to the immune system response to a stimulus with a synovial or systemic manifestation
- Classification depends on the clinical picture and the immunological markers
- Joint sepsis is often a differential diagnosis
- Most cases respond to simple measures, a few need a structured medical management plan. Surgery is indicated in 10% of cases. All require physiotherapy
- Complications may occur secondary to the disease or its treatment.

Introduction

Juvenile idiopathic arthritis (JIA) comprises a group of diseases that are classified according to mode and age of onset. Their aetiology is not understood. Initially, the classification criteria suffered because they had been adapted from adult criteria, and subsequently because the criteria developed differently across the continents. The current classification system is a research-based tool devised to ensure homogeneous groups of patients were being studied, both in the United States of America and Europe. It is used clinically but in a less rigorous manner and not all exclusion criteria are adhered to. The treatment principles for all forms of JIA are the same: to control completely the inflammation in the affected joint allowing normal growth, development, and function during childhood.

JIA is found worldwide with an incidence in the United Kingdom of 1:10 000 children. It is defined as an arthritis persisting for at least 6 weeks in a child under the age of 16. The arthritis itself is described as swelling of at least one peripheral joint or at least two of the following signs: limited range of movement; tenderness or pain on movement of a joint; or increased warmth of the skin overlying a joint (Box 13.2a.1). The cause may be a combination of genetic and environmental factors that relate to how the immune system responds to stimuli: the resultant inflammatory response may be limited to the synovium or manifested systemically.

Box 13.2a.1 Definition of JIA

- **JIA:**
  - Arthritis persisting >6 weeks in a child <16 years
- **Arthritis:**
  - Swelling of at least one peripheral joint or
  - Two of the following criteria:
    - Limited range of joint movement
    - Pain or tenderness on movement
    - Increased warmth over the joint.

There are a number of important conditions with an associated arthropathy that are not included within this classification system: inflammatory bowel disease, immune deficiencies and reactive arthritis.

Classification

**Oligoarticular (oligo) juvenile inflammatory arthritis**

Oligo JIA, previously known as pauciarthic JIA, is defined as involvement of up to four joints within the first 6 months of the disease. If more joints are involved after 6 months it becomes extended oligo JIA. Oligo JIA is the largest JIA subgroup accounting for 50% of cases. The disease onsets early (median age 5 years) and there is a female: male ratio of 5:1. The knee is the most commonly affected joint. If the child is anti-nuclear antibody (ANA) positive there is a strong association with uveitis. As the uveitis is asymptomatic, slit-lamp examination every 3 months for the first 2 years of the disease to screen for inflammation and thus prevent blindness is essential. Overall, 60% of cases are in remission by adulthood.

Patients with a family history of psoriasis, who are positive for rheumatoid factor (RF) or HLA-B27 or who have a HLA-B27 associated disease or an inflammatory bowel disease are excluded from a diagnosis of oligo JIA.
Polyarticular juvenile inflammatory arthritis

**Rheumatoid factor negative**

Poly JIA patients have more than five joints affected within 6 months of disease onset. It is the second most common subgroup and like oligo JIA, the age of onset is early (median age 6 years) and females are most commonly affected. The arthritis is symmetrical, often involving the wrists, metacarpophalangeal and proximal interphalangeal joint joints, the neck, and the temporomandibular joints (TMJs). If multiple joints are involved in one or more limbs, growth can be delayed.

Similar to oligo JIA, the child may be ANA positive and if so there is a risk of uveitis. Despite treatment, 10–15% of patients with RF-negative poly JIA will have severe functional limitation 10–15 years after disease onset.

**Rheumatoid factor positive**

RF positive poly patients comprise only 10% of the poly group and only 3% of all JIA cases. There is a marked female preponderance (female: male, 13:1) and the median age of onset is later at 9 years. The arthritis is aggressive, symmetrical, and similar to adult rheumatoid arthritis (Figure 13.2a.1).

![Click to view larger](Fig. 13.2a.1 AP radiograph of a wrist showing gross joint destruction in a child with RF positive polyarticular JIA. Her other wrist was similarly involved.)

The diagnosis of poly JIA (RF positive or negative) is excluded if the child is HLA-B27 positive.

**Systemic onset juvenile inflammatory arthritis**

This is the most severe form of the disease. It often presents as a pyrexia of unknown origin. There are three main criteria for diagnosis:

- **Fever**—classically, this daily (quotidian) or twice daily fever rises to more than 38 degrees centigrade and then falls back to or below baseline
- **Rash**—the salmon-pink maculopapular rash comes and goes with the fever (evanescent). It is rarely itchy.
- **Arthritis**—the arthritis may affect one or multiple joints but it may not appear for weeks or even months after the fever has subsided.

In contrast to the other JIA subgroups the female to male ratio is equal and there is no peak age of onset during the childhood years.

The systemic nature of the disease means that there is a generalized lymphadenopathy with hepatosplenomegaly and possibly a serositis (including pericarditis). Uncontrolled disease leads to osteoporosis and severe growth failure and causes a destructive arthritis in 30–60% of cases.

Patients who are RF or HLA-B27 positive are excluded from this diagnosis.

**Psoriatic juvenile inflammatory arthritis**

As the name implies, this subgroup of JIA patients must have an arthritis associated with nail pitting or dactylitis or have a first-degree relative with psoriasis. The condition is commoner in girls and the age of onset is between 7–11 years.

Patients must be RF and HLA B27 negative.

**Enthesitis-related arthritis**
This group of HLA-B27 positive patients used to be labelled as spondyloarthritis but the term is no longer used. It is the only subgroup of JIA that affects males more than females with a later median age of onset at 11 years. (Table 13.2a.1) Asymmetrical large peripheral joint arthritis is associated with enthesitis (inflammation of the muscular or tendinous attachment to bone) and tenosynovitis. Involvement of the axial skeleton is uncommon and usually a late feature.

**Other juvenile inflammatory arthritis**

This research group is used to ‘house’ patients who cannot be classified into any other category.

**Investigations (Box 13.2a.2 and Box 13.2a.3)**

Investigations should be used to help make a correct diagnosis and to exclude other similar conditions.

**Haematology**

Changes consistent with an inflammatory response such as anaemia, a raised platelet and white cell count, and a high erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Patients with oligo JIA may have no such changes.

**Biochemistry**

Patients with systemic JIA may show a transaminitis.

**Box 13.2a.2 Immunological markers in JIA**

- ♦ ANA positive: check for uveitis
- ♦ RF positive: acts like adult rheumatoid arthritis
- ♦ HLA-B27 positive: enthesitis and tenosynovitis.

**Immunology (Box 13.2a.2)**

A positive ANA or RF test clarifies diagnosis and influences prognosis. If the RF level is very high, a diagnosis of systemic lupus erythematosus (SLE) must be considered. HLA-B27 should be performed if the differential diagnosis includes psoriatic arthritis or ERA.

**Microbiology**

The presence of a fever may necessitate a septic screen, virological investigations, and a test to exclude *Borrelia*. If TB is suspected a Mantoux test (and a chest radiograph) should be performed.

**Musculoskeletal imaging**

Plain radiographs may show surprisingly little abnormality but in the more established case there may be periarticular osteoporosis, marginal erosions, and, at the wrist, carpal crowding. MRI will demonstrate synovial hypertrophy with contrast highlighting areas of active synovitis.

**Others**

Synovial biopsy is not required routinely but may be useful in excluding tuberculosis (TB) or sarcoidosis. Similarly, bone marrow aspirate (BMA) and measurement of urinary vanillyl mandelic acid (VMA) in patients with systemic disease excludes leukaemia.
and neuroblastomas (Box 13.2a.3).

**Box 13.2a.3 Investigation pitfalls**

- RF very high: suspect SLE
- Synovial biopsy: not required routinely but excludes TB/sarcoid
- BMA/urinary VMA: excludes malignancy
- Transaminitis: systemic JIA
- Inflammatory markers: may be normal in oligo JIA.

**Differential diagnosis**

The list of differential diagnoses varies a little from subgroup to subgroup of JIA. A careful history and complete examination are essential prerequisites for a correct diagnosis and may influence the line of further investigation. Sepsis should always be considered when only one or two joints are affected (some cases of oligo JIA) but it is less likely in systemic JIA where the involvement (unlike with sepsis) is symmetrical. (Table 13.2a.2).

**Treatment**

Patient and parent education is very important, as the diagnosis of ‘arthritis’ is often associated with incorrect preconceptions. In some cases, all that is required for management is analgesic medication and relative rest. Non-steroidal anti-inflammatory drugs (NSAIDs) help pain, stiffness, and fever whilst physiotherapy maintains range of movement and muscle strength or helps rebuild
muscle that may have wasted secondary to lack of activity and the release of inflammatory cytokines.

Other cases require a more structured medical management plan.

**Steroids**

If only a few joints are involved, intra-articular steroids may be used under general anaesthetic for children under 8 years and nitrous oxide for older patients. The steroid of choice is triamcinolone hexacetonide at a dose of 1mg/kg for each large joint.

Oral or intravenous steroids are used if systemic features are present or if there is multiple joint involvement.

**Other drug therapies**

- Methotrexate: this disease-modifying agent is used frequently but only in oligo JIA and if several joints are involved. If joints are not controlled by intra-articular steroids, methotrexate should be used promptly at a dose of 10–15mg/m²
- Sulphasalazine: used specifically in ERA patients
- Anti-TNF: antitumour necrosis factor drugs such as etanercept, infliximab or adalimumab are used if methotrexate fails to control the disease or the patient has axial ERA.

Occupational therapy has an important role particularly in patients with systemic disease or multiple joint involvement. Hand therapy is important but overall, joint splintage is not used frequently; the emphasis is on maintaining the activities of daily living with joint movement and normal weight-bearing activity when possible (physiotherapy).

### Outcomes and complications

#### Failure of normal growth and development

A generalized growth failure may occur due to disease activity, more commonly in patients with systemic JIA than with poly JIA. However, a localized failure of growth may occur at any affected joint and premature fusion of a growth plate may lead to a clinically apparent limb length difference. Some patients demonstrate an overgrowth phenomenon secondary to the inflammatory response and the associated increase in blood flow. This too may lead to limb length inequality or an alteration in limb alignment: commonly increased knee valgus.

Pubertal delay is uncommon and seen only in severe disease.

**Amyloidosis**

Amyloidosis is only seen in some systemic JIA patients after years of uncontrolled inflammation documented by persistently elevated ESR/CRP levels. With improvements in medical therapy, the incidence of amyloidosis has fallen.

**Macrophage activation syndrome**

This can occur secondary to any systemic inflammatory disease. Macrophage activation within the bone marrow causes macrophages to ingest red blood cells, platelets and fibrinogen. The patient becomes unwell acutely with a marked fall in platelets, fibrinogen, and ESR. The condition can be fatal.

**Osteoporosis/fractures**

Both complications can occur in patients with uncontrolled inflammation particularly in multiple joints and are thus more common in systemic JIA (and some poly JIA cases).

**Joint damage**

Restriction of joint movement secondary to pain and soft tissue contracture is common and all efforts must be taken to minimize this. Loss of cartilage leads to a reduction in joint space, problems with malalignment, and abnormal joint loading often requiring orthopaedic management (see Chapter 13.2b).

TMJ involvement in childhood may lead to micrognathia with dental and cosmetic consequences (Figure 13.2a.2). If associated with inflammation or fusion (Figure 13.2a.3) of the cervical spine there may be significant restriction of neck extension. Both problems may cause anaesthetic difficulties.
Three-dimensional CT scan of a child early onset JIA and temporomandibular joint involvement that led to reduced joint movement and micrognathia causing difficulties with anaesthetic intubation.

Fig. 13.2a.3
Lateral radiograph of a cervical spine showing posterior fusion from C2–C6 secondary to JIA.

Atlantoaxial dislocation is rare but has been noted in patients with poly JIA and ligamentous laxity.

Avascular necrosis of the hips is not uncommon and may be related at least in part to treatment with steroids, or persistent active disease (Figure 13.2a.4).

MRI scan of the pelvis showing avascular necrosis of the right femoral head and a joint effusion.
Summary points

- Approximately 10% of juvenile idiopathic arthritis cases will require a surgical procedure.
- Non-operative management aims to prevent deformity, promote normal growth, and maintain function.
- Perioperative problems must be anticipated and managed appropriately.
- Deformity may be treated by soft tissue release and/or osteotomy.
- Synovectomy may be useful if the articular surface is well-preserved.
- Arthrodesis is rarely indicated except in the wrist/hand.
- Arthroplasty is successful in restoring function.

Introduction

Juvenile idiopathic arthritis (JIA) is classified into three subtypes: systemic onset arthritis (10–20% of patients), typically involving fever and extra-articular manifestations, such as rash and myalgias; oligoarthritis (50–60% of patients) with four or fewer joints affected asymmetrically; and polyarthritis (20–30% of patients) characteristically involving multiple joints symmetrically. These are discussed in greater detail in Chapter 13.2a. The most common presentation to an orthopaedic surgeon is with subtalar arthritis and an associated valgus hindfoot but the most frequently involved joint is the knee.

As the aetiology and pathogenesis of JIA is unknown, treatment is supportive rather than curative, requiring specialist care from a multidisciplinary team. A holistic management plan to restore full function should include a rheumatologist, physiotherapist, occupational therapist, ophthalmologist, orthopaedic surgeon, and a psychologist for support and to ensure the child and their family cope optimally with the demands of JIA, enabling the child to integrate fully with their peer group.

Principles of management

Surgery now has a well-established role in the management of JIA with approximately 10% of children treated by a rheumatology unit requiring open surgical procedures. Short-term management is aimed principally at maintaining function, controlling inflammation, and reducing the resultant joint deformity, and thus in the long term, promoting normal growth and development and encouraging education and rehabilitation. The goal is to use the simplest, safest, and least invasive treatment strategy to maintain a normal lifestyle and to minimize morbidity and hospitalization.

Inflamed, arthritic joints will develop flexion deformities rapidly if managed inappropriately whilst prompt medical management, physiotherapy, and judicious splintage will maintain correct joint position and function. Should contracture occur despite this, the procedures to consider include intra-articular steroid injection, synovectomy, soft tissue release, epiphysiodesis, osteotomy, and arthroplasty. Arthrodesis is rarely indicated, other than in advanced disease of the hand or foot where splintage has failed.

Perioperative considerations (Box 13.2b.2)

The perioperative management of patients with JIA requires input from a multidisciplinary team. Anaesthesia can be problematic (Box 13.2b.2) due to the small airway, hypoplastic mandible, and stiff or unstable cervical spine and preoperative radiographic evaluation of the cervical spine is essential. Difficult airways may require malleable or fibreoptic intubation, or emergency tracheostomy. Laryngeal masks are useful in patients who cannot be intubated. To reduce the risk of postoperative infection, oral steroids should be stopped on the day of theatre; parenteral therapy is used during the perioperative period until the patient is able to tolerate oral medications.

Box 13.2b.1 Useful surgical procedures in JIA

- Intra-articular steroid injections
- Synovectomy
- Soft tissue release
- Epiphysiodesis—temporary/permanent
- Osteotomy
- Arthroplasty
- Arthrodesis—rarely in large joints.
Box 13.2b.2 Potential perioperative pitfalls for the JIA patient

- Stiff or unstable neck
- Micrognathia
- Inability to open mouth due to TMJ problems
- Side effects of steroid use
- Anaemia of chronic disease
- Osteoporosis.

Disease-associated hypervascularity in combination with disuse, means the bones of a JIA patient can be osteoporotic, especially when corticosteroids have been administered, so intraoperatively the limbs should be handled with care. Often the bones are smaller than normal due to growth retardation but, should JIA start in adolescence, bones may be of normal size with a large medullary cavity secondary to a thin cortical rim.

Postoperative rehabilitation can be hampered by general disease activity or more specifically adjacent joint disease activity. It is crucial to identify signs of JIA in adjacent joints preoperatively, as this will affect the success of the planned operation.

Intra-articular steroid injections

Due to their deleterious side effects, systemic steroids should be avoided where possible. Intra-articular injections of corticosteroid such as triamcinolone hexacetonide, have been shown to be safe and effective at controlling synovitis (see Chapter 13.2a). They provide rapid analgesia and facilitate physiotherapy allowing reduction or withdrawal of systemic therapy and a swifter return to normal activity than with systemic treatment alone. The early and repeated use of steroid injections reduces leg length discrepancy in oligoarthritis and prevents joint contractures. The joint effusion should be aspirated prior to injection and the fluid sent for microbiological analysis.

The post-injection regimen of rest, splintage, and physiotherapy remains controversial and has not been studied prospectively in children. It may be difficult to enforce rest in ambulatory children and whilst physiotherapy is helpful, splintage to prevent contractures is unnecessary given the efficacy of intra-articular steroids.

Outcome studies should be interpreted critically: there is inconsistency in the disease subtype studied and the time spans at which response is measured. In the largest published series to date (almost 1500 joint injections), the median duration of improvement was 74 weeks and the most effective injection was the first injection into a single joint.

The side effects of intra-articular steroid injections in JIA have not been studied prospectively but subcutaneous atrophy is a well-recognized complication. Infection rates following steroid injection are estimated at 1:100 000 with no reported cases of septic arthritis in the paediatric population. Damage to intra-articular structures has not been seen.

Synovectomy

Synovectomy is indicated when a persistent synovitis has not responded to medical management, in a joint with well-preserved articular cartilage. Given the high rate of spontaneous remission in children, judging the appropriate timing of surgical intervention can be difficult. Some units recommend waiting up to 18 months provided the joint space is maintained. Synovectomy is traumatic and can lead to a temporary increase in pain and this coupled with an uncooperative child can itself lead to stiffness and contracture. As joint damage is underestimated radiographically, MRI is recommended to assess the articular cartilage accurately prior to synovectomy (Figure 13.2b.1).

Click to view larger

Fig. 13.2b.1
A) Plain AP radiograph of knee affected by JIA. Pain and stiffness can make it difficult to interpret the extent of the joint pathology. B) An MR image of the same knee showing bony changes particularly in the lateral femoral condyle but with relative preservation of the articular cartilage.
Historically, synovectomy was most commonly performed in the wrist and knee. Recently, the trend has been to avoid wrist synovectomy and to concentrate on intensive physiotherapy and appropriate splintage. Should the wrist stiffen, maintaining an appropriate position will preserve function. Synovectomy of the knee is still accepted practice. Arthroscopic or open synovectomy can prevent the development of permanent contractures by relieving pain, conserving range of motion, and preventing articular damage. However, it will not improve range of motion or fixed deformity without associated corrective procedures.

There are few studies comparing open with arthroscopic synovectomy in the JIA patient. Open synovectomy requires a considerable incision and has a significant infection rate, whereas the arthroscopic procedure is less invasive and more accurate allowing early mobilization, preservation of range of motion, and reduced hospitalization. The recurrence rate for arthroscopic synovectomy is high (around 40%) and is more likely in patients who show systemic signs of disease progression. Synovectomy should not be delayed to allow systemic ‘flares’ to settle. The aim of synovectomy should be to lengthen the life span of articular cartilage and to remove pannus as once the articular cartilage is destroyed, articular function cannot be restored (Figure 13.2b.2).

Fig. 13.2b.2
AP radiograph of a knee 7 years after synovectomy showing a preserved joint space.

Soft tissue release

The initial management of a soft tissue contracture should be physiotherapy and splintage. If this fails, soft tissue releases are often used especially for the hips and knees. Prior to release, joint decompression with or without synovectomy should be undertaken in order to reduce intra-articular pressure. Elevated pressure can lead to ischaemia, subluxation, porotic fractures, cartilage necrosis, and subarticular microfracture.

Fixed deformities lead to accelerated articular damage and secondary deformities in the ipsilateral adjacent joints and corresponding contralateral joint. As movement is restored after release, joint congruency and overall joint nutrition is improved. Should disease remission occur simultaneously, healing of the articular cartilage can occur and prevent more radical operations. If, conversely, the disease progresses then the subsequent prosthetic replacement is more straightforward as the soft tissue release has improved joint alignment. Anterior hip and posterior knee releases are performed commonly. Hip involvement is the most important factor affecting mobility and independence and the typical deformity is that of fixed flexion and adduction. McCullough recommends the following algorithm:

1) Adductor and psoas tenotomy for a fixed flexion deformity (FFD) <25 degrees with an adduction contracture.
2) In addition to the previous step an anterior soft-tissue release with synovectomy for a FFD >25 degrees
3) Adductor and psoas release for an isolated adduction contracture with a laterally subluxed femoral head.

His colleagues report good short- to medium-term pain relief, improvement in gait, and reduction in fixed deformity with total hip replacement necessary in three of 17 patients at a mean 6.3 years after release.

Knee flexion contractures represent a major cause of disability in JIA patients. Soft tissue release can be considered as long as there is a joint space and the valgus deformity does not exceed 15 degrees. A particularly difficult problem is that of posterior subluxation of the proximal tibia, secondary to anterior cruciate ligament contracture; however, ligament resection still remains controversial. Soft tissue release of the knee is technically demanding and aims to release hamstring, long head of biceps femoris, and the origin of gastrocnemius if required, correcting the flexion deformity and improving mobility. Intraoperative isolation of the common peroneal nerve is vital to reduce the risk of nerve injury. Good improvements in FFD and pain have been reported.

Limb length discrepancy and angular deformity

Limb length inequality develops in JIA as a result of multiple local and systemic factors. Given the propensity for knee involvement in JIA, limb length discrepancy (LLD) most commonly occurs in the lower limb. The distal femoral and proximal tibial physes...
contribute around 2cm per year to limb length. As a result of the inflammatory process, the arthritic knee is hyperaemic adjacent to the physis causing accelerated growth. With oligoarticular disease, or early onset JIA, the medial and lateral aspects of the physis are usually affected equally, lengthening the limb symmetrically. Leg length can return to normal in 2 years with no intervention, either as the arthritis heals or the contralateral knee becomes involved. In a patient with polyarticular disease, a valgus deformity at the knee is common: this too tends to decrease with age. A LLD less than 2cm tends to be asymptomatic and should be treated conservatively with orthoses. If the LLD is due to a FFD that is not amenable to soft tissue release then osteotomy or physeal arrest is indicated. Examination of the ipsilateral hip and ankle is mandatory to ensure there is no other deformity present.

Temporary or permanent epiphysiodesis at the knee is a safe technique even in the immunocompromised child. In a child with JIA the traditional techniques of growth prediction, such as Greulich and Pyle atlas and the Eastwood and Cole graph, are less reliable due to systemic effects of corticosteroids limiting growth and local hyperaemia stimulating growth. Nevertheless, the aim is to achieve correction at skeletal maturity. This requires careful timing of surgery in addition to rigorous follow-up particularly if a temporary epiphysiodesis technique has been used. The possibility of rebound growth following staple removal or further growth of the arthritic joint must be taken into account.

The main indication for osteotomy is correction of an angular or a rotational deformity. Most commonly a supracondylar femoral osteotomy is undertaken to correct a valgus deformity at the knee. Care should be taken when performing the osteotomy as osteoporosis is common. Internal fixation is often difficult given the porotic nature of the bone and a plaster cast may be required for added stability and to maintain joint position. The plaster cast is usually removed at 1 month to enable early mobilization. Some patients require repeat osteotomies for recurrence of the deformity associated with excessive growth.

**Arthrodesis**

As the goal is to preserve range of motion, arthrodesis is rarely performed. However, arthrodesing a deformed wrist in a functional position is beneficial for hand function. This can be achieved by the use of a low profile arthrodesis plate or by intramedullary fixation with a Steinmann pin passed down the third metacarpal via the carpus into the distal radius.

**Arthroplasty**

Arthroplasty is reserved for those patients who have irreversible articular damage with associated restriction of movement, deformity, and significant pain. The choice of treatment and the timing may be influenced by the overall pattern of joint involvement (Figure 13.2b.3). Arthroplasty in a patient with JIA requires care pre-, intra-, and post-operatively to ensure that potential pitfalls specific to the patient group are avoided. Other treatments should be pursued prior to arthroplasty and whilst they may only delay prosthetic replacement, improvement in systemic symptoms and increased growth may be vital for the success of an arthroplasty. The survival rate of total hip arthroplasty (THA) and total knee arthroplasty (TKA) improves with increasing patient age. Currently, joint replacements are undertaken for the hip, knee, shoulder, elbow, wrist, and ankle.

![Click to view larger](image)

**Fig. 13.2b.3**

AP radiograph of the pelvis and lower lumbar spine. The patient has already undergone a spinal fusion and has bilateral hip destruction. The stiffness from all 3 sites has severely limited the patient's ability to mobilize. Bilateral hip joint arthroplasties were performed.

**Hip arthroplasty**

In JIA patients, THA has been used successfully, in terms of functional recovery, for 40 years. The main indications for THA in addition to those mentioned earlier are subluxation/dislocation and protrusio acetabuli. THA is usually undertaken once skeletal maturity has been reached. However, an open physes is only a relative contraindication to surgery as the proximal femoral physis only contributes 15% to limb length and is often damaged by JIA. There is a slightly higher rate of acetabular failure with an open triradiate physes and in our opinion THA should be performed when the triradiate is fused (which may be early as a result of JIA). The relationship between diaphyseal expansion of the femur and the longevity of a cemented or uncemented femoral prosthesis in a growing patient is still unknown. JIA patients are protected by their low weight and low activity but still experience significant...
rates of aseptic loosening. The growing, remodelling skeleton, associated osteopenia and steroid treatment may contribute to early prosthetic loosening. Component wear rates are low in JIA populations because of their low demand.

Should hip and knee arthroplasty be indicated, then the THA should precede the TKA. THA is less painful than TKA and rehabilitation post-THA is possible in the presence of stiff knees. Hip deformity can contribute to knee deformity and correction of the former may suffice. Conservative management of knee contractures are possible with a THA in situ and the best TKA outcomes are seen in patients with strong hip muscles.

In young patients, THA will not usually last a lifetime: the current consensus is, where possible, to use uncemented components. With cemented femoral prostheses, it is difficult to centralize the prosthesis and obtain an adequate cement mantle. Subsequent cement fracture, subsidence, osteolysis, and reduction in bone stock lead to failure. Although cementless stems are technically challenging, careful, gradual reaming and the use of longer modular stems helps preserve bone stock. In early press-fit design stems there was a higher failure rate due to a lack of early fixation. With the advent of porous and hydroxyapatite coating, the results of uncemented femoral components have improved. Despite the characteristics of JIA bone, rapid osteointegration has been demonstrated.

Early to mid-term function is improved in the JIA patient regardless of the fixation method. Postoperatively, function improves more slowly than in patients with other pathologies because of the polyarticular nature of the disease and systemic treatment but both sitting and activities of daily life show marked improvement. In one study, 94% of THA patients were wheelchair bound preoperatively but 88% were still ambulatory at 11-year follow up. Survival at 15 years for cemented THA in JIA is approximately 70% and 90% acetabular and 100% femoral component survival rates for uncemented prostheses have been reported at 13 years.

**Knee arthroplasty**

TKA is indicated in JIA patients with marked functional impairment or disabling pain from advanced joint involvement. As with THA, skeletal immaturity is only a relative contraindication. However, incomplete distal femoral physis closure can lead to progressive angular deformity and arthroplasty should be delayed in those patients with significant growth potential. Contraindications to arthroplasty include systemic or local knee infection, hyperextension deformity, quadriiceps weakness, and Charcot neuropathic arthropathy.

Preoperative physiotherapy and serial casting should be employed to minimize flexion contractures and facilitate the surgery. Postoperative bracing and manipulation to maintain or regain ranges of motion are preferable to increasing the distal femoral excision to accomplish intraoperative correction of deformity. This allows the knee to function more naturally and reduces the propensity to raise the joint line. As little bone as possible should be removed and bone graft used to address bony defects. At the time of TKA, JIA is usually burnt out; however any remaining synovium should be excised. The patella, which is frequently small, deformed, laterally subluxed, and high riding, should be resurfaced and the osteophytes excised.

In the presence of severe flexion contracture or posterior tibial subluxation, the posterior cruciate ligament (PCL) must be sacrificed to achieve optimal soft tissue balancing and alignment. Proponents of the PCL sacrificing prosthesis argue that it allows improved deformity correction, increases joint congruency, and reduces polyethylene wear. However, cruciate retaining prostheses preserve bone stock, allow femoral roll-back, facilitate stair climbing, and absorb shear forces better. There are no long-term studies comparing cruciate retaining or sacrificing prostheses in the JIA patient.

Potential long-term cement failure with component loosening and osteolysis has led to increased interest in uncemented prostheses. As JIA patients are young, uncemented prostheses have obvious benefits; maintenance of bone stock for revision, lack of biological response to polymethylmethacrylate, reduced operating time, no cement extrusion and associated wear debris. There are no long-term results for uncemented TKAs and as cement is tolerated better in the knee than the hip, there is less urgency to abandon its use in younger patients.

Radiolucent lines are common and remain a concern: the majority are asymptomatic and their clinical significance remains to be established. Regular and long-term follow-up of this young patient group is essential.

The literature indicates that TKA in JIA patients with severe and disabling knee joint involvement provides predictably good pain relief and functional improvement. Survival rates ranging from 100% at 4 years to 77% at 10 years have been reported.

**Shoulder hemiarthroplasty**

Shoulder involvement is seen later in the course of systemic or polyarticular JIA, with an incidence of 15% at 15 years. Indications for shoulder arthroplasty are pain, reduced function and joint destruction in patients who have failed more conservative treatments. Significant improvement in joint movement has been reported.

**Elbow arthroplasty**

Encouraging results have been reported following total elbow arthroplasty with 87% of joints showing increased function and a reduction in pain at 2 years postoperatively. Indications include destruction of the ulnohumeral joint with gross restriction of movement (<30 degrees) and pain.

Chapter: An overview of cerebral palsy

Author(s): Lucinda J. Carr

DOI: 10.1093/med/9780195506434.003.013003

Summary points

♦ Cerebral palsy is a permanent disorder of movement or posture due to non-progressive lesions of the immature brain
♦ Magnetic resonance imaging is generally recommended and can provide important prognostic information
♦ Only a minority of cases are due to birth trauma
♦ Modern classification systems incorporate function as well as anatomical involvement
♦ Management aims to maximize a child's potential both as an individual and within society. Other associated conditions may impact on quality of life and participation
♦ Multidisciplinary involvement is essential with use of physiotherapy, orthotics, and tone management (focal and systemic) as necessary.

Definition and introduction

Cerebral palsy is a descriptive umbrella term describing a permanent disorder of movement or posture due to non-progressive lesions of the immature brain. It is the most common childhood movement disorder with an incidence of around 1:400 live births (2–2.5/1000 live births). Despite improvements in obstetric and perinatal care, the incidence has not changed significantly over recent decades.

Although the cerebral lesion is itself static, the clinical manifestations typically evolve over time and with growth. For example, the abnormal movements of dyskinetic cerebral palsy are rarely seen in infancy and the full clinical picture is often only established by the second year. Children with a moderate diplegia often deteriorate during adolescence and become non-ambulant.

Cerebral palsy is defined as a motor disorder but there are often associated conditions, such as perceptual and sensory changes, disturbances of feeding and communication, cognitive and behavioural difficulties, and seizures. This has led to recent calls for a more inclusive definition that acknowledges the wider functional effects of cerebral palsy.

Aetiology

Over recent years a better understanding of the causes of cerebral palsy has been reached due largely to detailed epidemiological studies that have included neuroimaging. Magnetic resonance imaging (MRI) is the more sensitive tool. It allows assessment of the aetiology and timing of the cerebral insult and can provide important prognostic information for families, not just for the affected child but also for future pregnancies. A recent review identified abnormal neuroimaging in 80–90% of children with cerebral palsy. Scan abnormalities may be summarized into three main types as follows.

Brain malformations

Malformations most commonly result from disruption in normal neuronal migration during early pregnancy (<20 weeks' gestation). They account for around 10% of imaging abnormalities seen in children with cerebral palsy. Whilst the majority of these defects are sporadic, there are a number of recognized genetic, infective, and metabolic causes that should be excluded. Typically neuronal migration disorders result in the abnormal development of the gyral and sulcal patterns as in lissencephaly (Figure 13.3.1), pachygyria, and polymicrogyria, or in the periventricular heterotopic collection of abnormal neurones. Occasionally, an early destructive process impedes migration resulting in parenchymal clefts or cysts lined with heterotopic grey matter and often associated with cortical dysplasia (e.g. schizencephaly (Figure 13.3.2) and porencephaly). Infants are usually born at term with no obvious risk factors. The clinical features vary from mild hemiplegia to severe quadriplegia. Epilepsy is particularly common in these conditions.

Fig. 13.3.1
Lissencephaly type 1 (Classical): the term means ‘smooth brain’ and the MRI shows a thickened and poorly convoluted cortex with lack of sulci and gyri. There is reduced volume of white matter without gliosis. The characteristic cell sparse zone is
Grey and white matter damage

White matter abnormalities represent damage occurring before 34 weeks' gestation. They are most common in premature infants. The classical pattern is one of a loss of periventricular white matter (PVL, periventricular leucomalacia, Figure 13.3.3) associated with signal change on T1- and T2-weighted images. Changes generally affect the posterior periventricular regions in diplegia and are more extensive in quadriplegia. Characteristically there is associated irregular enlargement of the lateral ventricles and thinning of the corpus callosum. If the damage is more extensive, both cortical and subcortical changes may result (multicystic encephalomalacia) and a more severe clinical picture is seen.

Damage confined to grey matter is uncommon but is seen in children with dystonic cerebral palsy. Focal infarcts may also extend into grey and white matter. They are almost exclusively seen in children with hemiplegia, involving middle cerebral artery territory.

Ventriculomegaly, atrophy, and cerebrospinal fluid abnormalities

Hydrocephalus is not uncommon in cerebral palsy, particularly following intraventricular haemorrhage related to prematurity. This is distinct from secondary ventriculomegaly due to the volume loss of cerebral atrophy.

The causes of cerebral palsy are often multifactorial. It was once considered that the majority of cases were due to birth trauma but in term infants with cerebral palsy, the current consensus is that less than 10% are due to birth asphyxia itself. Infants that are already compromised in utero are likely to be more vulnerable during the delivery itself. As discussed later, different causal factors are implicated in the different forms of cerebral palsy.

Risk factors

Risk factors are generally divided into prenatal, perinatal (from labour to the end of the first week of life), and postnatal factors. In most term infants, the origins of cerebral palsy can be traced back to the prenatal period, whilst in preterm infants, damage usually occurs perinatally (Table 13.3.1).

Prematurity and low birthweight

Cerebral palsy risk increases with decreasing gestation and birthweight. Studies consistently show that prematurity (<37 completed weeks’ gestation) is the single most important risk factor for cerebral palsy; the risk being approximately eight times higher than in term infants. With intrauterine growth retardation (IUGR) where birthweight is significantly less than that expected for the gestational age, the risk of cerebral palsy is increased further. Although improvements in neonatal intensive care have increased the survival rate of extreme preterm infants, the risk of significant complications remains high, particularly in those of very low birthweight (<1500g). Around 15% of infants of very low birthweight will suffer severe intraventricular haemorrhage or PVL, the majority of whom will go on to develop cerebral palsy. Other major complications such as chronic lung and bowel disease (bronchopulmonary dysplasia and necrotizing enterocolitis) are common in this group. Overall, these children account for only 2.2% of all live births, but they comprise almost 40% of the cases of children diagnosed with cerebral palsy each year in the United States of America.

Multiple births

A multiple pregnancy increases the risk of premature delivery, intrapartum complications, and low birthweight. In itself it is an independent risk for cerebral palsy, particularly where there is fetal or infant death of a twin and this is probably due to monochorionic placentation resulting in twin-to-twin transfusion.

Postnatal factors

Postnatal factors are generally defined as events occurring outside the neonatal period (>28 days postdelivery) and distinguish acquired from congenital cerebral palsy. There is poor agreement as to the upper age limit for this definition which in different studies varies from 2–10 years. Postnatal causes account for 10% of cases of cerebral palsy and despite an improved understanding of the underlying causes in this group, the incidence has not changed significantly recently. The causes in order of frequency are listed in Table 13.3.1. The acquired injuries most commonly result in hemiplegic or four-limb cerebral palsy. An acquired diplegia is very rare.

Classification of cerebral palsy (Box 13.3.1)

Cerebral palsy syndromes are generally classified by the clinical nature of the motor disorder, namely the tonal abnormalities and the anatomical distribution of these abnormalities. There have been many attempts to refine this traditional classification that fails to consider underlying pathological or aetiological factors and any of the associated impairments. The clinical groups are themselves ill-defined: the distinction between asymmetric diplegia and hemiplegia, and between diplegia and quadriplegia is often inconsistent. By convention the predominant tonal abnormality is reported, but in reality, tone is often mixed with both pyramidal and extrapyramidal components.

Surprisingly, there is no measure of function within the current classification system but increasingly physicians are adding some measure of functional grading to the clinical description of cerebral palsy. The Gross Motor Function Classification System (GMFCS) is the most widely used validated measure that can be used as a basis for prognostic counselling and planning management. It is based on longitudinal observations and provides a description of the pattern of gross motor development by severity and age (Figure 13.3.4).
Box 13.3.1 Types of cerebral palsy

- Spastic motor disorders—approximately 60–70%:
  - Diplegia 33%
  - Hemiplegia 25%
  - Total body involvement <10%

- Extrapyramidal/dyskinetic—approximately 15%:
  - Dystonic 10%
  - Hyperkinetic 5%

- Ataxic <10%

- Unclassified—approximately 10%

Fig. 13.3.4

For the practising clinician, the traditional definitions (as described by Hagberg and Hagberg, 1993) still apply and are described here.

**Spastic motor disorders**

The spastic motor disorders are the most common and seen in 60–70% of children with cerebral palsy. Spasticity is just one feature of a wider ‘upper motorneuron syndrome’ and these other factors should also be considered when managing a child with spasticity. They comprise both positive and negative features as illustrated in Table 13.3.2.

Bilateral spastic cerebral palsy

Diplegia

This is the most common cerebral palsy syndrome accounting for around 33% of cases. Clinically, it is characterized by increased muscle tone with legs more affected than arms. Walking is often delayed but more than 50% of affected children will eventually walk. It is the most common consequence of preterm delivery; around 70% of children with diplegia have been born before 36 weeks gestation. The classical pathology of diplegia relates to the PVL seen in preterm infants. This damage typically affects motor fibres to the lower limbs. The nearby optic radiations are also vulnerable accounting for the visual difficulties and strabismus often seen in diplegia. Other associated conditions include epilepsy in around 15% of children and mild to moderate learning difficulties in 30%.

Quadriplegia (also known as tetraplegia, four-limb cerebral palsy, or total body involvement)

It is seen in less than 10% of children with cerebral palsy but these children are likely to have multiple difficulties and significant functional impairment. Damage may result from a variety of cortical and subcortical lesions particularly multicystic encephalomalacia but also from severe PVL and brain malformations. Tone is increased in both upper and lower limbs and often involves bulbar musculature so that typically these children show extensive feeding and communication difficulties. Only the minority will walk. Over 80% will have microcephaly and significant learning difficulties. Epilepsy is present in more than 50%.

Unilateral spastic cerebral palsy

Hemiplegia

Manifest as a unilateral paresis with spasticity, hemiplegia is the second most common cerebral palsy syndrome. It is seen in around 25% of children with cerebral palsy. It is often congenital and without any clear prenatal event. Focal ischaemic lesions and subcortical periventricular lesions are the most common causes. Unilateral brain malformations may be seen in term infants. Congenital hemiplegia often has an apparent ‘silent period’ with the absence of clinical signs in the first 4–5 months. The appearance of strong hand preference around this time may be the first sign of an abnormality. Fifty percent of children with hemiplegia will walk at the appropriate time and most are ambulant by age 2 years. Comorbid features are common, particularly undergrowth of the affected side with abnormal sensation. Visual problems in terms of hemianopia should be looked for. Epilepsy, which is strongly associated with learning difficulties, is present in 30% of cases and subtle behavioural problems are common.

Extrapyramidal/dyskinetic cerebral palsy

Extrapyramidal cerebral palsy

The abnormal movements or postures result from defective coordination and/or regulation of muscle tone. The group is subdivided into dystonic and hyperkinetic forms. In dystonic cerebral palsy (10% of cases), there are slow sustained tonic contractions of limbs or axial musculature, which are often provoked by emotion and effort and associated with persisting primitive reflexes, particularly the asymmetric tonic neck reflex. In hyperkinetic cerebral palsy (5% of cases) movements are purposeless and involuntary and may comprise athetoid movements that are slow, writhing, and distal, or jerky, more proximal choreic movements. There is often some associated spasticity. In the older child, the repeated, uncontrolled neck flexion and extension may lead to a secondary spinal cord myelopathy.

Dyskinetic cerebral palsy

Typically, the child with dyskinetic cerebral palsy is initially hypotonic before the classical features emerge by the second year of life. Dyskinetic cerebral palsy is seen in both term and preterm infants. In the term infant it is most often the result of acute severe peripartum hypoxia. In the preterm infant, it is associated with more prolonged severe hypoxia and/or hyperbilirubinaemia, where neonatal jaundice has led to kernicterus, defined as dyskinetic cerebral palsy associated with sensorineural deafness, abnormal dentition, and supranuclear ophthalmoplegia. Neuroimaging commonly shows basal ganglia changes, sometimes in conjunction with more widespread cortical damage.

Ataxic cerebral palsy

This is the least common subgroup (<10%) of cerebral palsy. The predominant clinical features are those of a non-progressive cerebellar ataxia with poor balance and coordination and intention tremor. The diagnosis is made with caution as there are a number of very slowly progressive disorders, such as Pelizaeus–Merzbacher disease that can mimic this clinically. Neuroimaging should always be performed.

Making the diagnosis

History and examination

From the history, a child may already be identified as ‘high risk’ for cerebral palsy, namely through antenatal detection or through perinatal events and such children should be assessed regularly and early intervention offered if when physical signs emerge. In many children the diagnosis of cerebral palsy is not suspected initially but even in these cases a careful history may reveal risk factors, not previously recognized and on assessment ‘warning signs’ of neurological abnormality may be detected (Box 13.3.2). The child who is labelled with cerebral palsy is presumed to have a static motor disorder. However, motor abnormalities may be the
earliest signs of a neurodegenerative disorder (genetic or metabolic disease) or they may be an early manifestation of more global developmental delay. The clinician should always consider an alternative diagnosis if the child with 'cerebral palsy' has a strong family history of motor disorder, or if history and investigation fail to provide an underlying explanation. Suspicions should also be raised if the physical signs themselves are unusual, such as clearly progressive or fluctuating in nature.

**Box 13.3.2 Early warning signs for the development of cerebral palsy**

- In high-risk neonate:
  - Abnormal tone
  - Irritability and/or seizures
  - Poor feeding
  - Abnormal head growth
- Later signs:
  - Delayed or deviant milestones
  - Persisting primitive reflexes
  - Abnormal tone
  - Microcephaly
  - Comorbid signs (e.g. abnormal visual behaviour).

**Investigation**

To establish the diagnosis of cerebral palsy, further investigation should be considered: neuroimaging is now widely available and is generally advised. It enables clarification of aetiology and more accurate discussion of the likely neurodevelopmental outcome. Neuroimaging will show characteristic abnormalities in approximately 85% of children with cerebral palsy. Many of the neurodegenerative conditions have distinct and characteristic scan abnormalities. Further genetic, metabolic, and neurophysiological tests are indicated if the diagnosis of cerebral palsy is not established or if an alternative diagnosis is suspected.

There are some rare conditions where diagnosis is best established by a ‘trial of treatment’. This is particularly true when despite investigation, cerebral palsy remains unexplained and is associated with a dystonia. There is a spectrum of dystonias which are partially or fully responsive to dopamine. The best described, Segawa syndrome, is often diagnosed initially as a spastic/dystonic diplegia. Children classically present with an abnormal gait that worsens through the day and is improved by sleep. Diagnosis is confirmed by genetic testing and measurement of cerebrospinal fluid (CSF) neurotransmitters. The presentation of the dopa-responsive dystonias is highly variable so that where there is uncertainty, paediatric neurologists advocate a 3–6 month trial of high dose L-dopa.

**Principles of management**

In 2001, the World Health Organization revised their classifications of impairment, disability, and handicap suggesting that classification should now be based on functioning and disability from the perspectives of the individual (structure and function) and society (activities and participation). The principal aim of management is to maximize a child’s potential both as an individual and within society. This requires a holistic approach that is responsive to the specific difficulties of each child and his/her family. For children in the United Kingdom with cerebral palsy, care is generally delivered through a multidisciplinary Child Development Team often coordinated by a key worker (Figure 13.3.5).
relies on communication both forward and backward (and sideways) between all members of the team. A lead clinician or team member should be identified to ensure that all care and communication is coordinated appropriately.

In the child with cerebral palsy, mobility and posture will be of particular concern but other associated conditions should always be considered and indeed there may be times when they are functionally more significant than the motor difficulties themselves. These may include aspects of feeding and communication and medical issues, such as epilepsy, the management of hydrocephalus, and visual problems. Support around behaviour, social care, and education is also essential and often, in more severely involved children, a large team of professionals is involved.

With respect to management, problems and priorities should be agreed between the child, parents, and therapists. Any intervention undertaken should have a clear aim and where possible the outcome measured objectively. In terms of physical management the aims are to maximize function and prevent the complications that result from abnormal tone. Physiotherapy is the first line of intervention and may be delivered through many different techniques. To date, no one method has proven superior. Physiotherapy generally includes muscle stretching and strengthening, to encourage the maintenance of active and passive ranges of joint movements and, where necessary, positioning and seating are addressed. Orthotics are often used to support this.

Systemic or focal medications may be indicated if abnormal tone is clearly affecting function and/or delivery of care. The means of administration and any potential side effects should be carefully considered. The goals of treatment should be agreed and re-evaluated after treatment and where possible objective measures taken. Table 13.3.3 summarizes the oral drugs most commonly used in the treatment of spasticity. In the United Kingdom, baclofen is the drug most widely used in children with spasticity. Baclofen can also be of benefit for dystonia but the anticholinergic drugs, particularly trihexyphenidyl, are the mainstay of treatment. In a minority of patients a trial of L-dopa is indicated.

| Table 13.3.3 Oral drug treatments for spasticity |
|---|---|---|
| **Drug** | **Mechanism** | **Side effects** |
| Baclofen | GABA₉ agonist | Sedation Weakness |
| Diazepam | GABA₆ & ₇ agonist | As above + tolerance |
| Tizanidine | α adrenergic agonist | Dry mouth Tiredness Hepatotoxicity |
| Dantrolene | Inhibits calcium release in muscle | Weakness Hepatotoxicity |
| Gabapentin | GABA analogue | Behavioural change Dry mouth |

Oral baclofen has poor CSF penetration but baclofen can be administered directly into the CNS using an indwelling intrathecal catheter and implanted intra-abdominal reservoir. Thus effective drug doses are delivered to the target areas minimizing systemic side effects. Although the treatment is expensive and specialized, its benefits in spasticity management are well described. It is not yet widely available in the United Kingdom.

To target treatment to more focal areas of spasticity or dystonia, intramuscular injections with botulinum toxin (BTA) should be considered (see Chapter 13.4). BTA injections can be a valuable adjunct in the management of children with cerebral palsy, not just in improving function but also for comfort, cosmesis, and for ease of care.

For comprehensive management, specialist clinics for children with cerebral palsy play a valuable role; in particular combined neurology/orthopaedic clinics, feeding clinics, and clinics assessing and augmenting communication. Close working with Education and Social Services is crucial in supporting the child and family and furthering participation. In the United Kingdom, a Statement of Special Educational Needs provides an individual statutory assessment and agreed care package for the child within an Educational Setting. There are ongoing government initiatives looking at improving the integration of these services.

There are many alternative therapies on offer for families and children and with the increasing use of the Internet this is an area many families will explore. Information online is not always accurate and claims are not always realistic. Ideally this can be discussed openly with the doctors and therapists and advice and information shared. Support groups, in particular SCOPE, offer factsheets about many standard and more alternative treatments. They also run a helpline for children and families.

Transition into adult medical services can be difficult for the child and family and needs careful preplanning. Adult services do not offer the inclusive service seen in paediatric practice and care can often become fragmented.

### Conclusion

Cerebral palsy remains a common condition. Whilst recent studies have improved our understanding of the associated risks and underlying causes we are still a long way from preventing its occurrence. It is important that clinical and scientific data can be
shared between centres and increasingly, clinicians recognize that an agreed systematic approach to describing the clinical and scientific data collected is needed. This will allow further clarification of the causes and better evaluation of any management interventions.

**Further reading**

Summary points

- All patients with cerebral palsy have lower limb involvement
- Determination of the pattern of neurological involvement and the degree of selective muscle control is important when considering orthopaedic intervention
- The neurological insult is non-progressive but the musculoskeletal effects do progress.
- Specific treatment aims must be identified and realistic targets defined
- The appropriate treatment must be selected for the child’s age and stage of development
- It is important to differentiate between dynamic and fixed contractures
- Surgery is only one of the management options and is rarely successful if considered in isolation.

Introduction

Lower limb involvement is universal in the group of disorders of posture and movement that come under the general heading of cerebral palsy. The clinical features of cerebral palsy may closely resemble those seen in older patients with traumatic head injury, stroke and near-drowning events, and the orthopaedic management of all such patients is governed by similar treatment philosophies. The aetiology of cerebral palsy is discussed in Chapter 13.3.

Classification (see Chapter 13.3)

Patients with cerebral palsy may be grouped according to which part of the body is affected. Thus, hemiplegia indicates involvement of the ipsilateral upper and lower limbs whereas diplegia means that although both sides of the body are involved, the lower limbs are most affected. The term quadriplegia has been replaced by total body involvement, reflecting the fact that those patients in whom all four limbs are affected also invariably demonstrate axial problems such as scoliosis and central problems with the bulbar musculature.

Cerebral palsy is also classified by the predominant nature of the underlying disturbance to the motor system remembering that mixed patterns are common.

- **Spasticity**, the most common abnormality and the one around which orthopaedic management is focused, is an increase in muscle tone that occurs as a response to hypersensitive stretch reflexes that a damaged cerebral cortex is no longer able to control
- **Rigidity** is characterized by an involuntary sustained muscle contraction that does not depend on stretching
- **Dyskinetic (choreoathetoid or dystonic) cerebral palsy** reflects damage to the basal ganglia, and is characterized by involuntary movements
- **Ataxic cerebral palsy** is due to cerebellar damage and features problems with balance and limb placement.

Determination of the neurological pattern is important when considering orthopaedic intervention. In general, the responses in patients displaying predominantly spastic patterns are more predictable and reproducible than those involving dyskinetic types. Impairment of selective muscle control in ataxia may limit the success of surgical procedures.

This chapter concerns patients with diplegia and the lower limb problems faced by hemiplegic patients. The hip dislocations encountered in severe total body involvement patients are covered in Chapter 13.6.

Natural history

Although the incidence of cerebral palsy is not decreasing, the prevalence of different types of cerebral palsy is changing. Spastic cerebral palsy is becoming more common and atetosis less so. Furthermore, severe total body involvement cerebral palsy related to prematurity and low birth weight appears to be becoming more common than diplegia due to perinatal asphyxia.

Motor development is delayed in cerebral palsy. Children may be late in reaching motor milestones or fail to develop some skills entirely. Furthermore, they often develop abnormal motor patterns. The persistence of primitive reflexes and the absence of postural reactions at the age of 2 years are associated with a poor prognosis for future walking ability, whereas a child who is able to sit without support by the age of 2 years is likely to be able to learn to walk.

Stretching is necessary for normal muscle growth but spastic muscle resists stretching and consequently, affected muscles become relatively short during skeletal growth. Unless treated, this leads to muscle and joint contractures in the limbs, which in turn contribute to abnormal loading of the skeleton and the development of bone deformity. This deterioration is exacerbated by abnormal postures and movement control problems resulting directly from the central brain lesion. Muscle and joint contractures
often deteriorate rapidly during growth spurts. The sequence of events is shown in Figure 13.4.1.

From the management point of view, it is important to differentiate between dynamic and fixed contractures as well as between mobile and fixed deformities. The term ‘dynamic contracture’ indicates that the muscle or joint in question functions through a restricted range of motion during activity while it still maintains adequate passive range. Similarly, a mobile deformity is one that can be passively corrected. Fixed contractures and deformities are not correctable passively.

Although the neurological lesion is non-progressive, the musculoskeletal consequences of cerebral palsy often change during the growing years. Dynamic contractures and mobile deformities may deteriorate and become fixed. Spastic muscle is not necessarily powerful muscle and muscle weakness is a common associated factor that will compromise function over time as both height and weight increase with growth.

Associated problems

Individuals with cerebral palsy often have other problems which not only influence their motor development, but which should also inform surgical management decisions. Seizure disorder, learning disability, behavioural problems, and abnormal visual perception are common. Impaired cognition may make rehabilitation from surgery difficult and prejudice the outcome of such interventions. However, it is important to remember that many people with severe cerebral palsy have average or above-average intelligence.

Central balance problems cannot be addressed by treating peripheral limb deformity; indeed, some children with severe balance problems may choose to adopt a crouched wide-based externally-rotated gait in order to lower their centre of gravity and achieve better stability.

Inherent muscle weakness has already been mentioned: any assault on spastic muscle will result in further weakening, even if (as in the case of myoneural blockade) this is temporary.

In their efforts to overcome some of their limitations, children with cerebral palsy use various compensatory mechanisms. Hemiplegic children, for example, often vault during walking to obtain clearance of their equinus foot. From the management point of view, it is important to recognize compensations. True primary problems that generate compensations should be addressed. Compensations themselves do not necessarily require treatment but if used over a prolonged period they can lead to secondary deformities.

Overview of clinical management

As mentioned in previous chapters, the care of a child with cerebral palsy is complex and challenging. Parents and other carers devote huge parts of their lives to looking after such children, for whom a mundane event such as feeding or dressing may represent a difficult and time-consuming activity. They are often determined and single-minded in their search for treatments, a wide variety of which are advertised on the Internet although they are often scientifically unsubstantiated.

The management of children with cerebral palsy requires a multidisciplinary approach because of the wide-ranging nature of their problems (see Chapter 13.3, Figure 13.3.4). It must be remembered that musculoskeletal problems are only one aspect of these children’s lives. Coordination between the various disciplines is important, as families may receive conflicting advice or information regarding therapy: a further source of frustration for the family.

Setting up priorities and defining realistic targets is crucial in the management of children with cerebral palsy. Indications for orthopaedic treatment are not always clear. Therefore, when approaching a child and their family it is important to clarify the family’s perceptions of the child’s orthopaedic problems, their priorities in his or her management, and their expectations from treatment.
History

The diagnosis of cerebral palsy is usually made before a child is referred for an orthopaedic opinion. However, occasionally, the orthopaedic surgeon will have the opportunity to make the diagnosis. The possibility of cerebral palsy should always be considered in a child presenting as a toe-walker or with a limp.

It is important to obtain as full a perinatal history as possible. In particular, it is essential to know the neurological type of cerebral palsy as this helps determine orthopaedic management. It is helpful if the child has already been seen and investigated by a paediatric neurologist.

The date at which motor milestones have been attained should be recorded as these give some indication as to what future achievements are possible. A child who cannot sit unsupported at 2 years of age or who has not walked by 4 years is unlikely to walk.

The current walking status should be noted (Box 13.4.1). It is important to establish how well they walk and whether this is stable, improving, or deteriorating. Community walkers can walk reasonable distances outdoors and the approximate walking distance or time should be recorded. Household walkers only walk indoors. Therapeutic walkers walk only limited distances under supervision and do not use walking as their main means of mobility. The use of any walking aids or orthoses is noted. Current or previous therapy and its frequency should be recorded, together with the use of postural management devices such as sleep management systems and standing frames. At the end of this assessment it should be possible to assign a Gross Motor Function Classification System (GMFCS) level to the child (see Chapter 13.3, Figure 13.3.3). This is a useful, clinically validated indicator of motor function that assesses the child’s progress during growth.

Box 13.4.1 Questions to ask the walking patient

♦ What aids do they use?
  • Frames, crutches, sticks
  • Orthoses

♦ How good are they?
  • Community walker
  • Household walker
  • Therapeutic walker

♦ What progress are they making?
  • Improving, static, deteriorating.

The history should also include the presence of associated conditions and details of any previous treatments and their outcomes (Box 13.4.2). It is important to maintain respect for the patient: whenever age and cognition allow, questions should be addressed to the child by name.

Box 13.4.2 Associated difficulties—do they influence choice of treatment?

♦ Increased perioperative risk:
  • Poorly controlled epilepsy
  • Gastro-oesophageal reflux
  • Absent gag reflex

♦ Problems with rehabilitation:
  • Limited cognitive function
  • Visual/perceptual difficulties
  • Poor balance.

Clinical examination

The effect of an unfamiliar or uncomfortable environment and a rushed consultation will be to increase spasticity and make meaningful examination difficult.

The clinical examination starts with an observation of posture: standing, sitting, and lying. Head and trunk control and limb posture
will give an impression of the child’s level of motor development. Balance reactions and primary reflexes may be observed and involuntary movements and obvious skeletal deformities recorded.

Lower limb examination assesses the passive range of motion of all joints and the presence of any fixed contractures (Box 13.4.3). Thomas’s test detects a fixed flexion contracture of the hip but if a knee contracture is also present, the test should be performed with the patient’s pelvis at the end of the table. Alternatively, Staheli’s test is used, where prone hip extension is tested with the patient’s pelvis at the edge of the couch.

**Box 13.4.3 Assessment of joint range—the use of eponymous tests**

- Thomas’s test: hip flexion supine
- Staheli’s test: hip extension prone
- Phelps test: hip abduction
- Duncan–Ely test: rectus femoris
- Silverskjold’s test: gastrosoleus complex.

Femoral anteversion is measured clinically with the patient prone and the knee flexed at 90 degrees. The hip is rotated until the greater trochanter reaches maximum prominence laterally. The angle between the tibia and the vertical is then equal to the femoral anteversion. From this position, the total arc of hip rotation can be assessed.

Hip abduction should be tested first with both hips and knees in maximum extension. Phelps’s test differentiates limited abduction due to adductor tightness from that due to hamstring (mainly gracilis) tightness. Abduction is tested with the knees extended and then with knee flexion: if flexion improves abduction the limitation in abduction is due mainly to hamstring tightness.

The popliteal angle assesses hamstring tightness. With the patient supine, both hip and knee are flexed to 90 degrees, the knee is then brought to maximum extension: the angle between the tibia and the vertical line is the popliteal angle. Normal subjects have a popliteal angle of less than 30 degrees. In the same position, fast extension of the knee is attempted. Spasticity of the hamstrings will prevent extension before the maximum ‘passive’ popliteal angle is reached. This test measures dynamic hamstring spasticity.

Spasticity of the rectus femoris muscle can prevent knee flexion in the swing phase of gait. It is assessed by the Duncan–Ely test. With the patient supine, the knee is flexed rapidly. If the rectus is spastic, it will contract, flexing the hip joint and causing the patient’s buttock to lift off the couch. If the same is observed with slow knee flexion of the knee, a fixed contracture of the rectus is present.

A shortened calf complex (gastrocnemius and soleus) presents as reduced ankle dorsiflexion. Silverskjold’s test involves assessing dorsiflexion with the ipsilateral knee flexed and extended. As the muscle origins of gastrocnemius and soleus originate above and below the knee respectively, this test differentiates between shortening in the two muscles. In estimating dorsiflexion it is important not to allow any hindfoot valgus (as this creates a spurious correction of equinus).

Lower limb examination also includes measurement of muscle power. This can be particularly difficult in the presence of spasticity and impaired selective muscle control. However, measurement of the main muscle groups should be attempted using the Medical Research Council scale. If selective muscle control is so poor that voluntary contraction of major muscle groups, such as the hip or knee extensors is impossible, this should be recorded.

An appropriate neurological examination of the child with cerebral palsy should be performed. The modified Ashworth scale (Table 13.4.1) is used to assess spasticity and the confusion test measures selective muscle control. A child without selective control of ankle dorsiflexion shows contraction of the tibialis anterior muscle when asked to flex the hip against resistance: a positive confusion test.
Table 13.4.1 The Modified Ashworth Scale (Bohannon and Smith 1987)

Gait analysis

Cerebral palsy is a disorder of movement and posture; in the ambulant child, examination of the lower limb is incomplete without an assessment of walking. The conventional static physical examination often fails to reveal the dynamic posturing adopted as soon as a child assumes an upright weight-bearing position: in the past, failure to appreciate the variable and dynamic nature of these postures has resulted in inappropriate surgery. Mistakes have also been made as a result of considering one joint segment in isolation and from failing to realize that the effects of muscle activity at one level (e.g. the ankle) have consequences at distant sites (e.g. the hip). Such relationships can be appreciated only through evaluation of an individual’s gait pattern. A knowledge of normal gait is essential before one can appreciate the errors that occur in cerebral palsy (Figure 13.4.2).

Gait analysis involves the systematic study of the body’s mobile segments and joints during locomotion. Movement is studied separately in the three orthogonal planes, namely sagittal, coronal, and transverse. Observational gait analysis employs video recordings in normal and slow motion to obtain qualitative information about gait. Instrumented gait analysis requires sophisticated laboratory equipment. Kinematic information on the three-dimensional movement of body segments and joints is derived from data generated from cameras tracking markers placed on anatomical landmarks. Data from force platforms relates forces occurring during gait to the kinematic data in order to produce information on moments and powers around joints during gait: kinetic information. Dynamic electromyography via surface electrodes or fine wires provides information on the pattern of muscle activity during gait. This is significantly deranged in many people with cerebral palsy. Energy expenditure is estimated by measuring oxygen consumption.

The information obtained during observational and instrumented gait analysis, combined with the clinical history and examination, aids the understanding of gait deviations and helps plan management. The reliability and reproducibility of gait data have been demonstrated and gait analysis is used in most centres that treat children with diplegic cerebral palsy (Figure 13.4.3). It is also a well-established outcome measure. However, instrumented gait analysis is only a tool that guides management: it should not be used as a prescriptive device that ignores the many other considerations surrounding surgical management of cerebral palsy.
**Fig. 13.4.3**  
Photograph of a child with diplegic cerebral palsy who is about to undergo an instrumented gait analysis. She walks with tripods as walking aids.

---

**Treatment modalities**

Different treatments or management regimens are appropriate for different children at different stages of their growth and development.

From the musculoskeletal viewpoint, the priority in the early years is to maintain muscle length and promote muscle growth in order to minimize risk of contracture and deformity. Muscle grows rapidly in the early years of life, doubling its length in the first 4 years. It takes another 12 years to double again. It is thus sensible, if possible, to avoid surgical interference during these critical early years.

**Physiotherapy**

Physiotherapy has a central role in the management of young children with cerebral palsy. It focuses on assisting motor development whilst preventing the development of deformity and contractures. Serial casting to improve passive range may augment joint range and muscle stretching regimens.

There are many different schools of physiotherapy and related techniques such as conductive education that will not be discussed in this chapter. Claims that one method is better than another are all hampered by a lack of randomized controlled trials. However, it is reasonable to accept that some form of structured physical therapy is of importance in the child with cerebral palsy.

**Orthoses**

Orthoses are used in children with cerebral palsy to aid function and prevent deformity. Immobilizing a muscle in an elongated position provides passive stretching and enhances its longitudinal growth. Orthoses also provide joint stability during gait. Ankle–foot orthoses (AFOs) stabilize the ankle and foot from the early stages of motor development (Figure 13.4.4). An orthosis can also use the ground reaction force during weight bearing to stabilize more proximal joints. Thus, the ground reaction AFO (GRAFO) aids knee extension. This rigid orthosis transfers the ground reaction force applied at the forefoot area to the pretibial area, encouraging extension of the knee (Figure 13.4.5).
Orthoses are used for the postural management of non-ambulant patients. Hip orthoses provide hip abduction in patients at risk of hip dislocation. Standing frames of various designs are used to support patients in the upright position. This is thought to help with the prevention of contractures and osteoporosis. The upright posture is also beneficial for gastrointestinal and urinary tract function, as well as morale.

**Nerve blocks and botulinum toxin**

Spasticity can be reduced by blocking the reflex arc. The previous practice of efferent nerve destruction using agents such as phenol has been abandoned in favour of localized interruption at the motor endplate (myoneural blockade). Although this can be done successfully with diluted (50%) ethanol, it is more commonly performed using botulinum toxin-A (BTA), a neurotoxin derived from *Clostridium botulinum*.

BTA prevents the release of acetylcholine at the motor endplate which results in reduced neural stimulation of the muscle. Over a period of 3–6 months new nerve ends sprout that allow the muscle function to return.

BTA is given as an intramuscular injection into the region of the muscle where the motor end plates are concentrated. Local anaesthetic, often combined with sedation, is used for the injection. Reduced spasticity should be noticed within a few days. BTA is effective in the presence of dynamic rather than fixed contractures: it has been shown to be effective in the treatment of dynamic equinus and is often combined with serial casting for more resistant contractures but there is no supportive evidence for this practice.

The long-term effects of treatment with BTA are unknown, although isolated histological studies of muscle that has been repeatedly treated with BTA are showing evidence of long-term damage and atrophy. To date, treatment has not been shown to prevent fixed contractures or delay the need for surgery. Views on optimal dose and frequency of injections vary. Potential complications, although rare, include local or generalized allergic reaction, fatigue, gastric dilatation, and temporary urinary incontinence.

**Intrathecal baclofen**

Baclofen is used as a systemic drug to control spasticity. However, the dosage required to reduce spasticity is often high leading to undesirable effects, such as drowsiness and confusion. Intrathecal use was introduced for patients with predominant lower limb spasticity. Low doses of baclofen are administered intrathecally via an implanted catheter and pump usually sited in the right iliac fossa (see Chapter 13.6, Figure 13.6.4). A test dose precedes implantation to confirm that the drug is effective for the individual patient at a reasonable dosage. Recharging of the pump or modification of the rate of drug delivery is possible on an outpatient basis. Close patient monitoring and a well-organized team are necessary. Potential complications include leakage of cerebrospinal fluid, migration of the catheter, and infection. The method does reduce lower limb spasticity in children with cerebral palsy.

**Selective dorsal rhizotomy**

This neurosurgical procedure reduces lower limb spasticity in diplegic patients. The operation involves partial (25–40%) division of the posterior nerve roots from L1 to S1. Functional improvement has been documented in the short term.

Patient selection is important and those with neurological involvement other than spasticity must be excluded. Rhizotomy should be performed before the development of any significant contractures. Muscle weakness is unmasked and a secondary spinal deformity may develop.
Orthopaedic surgery

The main indication for lower-limb surgery in the walking child is preservation or improvement of walking function. Unlike the totally involved child with a dislocating hip, pain is not a common problem apart from a group with intransigent anterior knee pain. Similarly, cosmetic considerations are rarely an indication for surgery in this group in contrast to patients with upper limb problems.

Deformity is common in children with cerebral palsy and its presence is not, in itself, an indication for intervention. The deformity must be responsible for current functional impairment or at risk of impairing future function if left unchecked.

The ability to walk and to continue walking is seen by parents and some clinicians as the ultimate goal but overall, patients themselves do not rank the ability to walk as highly as the ability to communicate effectively or to be independently mobile. Many teenagers are encouraged to struggle on with a laborious energy-inefficient assisted gait in the face of increasing weight and increasing demands on their time from other sources when they would be able to lead a more fulfilling and independent life as chair-users.

During the process of defining targets of treatment and planning intervention the potential risks and complications of any procedures should also be discussed as these can outweigh any potential benefit.

Hemiplegia

The vast majority of children with hemiplegic cerebral palsy maintain their ability to walk into adulthood. Orthopaedic referral is usually related to gait abnormalities: delayed or asymmetric walking, leg-length discrepancy, or unilateral equinus deformity. Hypertonia, brisk reflexes, and ipsilateral upper limb involvement lead to the diagnosis of hemiplegia. Posturing of the ipsilateral upper limb by flexing the elbow during gait is a subtle but important sign of a mild hemiplegia (Figure 13.4.6).

Winters et al. (1987) attempted to classify hemiplegic gait according to severity of involvement (Table 13.4.2). They suggested treatment choices for the four different types of hemiplegic gait in their classification. AFOs help with type 1 and some type 2, for fixed equinus in types 2, 3, and 4 surgery may be indicated but in types 3 and 4 management must address problems around the hip and knee simultaneously.

More recently, Hullin et al. described another classification of hemiplegic gait based on kinematic and kinetic gait data. The aim of this classification was to highlight the aetiology of various gait deviations (Table 13.4.3).

**Foot deformity**

The most common foot deformities in hemiplegia are equinus and equinovarus. Spasticity of the gastrocnemius is the primary cause but weakness of the dorsiflexors and the peronei often contributes. Spasticity of the tibialis posterior muscle may also be present. Planovalgus deformity with persistent hindfoot equinus and a collapsed midfoot is much more commonly seen in diplegia.

Clinical examination identifies the muscles responsible for the deformity and distinguishes between the hindfoot varus caused by an overactive tibialis posterior and the forefoot adductus and supination caused by an unopposed tibialis anterior.

Equinovarus foot deformity causes clearance problems during the swing phase of gait as well as stance phase instability as the foot turns into varus and inversion. Furthermore, the ipsilateral knee is subjected to abnormal loading and a tendency to hyperextension. Compensatory hip flexion may be observed.

The severity of the deformity depends on the age of the patient and the degree of involvement. A flexible deformity in young patients becomes more rigid with age although the true natural history is unknown. Some hemiplegic patients develop a fixed equinovarus foot deformity before skeletal maturity. Weight-bearing on a deformed foot should lead to degenerative changes in adult life but there are no long-term studies to confirm this.

The flexible deformity can be treated conservatively. Treatment aims are to improve gait and prevent a fixed deformity. Physiotherapy stretching regimens are used and an AFO maintains the foot in the neutral position, improving gait whilst protecting hip and knee from abnormal loading. BTA injections in the gastrocnemius and the tibialis posterior reduce spasticity. The treatment of fixed deformities may involve surgical lengthening of contracted muscles. In principle, simple Z-lengthening of the tendon should be avoided as this allows further contraction of the muscle belly with consequently reduced power and reduced stimulus to grow. When possible the muscle–tendon unit is lengthened as a whole by means of aponeurotic or intramuscular lengthening techniques.

In addition to muscle lengthening, tendon transfer surgery is frequently performed to achieve a longer lasting balance to muscle action around the foot. Depending on the major source of deformity, either the tibialis anterior or posterior tendons can be transferred separately. Tibialis anterior is often transferred in its entirety whilst split tendon transfers work well for both tibialis anterior and posterior with the split tendons acting like the reins on a horse to control the mid/fore foot. The split anterior tibial transfer is popular: the lateral half of the tendon is sutured to the intact peroneus brevis or transferred more distally via a bone tunnel. This operation works well in conjunction with simple lengthening of the tibialis posterior and gastrocnemius muscles.

Muscle/tendon lengthening is not recommended in early life when rapid muscle growth is occurring: failure to heed this advice results in a high recurrence rate. If surgery is delayed until the age of 7–8 years, the risk of recurrent equinus is minimal.

In the older child with significant fixed deformities, bony surgery may be necessary. This should be combined with lengthening of the deforming muscles. Hindfoot varus is addressed with a calcaneal osteotomy whilst additional deformity may require appropriate midfoot osteotomies. Triple fusion should be reserved only for the severe, symptomatic and rigid equinovarus foot.

**The hip and knee**

Hip dysplasia is uncommon in hemiplegia and dislocation rare.

Femoral derotation to correct anteverision and internal rotation of the leg during gait can be rewarding. It improves gait and prevents excessive knee loading. Extension and valgus can be included in the osteotomy to correct flexion and adduction at the hip. Most hemiplegic patients have a degree of pelvic rotation during gait, with the affected side retracted. This persists following derotation femoral osteotomy and can lead to unacceptable external rotation of the leg postoperatively if the femoral anteverision was corrected fully.

Operations around the knee are rarely indicated. hamstring lengthening to correct flexion contracture can sometimes be combined with equinus foot correction. As in diplegia (see [below](#)) spasticity of the rectus and patella alta may contribute to anterior knee pain. Treatment is challenging and in most cases it is for symptoms only. Interference with the quadriceps-patellar mechanism invites many problems including failure to relieve pain and exposing underlying weakness of the knee extensors.

**Leg-length discrepancy**
Neurological involvement of the affected lower limb results in reduced growth and a leg length difference is common. The discrepancy is rarely more than 1–2 cm and can work to the child’s advantage aiding clearance of the equinus foot in swing phase. For this reason, correction of the equinus deformity may need to be followed by provision of a shoe raise.

When the leg length discrepancy is more marked, gait compensations may be seen. These include increased hip and knee flexion on the unaffected side and pelvic obliquity. A shoe raise is usually all that is necessary, with contralateral epiphysiodesis being reserved for patients with marked discrepancies and relatively mild involvement.

**Diplegia**

The orthopaedic management of children with diplegia relates mainly to problems with their gait. Diplegic patients often have mild upper limb involvement affecting their ability to use walking aids (Figure 13.4.3).

At the severe end of the diplegic spectrum, lower limb involvement is marked, primitive reflex patterns persist, and upper limb involvement is pronounced. This group of patients (resembling the milder end of quadriplegic cerebral palsy) may lose their ability to walk as growth progresses and contractures develop. In contrast, the gait pattern of a child with mild spastic diplegia may seem normal to the casual observer, their problems limited to minor problems with tripping, balance and endurance. It has been suggested that 85% of children with diplegia maintain their ability to walk in the long term but this probably excludes many of the more severely involved children at the poorly defined interface between diplegia and total body involvement.

Diplegic gait is complex. The child with diplegia is delayed in acquiring standing and walking skills. Initially, an extensor pattern of activity is common, featuring a combination of adducted hips (‘scissoring’), stiff extended knees, and ankle equinus (toe-walking). As the child grows, the biarticular muscles (hamstrings, rectus femoris, and gastrocnemius) are the prime targets of impaired control and increased tone, leading to hip and knee flexion contractures and increasingly fixed equinus. The hips become increasingly internally rotated. The equinus is followed by a progressive planovalgus deformity, collapse of the longitudinal arch, and forefoot abduction: the so-called ‘mid-foot break’ (Figure 13.4.7). However, gait variation is infinite, and a classification of diplegic gait has not yet been possible.

**Early treatment**

The general principles of spasticity management apply. Joint ranges and muscle length are maintained, encouraging the acquisition of assisted standing and walking skills, with the help of orthoses. AFOs control equinus and improve limb stability. Myoneural blocks of the gastrocnemius reduce dynamic equinus and encourage a heel-toe gait pattern.

As with hemiplegic patients, surgery should be deferred when possible until the child is 7–8 years old as the risk of recurrent contracture following muscle lengthening at this age is low and any alteration in neural patterning (‘neuroplasticity’) that might have compensated for some of the centrally-mediated gait problems has been exhausted. Lastly, at this age, the concept of extensive surgery and rehabilitation can be explained and understood and some degree of cooperation expected.

**Single-event multilevel surgery**

In the past, poor understanding of the diplegic gait pattern compounded by an inappropriate reliance on static as opposed to dynamic assessment, frequently led to young children undergoing repeated operations each followed by an extensive period of rehabilitation.

The development of gait analysis has led to a much better understanding of the problems faced in spastic diplegia, and in particular how it is inappropriate to consider a joint or limb segment in isolation. This improved understanding, led to the concept of single-event multilevel surgery (SEMLS) in which, following detailed preoperative gait analysis, all gait abnormalities are treated in a single operative procedure with a single period of rehabilitation. This principle has been developed over the past three decades and has changed the management approach to children with diplegic cerebral palsy.

Multilevel surgery includes a variety of procedures tailored for the individual patient. Soft tissue procedures to correct fixed or dynamic contractures are guided by the principle of ‘lengthening without weakening’. Extensive soft tissue releases are avoided. Judicious lengthening is performed, usually at the musculotendinous junction. The muscles crossing two joints appear to be more
Judicious lengthening is performed, usually at the musculotendinous junction. The muscles crossing two joints appear to be more affected in cerebral palsy, probably because of their different function at each joint and thus inevitably more complex neurological control. These biarticular muscles frequently require surgical intervention (Box 13.4.4).

**Box 13.4.4 Site of muscle lengthening: biarticular muscles**

- Iliopsoas: over the pelvic brim
- Medial hamstrings:
  - Fractional lengthening
  - Mid/distal thigh
- Gastrosoleus complex: aponeurotic lengthening
- Rectus femoris: release and transfer.

Calculations of muscle length based on gait-analysis models can assist surgical decision-making. For example, the hamstrings in crouched gait are more often than not relatively long, not short.

Another biarticular muscle, the rectus femoris, is also often affected: activity of the spastic rectus in swing prevents adequate knee flexion and causes foot clearance problems. A positive Duncan–Ely test, together with reduced sagittal knee movement and electromyographic confirmation of rectus activity in swing characterizes this problem which can be dealt with by posterior transfer of the rectus to the sartorius or gracilis.

Excessive hip internal rotation results in the knee and ankle acting across the direction of body movement, which often causes a valgus thrust at the knee. Femoral derotation osteotomy either proximally or distally restores alignment. Compensatory external tibial torsion can be addressed by a simple supramalleolar derotation osteotomy.

Knee flexion contracture is a major problem in the older child with diplegia. Soft tissue surgery alone is unlikely to give good results and enthusiasm for bony surgery to address residual flexion contractures has been revived. Supracondylar knee extension osteotomies with or without accompanying distal transfer of the tibial tuberosity have been recommended. In the skeletally immature child the same result can be obtained safely and simply by anterior hemiepiphysiodesis of the distal femoral physis. This has the advantage of a slow correction, allowing the soft tissues to adapt to both sides of the gradually extending knee (Figure 13.4.8).

![Click to view larger](image_url)

**Fig. 13.4.8**
Lateral radiograph of the knee showing staples inserted anteriorly at the level of the distal femoral physis to give a gradual correction of the knee flexion posture.

Osteotomies to correct rotational malalignment of the leg and resulting abnormal moments across joints are included as necessary. Femoral anteversion affects the lever arm of the abductors and often causes a valgus thrust at the knee. Tibial derotation may be indicated in some children.

Surgery to correct foot deformity is indicated in a number of children. As a rule, there is no place for muscle lengthening or tendon transfer surgery in the valgus foot in diplegia, with the exception of the gastrocnemius, whose contracture may be responsible for exacerbating the valgus. Severe hindfoot valgus that is impeding gait and causing pain may be treated by extra-articular subtalar arthrodesis. A calcaneal lengthening osteotomy treats the valgus foot with a collapsed longitudinal arch and forefoot abduction. The operation offers good correction of all three elements of the deformity in the reasonably flexible foot and can be combined, if necessary, with a subtalar arthrodesis. Gastrocnemius lengthening to correct equinus may be necessary. Triple fusion is reserved for the severely deformed, rigid, and symptomatic foot. Hallux valgus is treated by arthrodesis of the first metatarsophalangeal joint with recognition that the deformity is often secondary to more proximal midfoot deformity which may need addressing.

Multilevel operations should be planned and performed in centres where there is an appropriate interest and expertise and multidisciplinary approach. Careful assessment of potential patients, carers, and local support services is needed to ensure good patient selection and detailed planning is essential to ensure that there is a seamless transition from hospital to community care for rehabilitation. Experienced paediatric anaesthetists, postoperative epidural analgesia, and pain teams are essential to ensure that the patient does not enter into the pain/spasm/pain spiral that causes so much distress and which is responsible for many
poor operative results. A comfortable, confident child is able to mobilize quickly, be discharged promptly and continue rehabilitation at home. Rehabilitation may continue for as long as 12–18 months.

Midterm results of multilevel surgery or of specific procedures are encouraging but studies into adult life are required to establish the long-term results. Such studies are difficult to conduct due to the inherent variability in patient characteristics, use of other treatment modalities and ethical issues over the use of control groups.

Hip dysplasia

Mild hip dysplasia is common in diplegic cerebral palsy. As before, the incidence is difficult to ascertain due to the difficulty with diagnostic labelling at the severe end of the diplegia spectrum. The ability to walk does not exclude the possibility of progressive hip subluxation and hip monitoring should be part of the regular follow-up of these patients. The management of hip subluxation and dislocation is considered in the following section on the management of patients with total body involvement.

Lower limb management in the adult

Increasing height and weight in the teenager expose underlying problems with muscle weakness. Those who as younger children coped well, ‘walking on their spasticity’, find to their frustration and disappointment that despite maintenance of joint ranges their exercise tolerance decreases significantly in early adult life. Major surgical interventions are not generally indicated for fear of contributing further to the weakness. Appropriate management involves advice regarding regular exercise (in gyms and swimming pools), with occasional courses of physiotherapy to target specific problems. Increasing crouch posture with a contracted and weak quadriceps leads to a high-riding patella and patellofemoral joint problems. This in turn leads to increasing reliance on walking aids. There is no reliable operative solution. Degenerative hip disease occurs in the older physically active patient with diplegia and this is best treated with total hip replacement. Overall, the natural history of diplegia in adult life is unclear. Moreover, the influence of orthopaedic treatment on the long-term walking potential of diplegic patients is unknown.

Further reading

Evaluation of the upper limb must assess all aspects of sensation, motor control, and function. Will the hand be used for bimanual activities?

Individual treatment goals must be established

Non-operative treatment may encourage use and awareness of the more affected limb

Many muscles cross two joints and therefore the limb must be considered as a whole and not as a series of isolated joints.

Introduction

The upper extremity is involved in all varieties of cerebral palsy. These limbs display the ‘positive’ features of the upper motor neuron syndrome—spasticity, hyper-reflexia, clonus, and co-contraction—but they also demonstrate the negative features including weakness, sensory deficit, poor selective, motor control (see Chapter 13.3, Table 13.3.2), as well as dystonia, which further influence the fine motor skills. Upper limbs perform a multitude of tasks and must work together, although they have differing functions depending on dominance. Whereas children need both lower limbs to walk, many upper-limb tasks can be performed single-handedly, and neglect or ‘learned non-use’ of the other hand can be a problem. Management of the upper limb in cerebral palsy involves detailed assessment by a multidisciplinary team (see Chapter 13.3, Table 13.3.4) and careful planning.

Classification (see Chapter 13.3)

Cerebral palsy is classified by the predominant type of movement disorder: spasticity is present in 85% of those affected and is the most amenable to treatment. It is also classified by topographical involvement. Those with total body involvement have the greatest problems with motor control, spasticity, sensory deficit, and contractures leading to poor function. Goals of treatment are usually to improve hygiene and ease of dressing for these patients. Spastic diplegic patients have meagre involvement of the upper extremity and so rarely require intensive upper limb therapy or surgery. Hemiplegic patients can be helped most in terms of function and cosmesis.

Clinical evaluation

A careful and repeated evaluation should be performed evaluating the factors listed in Box 13.5.1.

Box 13.5.1 Important factors in assessing the upper limb

- Sensation
- Spasticity
- Motor ability
- Contractures
- Function.

Sensation

Sensory status is a predictor of the degree of spontaneous use of the limb.

Light touch, pain, and temperature sensations are present in cerebral palsy, but whether they are ‘normal’ is difficult to determine. They are ‘normal’ for that patient who will report them as such. Proprioception is measured objectively and tends to be more affected distally. Stereognosis is the child’s ability to recognize objects by feel, and its reduction correlates with a decrease in limb size. Graphesthesia is the recognition of pictures or letters drawn on the palm. Two-point discrimination is considered satisfactory if less than 5–10mm.

Spasticity

Resting posture gives an idea of the amount of spasticity present. It tends to cause shoulder adduction and internal rotation, elbow flexion, forearm pronation, and wrist flexion. Fingers are flexed or show swan-neck deformity. The thumb may be adducted, or adducted and flexed, the so called ‘thumb-in-palm’ deformity. Stretching of the affected muscles meets with resistance which is velocity dependent and correlates with the degree of spasticity present. This can be assessed further with the Modified Ashworth and the Modified Tardieu Scales.
Motor ability

Spasticity often predominates in the shoulder adductors, elbow flexors, pronators, wrist, and finger flexors, and these muscles often overpower their antagonist muscles. The wrist and finger extensors, supinators, and abductor pollicis longus can be weak with poor voluntary control. Assessment of their power may only be possible after spasticity in other muscle groups has been reduced (by motor blocks or botulinum toxin A).

Contractures

Spasticity, fibrous contractures within spastic muscles, and joint contractures can be difficult to distinguish. It is usually possible to overcome spasticity, unless severe. Fibrous contractures cannot be overcome by passive movement, but can sometimes be distinguished from joint contractures by altering joint positions when testing muscles that cross more than one joint. For example, if finger flexors are tight, passive finger extension may only be possible with wrist flexion. Joint contractures such as elbow and wrist flexion and a pronation contracture due to shortening of the intracapsular membrane may develop in adolescence or adulthood. Occasionally the radial head may dislocate.

Function

A number of objective, reproducible, validated tests, such as the Melbourne Unilateral Upper Limb Assessment, the Quality of Upper Extremity Skills Test (QUEST), the Assisting Hand Assessment (AHA), and the Shriners Hospital Upper Extremity Evaluation (SHUEE) can help assess and score the child’s functional ability. Functional tests should be recorded on video and form a useful outcome measure after surgery. Bi-manual tests which measure what the child actually does rather than what he or she is capable of (the performance gap) will give a better measure of actual function. The chosen test needs to be responsive to change in order to be a good measure of outcome. In addition, the Manual Ability Classification System (MACS) reports the child’s ability to handle objects in daily life. It does not assess the hands independently of each other. It gives a score of I–V and correlates well with Gross Motor Function Classification System (GMFCS) level ratings. The House score assesses the affected limb (Table 13.5.1).

Wrist flexion and thumb deformities have been shown to be major contributors to functional problems and in fact the House score was originally used to assess function before and after thumb surgery (Figure 13.5.1).
Fig. 13.5.1
A) Grasp. During grasp the wrist is flexed rather than extended. This slackens the finger flexors, making grasp more difficult. The thumb metacarpal is adducted, and to increase span the interphalangeal joint has become hyperextended. B) Attempted release. The wrist flexes further to aid finger extension. Swan necking of the fingers becomes evident as the extensors contract. The thumb is still unable to abduct and so release is not successful.

Investigations

Three-dimensional motion analysis for the upper limb is in its infancy and not yet standardized between different centres. Electromyography may help determine which muscles are used in grasp and which in release, but is not widely used. Radiographs are rarely necessary.

Treatment

Goals

The treatment goals must be realistic and clearly defined by patient, carers, therapists, and surgeon together. In the severely affected quadriplegic patient, the goals may be to improve hygiene and ease of dressing. In many hemiplegic patients it is possible to improve function. Older children may simply seek an improvement in appearance but often do not admit to this unless directly questioned. Treatment must be individualized.

Non-operative treatment

Physiotherapy and occupational therapy

A number of treatments are available. Splinting to serially stretch contractures or to position the limb to its biomechanical advantage; stretching spastic muscles or strengthening weak ones; neurodevelopmental therapy to encourage functional movement patterns and inhibit primitive posturing; conductive education which practises motor skills for functional use and constraint induced movement therapy to encourage use and awareness of the more affected limb by restricting the more able hand, in much the same way as eye patches are used over a good eye to help train the ‘lazy’ eye.

Botulinum toxin A

Botulinum toxin blocks the presynaptic release of acetyl choline at the neuromuscular junction. The dose is calculated according to the patient’s bodyweight, and each target muscle should be located with a nerve stimulator or ultrasound probe to ensure accurate drug placement. Splinting and stretching as well as strengthening programmes for weak antagonists should be implemented following injections.

Operative treatment

Many muscles of the upper limb cross more than one joint and therefore the limb must be considered as a whole and not as individual joints in isolation (Table 13.5.2). For example, a flexor-pronator slide will release the tight pronator, finger and wrist flexors, but will also slightly improve elbow extension. A flexor carpi ulnaris to extensor carpi radialis brevis transfer will augment wrist extension, but will also significantly increase active supination. Equally, a wrist should not be arthrodesed in a neutral position without addressing tight finger flexors or the patient will no longer be able to release their grasp. It is also important to remember that the primary issue is with brain function and not to see the problem as a purely biomechanical one. A neglected limb is unlikely to gain function despite surgery. Generally, the surgeon has the following options for treatment:

* Spastic or contracted muscles may be released, either at their origin, or at the musculotendinous junction, or within the
tendinous portion

- These muscles may be transferred in order to augment the function of a weak antagonist
- Joints may require release, or stabilization by capsulodesis, or occasionally arthrodesis.

ECRB, extensor carpi radialis brevis; ED, extensor digitorum; EPL, extensor pollicis longus; FCU, flexor carpi ulnaris; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; MCPJ, metacarpophalangeal joint.

Motor nerves may be divided, partially resected at the neuromuscular junction, or injected with phenol.

If possible, all the applicable procedures should be performed in one sitting (multilevel surgery for the upper limb).

Postoperatively the arm is immobilized in a cast, the position dependent on which procedures have been carried out. This is maintained for 6 weeks and then replaced with a thermoplastic splint to be worn at night time for 3 months or more to prevent recurrence of contractures. Movement is commenced on the non-immobilized joints immediately postoperatively, and therapy is intensified once the cast comes off. Occupational and physiotherapy are essential adjuncts to medical and surgical treatment.

### Results

A systematic review of the literature on BTA identified 12 studies of high methodological quality. Six of ten that measured spasticity showed improvement; three of ten showed increased range of movement and six of ten showed improvement in function. The authors concluded, however, that due to differences in treatment goals, invalid assessment instruments and insufficient statistical power there was insufficient evidence to state that injections were beneficial.

Although there are no prospective randomized controlled trials assessing the efficacy of surgical treatment for the upper limb in cerebral palsy, from the large retrospective studies, the literature would seem to support surgery for improvement in function, cosmesis, and hygiene. A review of the literature from 1966–2006 concluded that surgery improved the position of the hand and there are indications that it might improve hand function.

### Future directions

Prospective studies using validated outcome measures and long-term follow-up of treated patients, as well as the development of valid three-dimensional upper-limb modelling, will enhance our understanding of the effect of interventions on the upper limb in cerebral palsy.
Conclusions

Management of the upper limb in cerebral palsy requires assessment by a multidisciplinary team with an understanding of neuromuscular disability and of anatomy. Realistic goals need to be agreed with the patient and family, and validated outcome measures need to be documented. This is an exciting field for clinicians and researchers, with ample scope for future development and research.

Summary points

- The most common musculoskeletal problems in TBI are scoliosis and hip dislocation
- Hip screening is necessary in young non-ambulant children
- The role of soft tissue surgery to prevent hip displacement is unclear
- Bony surgery offers more predictable results but complications are frequent
- Spinal stabilization should be considered for curves exceeding 50 degrees.

Introduction

This group includes children with severe motor disability that affects control and posture of all four limbs, the trunk, and the head. The majority of children are non-ambulant or therapeutic/household walkers (Gross Motor Function Classification System (GMFCS) IV or V). As a result of the severity of their neurological condition and their limited mobility most develop a variety of secondary musculoskeletal deformities but deformity in itself is not an indication for orthopaedic treatment. Management of the child with total body involvement cerebral palsy (TBI CP) should have well-defined aims and targets. Parents/carers as well as a multidisciplinary team of health professionals involved in the care of the child should take part in the decision-making process (see Chapter 13.3, Figure 13.3.5). Orthopaedic interventions are indicated to relieve or prevent pain, to improve quality of life, and to maintain or improve function.

Prevention of musculoskeletal deformity is an essential part of the management of these children. The treatment modalities that are used have been discussed in the preceding chapters and include physiotherapy, postural management, orthotics, casts, and botulinum toxin injections. The use of intrathecal baclofen treatment may also have a place in the management of intractable spasticity that affects the lower body predominantly. Dorsal rhizotomy is usually restricted to those children with spastic diplegia.

The most common musculoskeletal deformities requiring orthopaedic treatment in the TBI CP child are scoliosis and hip displacement (subluxation or dislocation). Indications for other orthopaedic interventions are less common and require careful, individual consideration.

Hip displacement

Hip displacement in CP is a common problem, particularly in non-ambulant patients. Depending on age and severity of involvement, the incidence of hip displacement varies from 10–70%. Lack of weight-bearing stimulation to the femoral head and acetabulum, muscle spasticity, and asymmetrical posture may explain the higher incidence of displacement in the non-ambulant children. The displacement is gradual and secondary changes occur on both sides of the joint. The femoral head becomes oval-shaped while acetabular dysplasia develops gradually with the formation of a groove-shaped deficiency. In the majority of patients, the direction of displacement is superoposterior. Posterior acetabular defects are more often seen in patients who progress to subluxation, while global defects are more common in patients with fully dislocated hips.

Both the Reimers migration percentage and the acetabular index can be used to quantify the severity of the displacement but problems with the reliability of both measurements have been reported (Figure 13.6.1). Three-dimensional imaging, particularly as part of preoperative planning may be appropriate in determining the direction of instability and the site of acetabular deficiency.
Indications for treatment of hip displacement in CP include pain during the displacement process and prevention of pain from the secondary degenerative changes that develop with chronic, established displacement. Correction of posture and improvement in the range of hip movement facilitate better sitting as well as easier care and hygiene.

Management

There are several areas of controversy in the management of hip displacement in TBI CP that will hopefully become clearer over years to come with a better understanding of the outcome of intervention in various subgroups of CP.

Screening for hip displacement

The indications for early screening and any preventative interventions are unclear. The acetabular index represents the single most important predictor of hip dislocation in children with CP. A normal index at the age of 3 years predicts normal hip development, provided that the clinical examination remains normal and that no scoliosis develops. Similarly, it has been suggested that the migration percentage is the best guide for hip surveillance. A population study has recommended that all children with bilateral CP should undergo a standardised position AP pelvic radiograph at the age of 30 months, in order to predict the risk of dislocation. Another population-based study in southern Sweden claimed that, with adequate screening and early intervention, the incidence of dislocation dropped significantly, when compared with historical controls. The screening was based on a register of children with CP and relied on this for its validity.

Overall the existing literature suggests that all children with bilateral CP should undergo an anteroposterior (AP) pelvic radiograph around the age of 2–3 years in order to assess the risk of hip dislocation (Box 13.6.1). The presence of an abnormal acetabular index (> 30 degrees) or an abnormal migration percentage (>15%) would indicate a significant risk of dislocation (Figure 13.6.2). A normal radiograph at this age would be reassuring but ongoing clinical surveillance is still essential. There is consensus in the literature that non-ambulant children (GMFCS IV and V) are at higher risk and should be screened regularly.

Box 13.6.1 CP hip surveillance—pelvic radiograph age 2–3 years

High risk:
- Acetabular index > 30 degrees
- Migration percentage >15%
- GMFCS IV or V.

Natural history and indications for treatment

Hip displacement in CP is a slow process that allows secondary structural changes in the femoral head and the acetabulum to develop. These secondary changes occur early and, in some cases, before the evolution of hip instability.
Poor sitting balance as well as prevention of windswept posture and the resulting pain have been suggested as indications for treatment of the displaced hip in CP. Loss of mobility in ambulant children as well as decubitus ulceration and secondary deformity of the spine in the non-ambulant patients have also been suggested as indications. However, a comparison between quadriplegic children with scoliosis and hip displacement and similar children with spinal deformity but no hip displacement showed no effect of hip displacement on the progression of the spinal curvature, despite the higher incidence of pelvic obliquity in the group with hip displacement (Box 13.6.2).

**Box 13.6.2 Hips and spines**

Hip dislocation does not increase the risk of scoliosis progression.

Pain in the non-ambulant child and loss of mobility in the ambulant one are suggested as the main indications for treatment. Posture, care, and hygiene are secondary indications.

**Prevention of hip displacement**

**The role of soft tissue surgery (Box 13.6.3)**

The role of soft tissue surgery around the hips in the prevention of hip displacement in children with bilateral disease is controversial. Some have suggested that such surgery can result in long-term radiographic stability in previously displaced hips in approximately 65% of treated patients but the effectiveness of adductor tenotomy alone in comparison with more extensive releases and obturator neurectomy is unclear. There is agreement that a preoperative migration percentage of less than 40% predicts a successful outcome and early surgery, before the age of 6 years, with postoperative bracing leads to good results. Approximately two-thirds of patients maintain hip stability at 8–10 years from surgery.

An American Academy of Cerebral Palsy and Developmental Medicine (AACPDM) evidence report concluded that the published evidence on the effects of adductor surgery in CP should be ‘regarded as preliminary at best’. The lack of long-term studies and comparison with controls was highlighted, as was the need to study the reliability and validity of the radiographic methods used.

**Other measures**

In a Swedish population-based study, it was shown that the introduction of preventative measures to treat spasticity or dystonia reduced the incidence of hip dislocation compared with historical controls. Preventative measures included selective dorsal rhizotomy, continuous intrathecal baclofen infusion, botulinum toxin injections, and non-surgical treatment of contractures.

**Bone procedures for hip displacement and dislocation**

**Choice and results (Box 13.6.4)**

Surgical correction of hip displacement in CP may include a combination of femoral and/or pelvic procedures. The choice of surgical procedure to treat displacement or to salvage the painful chronically dislocated hip remains controversial. Furthermore, there is also the question of whether or not to treat the contralateral hip.

Femoral varus/derotation osteotomy used in isolation for the treatment of the displaced hip in CP is associated with a relatively high risk (10–40%) of redislocation, particularly if acetabular dysplasia is already present when treatment is undertaken (Figure 13.6.2 and Figure 13.6.3).

Fig. 13.6.3

AP radiograph of a teenager with a painful subluxation of the right hip A) which was treated by hip reconstruction involving a soft tissue release, a shortening varus/derotation femoral osteotomy and modified Dega acetabuloplasty B). C) AP radiograph of bilateral hip reconstructions using blade plate fixation devices.

A variety of procedures have been suggested to treat the acetabular deformity and deficiency. The Salter and Pemberton osteotomies, designed for the treatment of developmental dysplasia, offer improved anterolateral cover that may not be appropriate in CP hip displacement. Results with the Chiari osteotomy have also been unsatisfactory. The triple pelvic osteotomy offers good stability but adds significantly to the complexity of the surgical procedure.
**Box 13.6.3 Soft tissue surgery**

- Prevents hip displacement in approximately 2/3 of young children
- Good results with migration index <40% and age <6 years.

**Box 13.6.4 Bony surgery: hip reconstruction**

- Combined femoral and pelvic osteotomies lead to better results
- Beware the contralateral hip: treat appropriately
- Surgery is associated with a high complication rate.

The Dega osteotomy and its modifications address posterolateral instability and may carry advantages over conventional pelvic osteotomies performed for developmental hip dysplasia. The common principle of these procedures is that they leave the medial cortex of the ilium intact and centre the osteotomy on the triradiate cartilage. The claim is that they reduce the volume of the acetabulum and provide posterolateral articular cartilage cover whilst maintaining some stability by preserving the medial wall of the ilium. Such an acetabular procedure, in combination with femoral varus shortening derotation osteotomy, provides more consistent satisfactory results in the treatment of CP hip displacement with improvement in pain, hip mobility, and sitting balance (Figure 13.6.3). Additional soft tissue releases may be required. Satisfactory clinical and radiographic results in over 90% of patients at 5 –10 years of follow-up have been reported from retrospective reviews.

In children with TBI CP, by definition, both hips are at risk of displacement and dislocation. In two retrospective studies, unilateral surgery to treat hip displacement in non-ambulant CP patients was shown to be associated with progressive deformity and displacement of the contralateral non-operated hip in over 50% of cases. Bilateral pelvic and femoral osteotomies were shown to carry similar perioperative risks as unilateral or staged surgery.

**Windswept hips**

Patients with TBI CP may demonstrate significant asymmetry and develop a windswept posture with one hip lying abducted and the other adducted. This posture is frequently associated with pelvic obliquity. The pseudo-Galeazzi sign identifies apparent shortening of the thigh; due more to a fixed abduction of one hip and an associated pelvic tilt rather than a true discrepancy in femoral length. The abducted hip may benefit from release of the gluteus maximus and tensor fascia lata with or without preventative bony surgery as discussed earlier. If there is clinical subluxation with a femoral head palpable in the groin, a hip reconstruction including a varus/derotational femoral osteotomy and acetabuloplasty is indicated (Figure 13.6.4).

**Established dislocation**

The established hip displacement in CP may develop secondary degenerative changes and pain, which may result in further functional compromise affecting the patient and carer’s quality of life (see Figure 13.6.4). Hip reconstruction can still be considered if there is a reasonable chance of creating an acetabulum to contain the femoral head which is often deformed and degenerate but the recovery period is prolonged and the outcome variable. Hip replacement surgery, excision/interposition arthroplasty with or without valgus femoral osteotomy and hip arthrodesis have all been suggested as treatment methods. However, the existing literature reports a limited follow-up on small numbers of patients with no control group. If an excision arthroplasty is considered this should be performed as a proximal femoral excision below the lesser trochanter with a repair of the soft tissues over the acetabulum (Figure 13.6.5).
Complications

Non-ambulant patients with CP often suffer with reflux, absent gag reflex, epilepsy, and respiratory problems. Therefore there is a small but significant mortality rate and they are more at risk of perioperative complications, particularly respiratory problems. It has been suggested that 25% of CP patients undergoing hip osteotomies suffer at least one complication. Surgical complications of hip reconstruction include infection, skin sores, metalwork failure, heterotopic ossification, femoral head osteonecrosis, redislocation, persistent pain, and loss of ambulation. Some studies suggest that many of these complications are more frequent in patients who were casted following surgery compared to those who were not.

Anterior dislocation

Whilst most CP hips displace in a posterolateral direction, some hips lie in abduction, extension, and external rotation and are at risk of anterior subluxation or dislocation. This may result in painful restriction of hip flexion which has a significant effect on sitting ability and thus quality of life (Figure 13.6.6).

An early soft tissue release (as mentioned previously for the abducted side in windswept hips), often combined with femoral shortening varus derotation osteotomy may help in maintaining a balanced sitting posture. Treatment of the established anterior dislocation is difficult and salvage with proximal femoral resection may become necessary.

Spinal deformity

A large number of patients with TBI CP develop a scoliosis and once it has developed it does tend to progress. The curve pattern is classically a long ‘C’ shaped curve. The pelvis frequently becomes part of the curve and the subsequent pelvic obliquity leads to an unstable sitting base which may cause more functional problems than the curve itself. Children with low-toned CP develop a thoracic kyphosis (Figure 13.6.7).
A) AP radiograph showing a severe scoliosis with pelvic obliquity pre-operatively. B) AP and C) lateral views of the same spine following posterior instrumentation. Fixation is to the pelvis. The pelvic obliquity has been corrected and the lumbar lordosis restored.

Severe curves may lead to back pain and respiratory compromise but the main problems are associated with an unstable sitting posture which often limits upper-limb function if one arm is needed to support the body position. Abdominal discomfort secondary to chest wall impingement on the pelvis is common.

**Curve prevention and control**

There is no good evidence that spinal deformity can be prevented but care with seating and posture is considered good practice. Seating with adequate trunk and pelvic control may delay the onset of scoliosis. Deformity often becomes clinically apparent between the ages of 5–10 years and once progression has been documented, brace wear should be considered. Spinal braces are often poorly tolerated particularly in these children with multiple other problems and who are ‘peg fed’ in which case reliance on adapted seating with a tilt-in-space facility and good lateral supports may be more appropriate. The aim of bracing is to delay the progression of deformity rather than to halt it: allowing surgical correction to be delayed until sufficient spinal growth has taken place.

**Curve correction**

Untreated curves do tend to progress throughout adulthood and may leave the patient in a position where they are unable to sit and must be cared for in bed. Thus, once the curve has reached a Cobb angle of approximately 50 degrees, surgical correction should be considered and a full explanation of the risks and benefits of the procedure given to the parents.

Spinal fusion is usually undertaken posteriorly from T2–pelvis using a segmental instrumentation system. It is important to correct pelvic obliquity and to recreate a normal lumbar lordosis (see Figure 13.6.7). A failure to do so may exacerbate rather then relieve seating problems. As the spinal fixation is usually secure, prompt mobilization is possible. In these children, there are frequently associated hip problems and postoperative rehabilitation may be hampered initially by increased stiffness and discomfort at hip level, particularly if the pelvic position and effective hamstring length have been altered.

Preoperative assessment must pay close attention to the patient’s nutritional status as well as to respiratory compromise. A poor swallowing reflex combined with the supine position and potential ileus postoperatively mean that oral feeding should be delayed until the patient is able to be in a more upright position and swallow safely.

**Other considerations**

The ability to perform a weight-bearing transfer is a significant factor in maintaining quality of life and a degree of independence. Patients who can perform such transfers or have the potential to achieve this may be candidates for correction of knee contractures over 15–20 degrees. Hamstring lengthening should provide enough correction for this purpose (Box 13.6.5) and supracondylar femoral extension osteotomies are rarely indicated. Lengthening of the hamstrings may also improve sitting posture by reducing posterior pelvic tilt.

**Box 13.6.5 Hamstring lengthening**

Be careful not to stretch the sciatic nerve.

Foot deformities may also require correction to aid standing transfers or simply to accommodate the feet more comfortably on the foot-plates of the wheelchair. Severe foot deformities may also merit treatment if they risk skin ulceration over prominent bones or due to external pressure. In addition, severe upper or lower limb contractures may require treatment to facilitate care and hygiene. Any upper limb interventions should be carefully considered to avoid compromise of existing function, such as the use of an electric wheelchair control (the ‘joystick’), computer keyboards or communication devices.

The orthopaedic management of myelomeningocele

Summary points

- Myelomeningocele is a congenital failure of neural tube development
- Hydrocephalus is a common association
- Multidisciplinary management is important
- An alteration in neurological status requires further investigation
- Beware the insensate skin
- A supple plantigrade foot aids independence.

Introduction

Myelomeningocele or spina bifida is a congenital condition in which the embryological development of the neural tube is incomplete. The neurological effects are due to the combination of the absent or damaged neural elements at birth and the secondary effects of tethering of the spinal cord at the site of the lesion during growth.

For the orthopaedic surgeon, the main challenges are the position and stability of the hip joints and the management of foot deformities. The management of the spine itself in patients with myelomeningocele is dealt with in Chapter 13.8.

Incidence

The incidence in the United Kingdom is currently approximately 1:1000 live births. It has fallen over the last three decades particularly in Wales and Northern Ireland. This fall is probably attributable to the routine use of folate supplements in pregnancy, improved prenatal diagnosis, and the termination of affected pregnancies.

General principles of management

The neurological effects of a myelomeningocele are not restricted to the musculoskeletal system. Many patients develop a hydrocephalus that requires a ventriculoperitoneal (VP) shunt and neurosurgical monitoring. Bowel and bladder function is also often abnormal and appropriate medical and surgical care essential. Hence, many centres employ a multidisciplinary approach to the management of these complex cases.

The orthopaedic goal of management is to optimize the patient’s comfort and mobility while avoiding overtreatment. Surgical treatment must be planned in the context of the individual’s abilities and circumstances; the number of surgical episodes should be minimized, and postoperative immobilization must be as brief as possible. Latex allergy has been reported in patients with spina bifida and latex-free equipment should be used in areas such as the operating theatre suite.

Whilst a rough prediction of lower limb function can be made by assessment of the level of the neurological lesion, it is not possible to make absolute or accurate forecasts of future mobility for any individual infant. Many other factors influence function. The asymmetric and often ‘patchy’ nature of the peripheral neurological lesion, the variability of the effects on the central nervous system, individual personality and drive, the possible effects of spinal cord tethering with growth, weight gain, and bone fragility are just some of these factors. Many children require the aid of orthotic devices to stabilize and support joints to achieve independent mobility and many are predominantly wheelchair users (Figure 13.7.1).

Fig. 13.7.1
A) A child with spina bifida who achieves independent mobility with the aid of a reciprocating gait orthosis (RGO) and a Kaye walker. B) Photograph of a RGO. C) Photograph of a HKAFO (hip–knee–ankle–foot orthosis).
As a general rule it makes sense to treat identifiable musculoskeletal problems as simply and effectively as possible in the infant, then tailor future treatment to the individual as their particular pattern of involvement and development unfolds. In practice this involves early, minimally invasive treatment of selected hip dislocations and foot deformities in the young child, and more complex surgery where needed in older patients. It is true that with growth and associated weight changes, the child’s function may change but a change in their neurological status must also be considered and excluded by appropriate investigation (Box 13.7.1).

Box 13.7.1 Changing Neurological Status?

Consider:

♦ Developing hydrocephalus
♦ Blocked VP shunt
♦ Tethered cord.

The hip

Hip deformities in spina bifida are associated with lesions at all neurological levels but are more common with higher lesions. An absence of muscular control appears to be the major influence on hip stability rather than muscular imbalance across the joint. Hip dislocation alone has not been shown to influence gait efficiency, sitting balance, or the formation of pressure areas around the pelvis. The hip joint may have sensation even in high lumbar lesions, however, and these patients may develop pain in subluxated or dislocated joints.

Hip flexion contracture

Hip flexion contractures are more troublesome in thoracic and high lumbar neurosegmental patients. In non-ambulant patients with a thoracic lesion, a progressive deformity develops which has a tendency to recur after surgical release. Well-controlled seating following surgery may be effective in younger children but a progressive deformity in the older child or adolescent is difficult to reverse.

A hip flexion deformity of more than 30 degrees in the ambulant child, with or without orthoses, is best managed with a soft tissue release to allow an upright stance and comfort when using orthotic supports and walking aids (see Figure 13.7.1B,C).

Hip dislocation

Hip dislocation, noted at birth, in lumbar and sacral neurosegmental patients can, as a rule, be reduced surgically though a medial approach in early infancy. There is no benefit to reducing the hips in patients with a definite thoracic neurosegmental lesion.

Surgery for subsequent or later subluxation or dislocation remains the subject of debate in the high lumbar neurosegmental group. No clear benefits have been demonstrated from surgical relocation in terms of gait, standing ability, or sitting balance, even for unilateral dislocations. In the event of a painful subluxation or dislocation, joint stabilization is indicated. Children with low neurosegmental levels are better candidates for surgery. Typically, this involves osteotomies above and below the joint in addition to soft tissue surgery. Unfortunately, the results of surgery are unpredictable and recurrent subluxation and dislocation does occur (Figure 13.7.2).

Fig. 13.7.2

A) AP pelvic radiograph of a child with spina bifida 6 months after successful open reduction of the right hip with an acetabuloplasty and associated soft tissue release. Note the presence of a VP shunt. B) AP pelvic radiograph 12 months later shows that the right hip has redislocated and the left hip has also dislocated.
Muscle balancing surgery is less commonly performed now but some centres still advocate muscle transfers around the hip in association with bony surgery in patients with a low lumbar level (Figure 13.7.3 and Box 13.7.2).

Fig. 13.7.3
AP pelvic radiograph of an adult patient with spina bifida who was treated as a child for a dislocated left hip. Note the hole in the iliac wing which denotes the site of a previous psoas transfer.

Box 13.7.2 Joint stability

Absence of muscle control is more important than muscle imbalance.

The knee

Flexion deformity

As with the hip, the more severe knee flexion deformities are associated with high neurosegmental lesions and are not directly related to muscle imbalance. The late onset of a knee flexion deformity with associated hamstring tightness or an unexpected deterioration in an existing deformity should raise the possibility of a tethered spinal cord.

A knee flexion deformity of more than 30 degrees in a potential walker is an indication for soft tissue release in children below the age of 7 or 8 years. In older children, surgery is best delayed to closer to skeletal maturity at which time anterior hemiepiphyseodesis or extension osteotomies can be used to correct residual flexion. (see Chapter 13.4, Figure 13.4.8)

Extension deformity

This is a much less common deformity. In the neonate, manipulation and serial splints or casts will achieve adequate correction in many cases. Surgical treatment can involve quadriceps lengthening with relocation of the hamstrings in patients with low lesions, or tenotomy of the patella tendon in those with no quadriceps function.

Torsional deformities

Both external and internal deformities are recognized and may be treated by derotational osteotomies. It is essential that prior to surgery any existing ankle deformity is identified.

The foot

The goal of treatment is a supple plantigrade foot: whatever the function of the patient, stiffness and deformity increase the risk of skin ulceration in a foot with impaired or absent sensation.

The principles of Ponseti’s method of foot deformity treatment (see Chapter 13.21) can be applied to the foot in spina bifida, much as they can in idiopathic cases and in arthrogryposis. Where surgery is judged inadvisable, adaptive footware can allow continued ambulation. Development of new deformities throughout childhood should raise the possibility of a tethered spinal cord.

Equinovarus deformity

Treatment in the neonatal period begins with manipulations and serial casts complemented where appropriate with minimal surgery to release tight tendons. Some children present with a rigid foot deformity similar to that seen in arthrogryposis, and can be treated similarly with a more prolonged series of gradual manipulations and casts. An Achilles tenotomy is usual and may need to be
performed earlier than with the idiopathic foot. Relapsed or resistant deformities may be treated with more extensive surgery but at the risk of causing more stiffness in the long term. In older children, equinovarus deformities can be corrected with osteotomies, whilst many surgeons consider a triple arthrodesis as the definitive salvage procedure suitable for use from adolescence onwards. An alternative in severe deformity is the ilizarov method of gradual correction using an external fixator. This is surprisingly well tolerated in this patient group and may avoid the problems associated with a rigid insensate foot following arthrodesis.

**Vertical talus**

This foot deformity traditionally required extensive open surgery to correct the troublesome rigid rocker-bottom foot. Recently the Iowa group have described a method of serial manipulations and casts complemented by minimal surgery, derived from the Ponseti clubfoot treatment. This method has the advantages of less extensive surgery and a reduced risk of significant stiffness.

**Cavovarus deformity**

A progressive cavus deformity may indicate a tethered spinal cord and this possibility must be investigated before surgery to the foot is performed. Molded insoles can accommodate minor deformities but prominence of the metatarsal heads combined with impaired sensation is a common cause of skin breakdown and recurrent infection. Metatarsal and calcaneal osteotomies may be needed to realign the foot. Severe deformities may require triple arthrodesis or correction using the ilizarov method.

**Calcaneus deformity**

This troublesome deformity gives an unstable base for stance and causes point-loading on the prominent calcaneum with associated risks to the skin. Management consists of serial manipulations and casts to relax the dorsal structures followed by dorsal soft tissue release and osteotomies of the mid-foot and calcaneum (Figure 13.7.4).

**Amputation**

Rigid foot deformities in an ambulant patient with impaired sensation are associated with recurrent skin ulceration, deep infection, and osteomyelitis. In intractable cases, amputation may be a robust practical solution, particularly where the prosthesis loads through a sensate area, such as a patellar-tendon-bearing socket in a patient with a low lumbar lesion. Amputation should be delayed where possible till skeletal maturity to avoid the complication of appositional bone growth.

**Further reading**

Summary points

- Spinal neurological problems may be a focal anomaly or part of a systemic disorder.
- The neuro-orthopaedic syndrome should be considered in any dysraphic patient with a changing clinical picture—urological symptoms respond well to prompt untethering.
- Ten per cent of central nervous system tumours originate in the spinal cord—they may be intramedullary, intradural extramedullary, or extradural.

Introduction

Spinal neurological conditions in the paediatric population can be part of a systemic disorder or a focal abnormality within the spine and neural axis (Table 13.8.1). When a child presents with signs and symptoms of possible underlying neurosurgical pathology, both developmental and acquired aetiologies must be considered.

Spinal dysraphism

Normal spinal cord development can be divided broadly into three processes. Aberrations at each of these stages may be responsible for clinical disorders that are included under the broad term spinal dysraphism.

The first stage in development of the neuraxis is gastrulation. It is during this stage that the germ cell layers of the embryo are established: these comprise ectoderm, mesoderm, and endoderm. Anomalies that have their origins early in development will commonly affect each of these layers. This is exemplified with neurenteric cysts where there is a persistent connection between the gut epithelium and the nervous system or split cord malformations where there is duplication of the spinal cord and vertebral body defects.

By the end of gastrulation the ectodermal plate has been formed and soon after the process of neurulation begins.

In primary neurulation a midsagittal groove is seen in the neuroectodermal plate. As this deepens, the edges of the groove fold towards each other and eventually join to form the neural tube. This process forms the brain and the spinal cord as far as the conus medullaris.
Secondary neurulation describes the process by which the terminal components of the CNS are formed: the tip of the conus medullaris, the cauda equina, and the filum terminale. This involves tissues located within the tail bud, caudal to the neural tube, known as the caudal cell mass. Vacuoles form within the caudal cell mass. These cavities become confluent with the central canal of the neural tube. This terminal dilatation forms the distal neural tube. Much of the dilatation regresses in a process termed caudal regression or retrogressive differentiation. The associated differential growth of vertebral column and neural tube results in a more cranial placement of the conus. The filum terminale remains as a connection between the conus and its original caudal attachment.

Spinal dysraphism is a term encompassing a broad spectrum of spinal anomalies arising from any disturbance during any of the stages of neural development and categorized broadly into open and closed neural tube defects.

Open neural tube defects

Failure of the neural tube to fuse leads to open defects such as myelocoeles and meningomyelocoeles. Neural tissue is exposed or covered by a thin meningeal layer. Neurulation is a process that is in part dependent on folate metabolism and folate deficiency is a major aetiological factor in open neural tube defects. Supplementation of the diet with folate prior to conception significantly reduces the risk of an open neural tube defect. Antenatal diagnosis can be made on ultrasound examination, by a raised maternal serum alpha feta-protein (AFP), or by amniocentesis measuring AFP and acetylcholinesterase.

Developments in the management of prenatally identified meningomyelocoeles include in utero repair of the defect. The benefits of this intervention compared to early postnatal closure are still undergoing evaluation through a randomized controlled trial. Some of the perceived advantages of in utero surgery are reduced hindbrain herniation (Arnold–Chiari II malformation) and a reduced need for a ventriculoperitoneal (VP) shunt.

A multidisciplinary approach is required to manage open neural tube defects and this should be undertaken in a unit with appropriate expertise.

Initial management

Following delivery, it is important to maintain a sterile environment for the exposed tissues and a sterile, moist, non-adhesive dressing which prevents pressure on the neural sac should be applied to the open defect. The child is nursed prone. There is a high incidence of latex allergy and latex exposure should be avoided.

Surgical closure of the defect is usually required within the first few days of life after appropriate imaging for brain ventricular size and following a thorough evaluation to assess the neurological level of the lesion and exclude associated cardiac and renal anomalies. In the perioperative period, the clinician should look for cerebrospinal fluid (CSF) leaks, superficial or deep wound infection, deterioration of neurological level, or the development of acute hydrocephalus. Shunt placement to control hydrocephalus is required in between 50–70% of cases.

Later management

Open neural defects are associated with significant long-term implications in respect of urological function, mobility, spinal deformity, and cognitive development. Minimizing the risk of urinary tract infections during infancy and the early introduction of clean intermittent catheterization helps reduce the incidence of renal scarring. Long-term mobility is strongly correlated with the neurological level of the lesion: lower lesions resulting in better prospects for independent ambulation. Lower limb treatment may involve surgical correction of deformity and the use of orthotic supports (see Chapter 13.9). Comorbidities such as respiratory compromise and weight gain contribute to the loss of mobility seen in adulthood.

Closed neural tube defects

Closed neural tube defects include a group of anomalies of caudal spinal cord development in which the neural tissues, in contrast to myelomeningocele, are covered by overlying skin. The term occult spinal dysraphism or spina bifida occulta is used to describe this group. The term occult is a misnomer as in many instances there is some feature of the overlying skin that signifies an underlying anomaly: such features are known as the cutaneous stigmata of spinal dysraphism. The following conditions are included under the term spina bifida occulta.

Diastematomyelia

The split cord malformation can occur with or without the presence of a dividing bony, cartilaginous, or fibrous septum. The two cords may lie within the same dural sac or separately. The two hemicords are often asymmetric with the smaller cord usually on the side of a smaller limb or foot. A focal hairy patch is the cutaneous stigmata commonly associated with this condition (Figure 13.8.1).
Lumbosacral lipomas

Most commonly a subcutaneous lipoma passes through a defect in the lumbosacral fascia, the posterior bony elements and the dura to be attached to the terminal spinal cord (Figure 13.8.2). Various anatomical forms are recognized depending on the point of attachment of the lipoma in relation to the conus. For practical purposes, the terms lipomyelomeningocele, lipomyelocoele, and spinal lipoma are synonymous. These are complex developmental malformations which may or may not be associated with neurological or urological symptoms at the time of presentation. Symptoms may occur as a result of primary neuronal dysgenesis or as a result of mechanical stretching (tethering) as the child grows.

Thickened filum terminale

This is perhaps the mildest of the dysraphic states. It is thought to result from a developmental defect of secondary neurulation and regression of the caudal cell mass. The filum terminale is shortened resulting in a low conus and thickened (>2mm diameter) by abnormal fatty or fibrous infiltration that affects its viscoelastic nature (Figure 13.8.3). This may result in undue traction on the conus during flexion and extension of the spine.
Dermal sinus tracts

These are remnants of the embryological connection between the skin (cutaneous ectoderm) and nervous tissue (neuroectoderm). An epithelial lined, midline tract extends from the skin surface through the subcutaneous tissue and spinal coverings to the intradural compartment where the tract terminates usually on the dorsum of the spinal cord. These tracts are significant as they can act as a portal for infection (spinal abscess or meningitis) or as a nidus for intraspinal dermoid formation.

Neurenteric cyst

These intraspinal cysts of endodermal origin are thought to represent a persistent communication between the ectoderm and the underlying endoderm. They have a lining of mucus secreting or gut epithelium. There is commonly a ventral defect through the vertebral body connecting to a cyst in the retroperitoneum or posterior mediastinum.

Tethered cord syndrome

Any of the anomalies described earlier can be associated with the tethered cord syndrome. This is not a pathological entity in itself but rather a clinical syndrome that results from traction on the spinal cord or nerves as the child grows.

Experimental studies on the pathophysiology of tethered cord syndrome suggest that excessive traction on the spinal cord can produce impaired oxidative metabolism in the spinal cord, diminished blood flow, and local ischaemic changes. The severity and reversibility of these changes probably relate to duration and magnitude of the traction highlighting the importance of identifying this condition early.

Clinical symptoms and signs

The clinical syndrome of tethering is sometimes referred to as the neuro-orthopaedic syndrome and comprises a variety of symptoms that might be orthopaedic, urological, or neurological. It should be considered in any dysraphic patient presenting with new, changing or progressive symptoms.

Midline cutaneous stigmata

A subcutaneous lipoma, midline cutaneous punctum (particularly if associated with a history of discharge) lumbosacral appendage, or focal hairy patch is highly suggestive of occult spinal dysraphism (Figure 13.8.4). Lower-risk lesions include very low, sacrococcygeal dimples and gluteal crease deviation. Diffuse hypertrichosis, haemangioma, and naevi, if found in isolation, are of less concern.
Growth discrepancies/deformities

The development of foot deformity (pes cavus, claw toes) or a rapidly progressive scoliosis may indicate a tethered cord or a recurrence following initial release. Asymmetry in foot size or a leg length discrepancy may also indicate tethering.

Sphincter dysfunction

A spectrum of abnormalities can occur including a neurogenic bladder, faecal and urinary incontinence, and frequent urinary tract infections. A formal assessment with urodynamic studies is essential.

Neurological signs and symptoms

There may be upper or lower motor neuron signs or a combination of both. Asymmetrical weakness may present as decreased leg movements in the infant whilst the older child may present with delayed ambulation and gait abnormalities. Trophic ulceration of the feet may occur as a result of sensory deficits.

Back/leg pain

Classically the pain worsens on spinal flexion or with vigorous exercise. The pain is often poorly localized and usually does not have the typical features of sciatica.

Imaging

A clinical suspicion of tethered cord syndrome should be confirmed by further investigations.

Ultrasound

This has limited application as the acoustic window into the lumbar spine closes after 2–3 months of age: in the infant it is a useful technique to assess the level of the conus.

Plain radiographs

These are of little diagnostic help and their role is primarily in the monitoring of spinal deformity.

Magnetic resonance imaging

This is the imaging modality of choice in dysraphic disorders. It has a very high specificity and sensitivity and permits evaluation of the position of the spinal cord, the anatomical features of the dysraphic anomaly and any associated abnormalities such as syringomyelia.

Treatment

Surgical treatment can halt the progression of established neurological deficits in the majority of patients. Symptoms vary in their response to untethering, pain will commonly resolve after successful untethering whereas foot weakness or deformity is less likely to improve.

Numerous clinical studies have demonstrated that patients with urological dysfunction fare better with prompt detethering. An objective assessment of urological function can be made using urodynamic measurements. Postoperative measurements can be useful during long-term surveillance demonstrating early recurrence of cord tethering and the need for further intervention.
Although the role of surgery in symptomatic patients appears clear, in asymptomatic patients, it remains controversial. Many clinicians will advocate prophylactic surgery in order to prevent the development of neurological deficits that may not recover with therapeutic surgery. The exception to this is dermal sinus tract where the perceived natural history and risk of infective complications make prophylactic surgical intervention essential in the majority of cases.

Other considerations with tethered cord syndrome are the associated spinal and foot deformities. Studies suggest that detethering procedures in patients with a myelomeningocele, tethered cord and scoliosis measuring less than 40 degrees will produce a plateau in curve progression. Larger curves will continue to progress necessitating operative correction and ultimately fusion.

**Spinal tumours**

Although central nervous tumours are the second most common type of childhood neoplasia, tumours of the spinal cord are relatively rare. The majority of central nervous tumours are intracranial and only 10% are located in the spine. Spinal tumours are classified into three broad groups.

**Intramedullary**

Intramedullary lesions (Figure 13.8.5) make up 40% of spinal cord tumours, the most common types being astrocytomas and ependymomas. Although 10–15% of astrocytomas are high-grade malignant tumours, the majority of these intramedullary lesions are low grade and present in an insidious manner.

![Click to view larger](Fig. 13.8.5 Sagittal MRI showing an intramedullary spinal tumour.)

**Clinical features**

**Pain**

Characteristically, the pain is a diffuse axial pain that worsens at night secondary to venous congestion and the associated dural distension. Pain usually precedes the onset of neurological symptoms.

**Neurological dysfunction**

This is of gradual onset. As intramedullary tumours are usually centrally located, dorsal column abnormalities are uncommon, motor signs appear early whereas sphincter dysfunction tends to develop late.

**Hydrocephalus**

May occur in the context of intramedullary spinal neoplasms and is thought to be related to the high protein concentration in the CSF.

**Spinal deformity/torticollis**

Pain and an abnormal posture or deformity should raise the suspicion of a spinal tumour.

**Management**

Surgical excision is the mainstay of treatment for intramedullary spinal tumours. The degree of surgical clearance possible will be governed by the tumour type. Infiltrative astrocytomas are less amenable to radical excision and high-grade tumours have a poor prognosis with median survival of 6–12 months. Removal of ependymomas is often curative. Patients should be monitored for
development of postlaminectomy spinal deformity. The laminoplasty approach, which preserves the posterior tension band of the vertebral column, reduces this risk.

**Intradural extramedullary**

This group (Figure 13.8.6) comprising 20% of spinal cord tumours includes meningiomas and peripheral nerve sheath tumours. Again the most common feature is pain followed by neurological dysfunction. Both tumour types are associated with neurofibromatosis.

![Click to view larger](image)

**Fig. 13.8.6**
Sagittal MRI demonstrating an intradural extramedullary tumour.

Magnetic resonance imaging (MRI) of the whole neural axis will help distinguish between solitary lesions and those arising from metastatic spread from an intracranial primary. Peripheral nerve sheath tumours produce characteristic erosion and enlargement of the neural foramina seen on plain radiographs.

The treatment of choice is surgical excision. Incomplete excisions run a high risk of recurrence. Malignant transformation of peripheral nerve sheath tumours is also a concern, especially in patients with NF-1 and those treated with adjuvant radiation.

**Extradural**

Primary or metastatic extradural tumours make up 40% of spinal cord neoplasms. Metastatic lesions from a systemic malignancy can produce spinal cord compression in up to 5% of cases. Primary extradural lesions originate from various structures.

**The bony structures of the spinal column**

**Ewing’s sarcoma**

This is the sarcoma that most frequently affects the paediatric spine. The lytic lesions within the vertebral body are often associated with soft tissue masses, the commonest site being the sacrum. The recent improved chemotherapeutic agents have produced better 5–10-year survival rates.

**Osteoid osteoma and osteoblastoma**

These are histologically similar lesions, differentiated on size. Osteoblastomas are larger than 1.5cm in diameter. The lumbar spine is a common site with the posterior elements more frequently affected than the vertebral bodies. Patients may present with a painful scoliosis, the lesion being located on the apex of the curve convexity. The pain is classically worse at night and relieved by non-steroidal anti-inflammatory drugs. The typical appearance of the central nidus can be identified on computed tomography (CT) scanning. Radionucleotide bone scans and MRI are also helpful. Although osteoid osteomas usually run a self-limiting course, osteoblastomas often require surgical intervention.

**Eosinophilic granuloma**

Otherwise known as Langerhans cell histiocytosis, can produce either solitary or multiple lytic lesions in the spine. Pathological fractures of the vertebral body may result in a vertebral plana deformity. There may also be an intraspinal extension of the soft tissue tumour. The usually self-limiting nature of this condition makes it amenable to symptomatic management with a period of spinal bracing. More aggressive lesions may require surgery, chemotherapy and low dose radiation.

**Aneurysmal bone cysts**

Approximately one-third of aneurysmal bone cysts (ABCs) are found in the spine, most frequently the posterior elements. They are expansile thin-walled lesions with a multiloculated appearance and fluid-fluid levels on MRI or CT imaging. Pain, a palpable mass,
spinal deformity, and neurological deficits are common presenting features. Embolization has been used both as a treatment modality and preoperatively to reduce bleeding during surgical excision. Recurrence rates are almost 30% and tend to occur within the first year.

**Osteochondromas**

Osteochondromas are benign cartilage capped bony protuberances. Five per cent of cases are located in the spine, commonly affecting either the transverse or the spinous process. Multiple lesions can be found in hereditary multiple exostosis. In those patients with multiple lesions, the risk of malignant transformation to a chondrosarcoma is higher. In solitary lesions the risk is less than 1%. Surgical excision is the treatment of choice.

**The paravertebral tissues**

**Neuroblastoma** is an embryonal tumour originating from neural crest cell precursors. It is the fourth most common paediatric malignancy. Half of these cases will occur before the age of 2 years. The majority will be located in the abdomen either in the adrenals or in the paraspinal sympathetic chain. Most will have raised serum and urinary VMA (vanillylmandelic acid) and HVA (homovanillic acid) levels. Treatment options include chemotherapy, radiation, steroids, and surgery depending on whether the tumour is localized or disseminated.

**Within the epidural space**

Lymphomas and leukaemia usually occur in the spine as a result of metastatic spread but rarely the spine may be the primary tumour site. In general these tumours are very sensitive to chemotherapy and radiotherapy. Surgical decompression should only be considered if these treatments fail or if the neurological state is deteriorating rapidly.

**Summary**

The combination of a varied clinical presentation and the diverse nature of the conditions producing neurological abnormalities in the paediatric patient can pose a clinical challenge. A multidisciplinary approach that allows for a thorough assessment and investigation of the paediatric patient with axial pain and neurological signs is essential.

**Further reading**

Summary points

♦ A rare condition with the potential to cause serious physical disability
♦ Early recognition and treatment reduces the impact of the condition on the individual
♦ Physiotherapists, occupational therapists, and orthotists play a pivotal role in patient management and a coordinated multidisciplinary team is required
♦ Many children need orthopaedic surgery but the treatment principles differ from those applied to unaffected children with similar individual deformities
♦ Prolonged postoperative splinting reduces the risk of recurrent deformities
♦ Individuals with amyoplasia or distal arthrogryposis often have normal intelligence and great potential to cope with their physical disability.

Introduction

Arthrogryposis, or arthrogryposis multiplex congenital (AMC), is purely a descriptive term: it means ‘hooked or curved joints present at birth’. If a child has joint contractures present in two or more different body areas associated with muscle wasting, then the child can be said to have arthrogryposis but there are over 300 different, specific conditions that present in such a way. The clinical features, inheritance patterns, and prognoses of these conditions vary considerably, so an accurate diagnosis is imperative. Three broad groups have been identified which occur with approximately equal incidence (Box 13.9.1). Firstly, there are those with primarily joint involvement. Secondly, there is a group that includes children with involvement of another body system as well as their limbs. The third group includes those with limb and central nervous system involvement in which there is a high mortality in early life.

Box 13.9.1 The three ‘groupings’ of arthrogryposis

♦ Joint involvement alone:
  • Amyoplasia or classical arthrogryposis
  • Distal arthrogryposis
♦ With involvement of another body system:
  • Freeman–Sheldon syndrome
  • Osteochondrodysplasias
♦ With central nervous system involvement: high early mortality rate.

This discussion relates principally to children with amyoplasia and distal arthrogryposis but the principles are common to all those with multiple congenital contractures.

Aetiology, pathogenesis, and pathology

The joint contractures are caused by limb deformation in utero. The deformities are not a result of primary limb malformations. A lack of fetal movement, or fetal akinesia, is thought to be the final common pathway in the development of the clinical picture but many other factors may play a role and both myopathic and neuropathic aetiologies have been implicated. The lack of joint movement leads to extra connective tissue around the joint, shortened tendons, and modelling of joint surfaces. Although the contractures are not progressive they have a tendency to recur rapidly after correction. Correction can be difficult because the tissue planes encountered during surgery are significantly less well defined than normal as are the individual muscles. Muscles are generally weak, sometimes profoundly so, but the pattern and extent of muscle weakness is very variable. Preservation of muscle strength is an important principle of treatment.

Epidemiology and genetics

Multiple congenital contractures occur in 1 in 3000–5000 live births but true amyoplasia is less frequent (1 in 10 000). Most case series in the literature report on less than 20 patients. Amyoplasia is a sporadic condition whilst at least one form of distal arthrogryposis is inherited in an autosomal dominant fashion with the defect mapped to the short arm of chromosome 9.
Clinical features (Box 13.9.2)

A child with amyoplasia will usually have symmetrical limb deformities and the majority have all four limbs affected (Figure 13.9.1). Birth fractures may be identified in one in five children. The skin is shiny and joint creases are reduced or absent in affected limbs. The deformities are symmetrical with severe equinovarus (CTEV) deformities of the feet and extended elbows; 10% have abdominal wall defects. The limb deformities are most severe at birth and often quite alarming. However, some of the deformities are positional and will respond to treatment in the neonatal period. Resistant deformities will require more intensive therapy or surgery.

![Clinical photograph of a child with amyoplasia. All four limbs are affected. The symmetrical involvement of the lower limbs is obvious.](Click to view larger)

Distal arthrogryposis is characterized by medial deviation of the digits, camptodactyly, clenched fists, and foot contractures. Mild proximal joint involvement can occur. Problems related to each joint or region will be discussed in the following sections.

Prognosis

Most families will not have heard of arthrogryposis but most adapt well to the diagnosis. Organizations such as The Arthrogryposis Group (TAG) in the United Kingdom can provide invaluable support for families of affected children. Childhood can be challenging because of the intensive treatment required in the early years of life and the considerable effort required to ensure that the child functions safely in his/her environment. Although they may be affected profoundly by multiple joint contractures, they do not have the same communication problems, sensory abnormalities, perceptual, and balance problems that affect children with cerebral palsy and spina bifida. The prognosis for walking, without treatment, is poor particularly in the amyoplasia group. With treatment, the majority of children with amyoplasia should be able to walk in childhood but they may lose this ability as they pass through adolescence into adult life. The children have near-normal or normal levels of intelligence and tend to be very determined: described by their mothers as ‘kind, social, attractive but more persistent or even stubborn than their siblings’. The life expectancy for those with distal arthrogryposis is thought to be normal and for those with amyoplasia a survival rate of 94% at 20 years has been reported.

As far as personal and social development are concerned, one demographic study reported that 64% of older children in one series were in an educational setting appropriate for their age with 75% independent for feeding, 20% for grooming, 10% for dressing, 35% for toileting, and 25% for bathing. Another study found that half of their adult patients were employed, a third were married, half were independently mobile (with wheelchairs as necessary), and 70% had no limitations in activities of daily living. Their conclusion was that their dependence upon others ‘was not related to physical deformity but to their personality, their education and to their coping skills’. Clearly orthopaedic surgery is only one aspect of the care needed by these children and their families.

Box 13.9.2 Clinical features

- Symmetrical involvement
- Smooth ‘featureless’ joints
- Rigid deformities.

Treatment

General principles (Box 13.9.3)
Coordination between health professionals is essential in managing these children and a multidisciplinary team (MDT) approach is recommended. Treatment must be directed at enhancing function and independence throughout their lifetime. It is therefore important that treatment interferes as little as possible with the child’s normal development, education, and family life. Treatment should begin as soon after birth as possible. Serial casting and orthoses are used to correct the positional deformities of the limbs, reassuring the parents that the deformities are always the most severe at birth. Most authors recommend correcting fixed deformities in infancy with ‘fine tuning’ procedures later in life and the Seattle group have recommended the following approach to treatment:

1) **Infancy** is the time for surgical correction of most fixed contractures. Surgery should be decisive and achieve permanent correction. The worst outcome from surgery is incomplete correction with recurrent contracture.
2) During **early childhood** it is important to prevent recurrence following surgery by splinting at night and encouraging play and independence during the day. This will also help to preserve muscle strength.
3) In **later childhood**, education and the development of skills for life are more important and few if any interventions should be undertaken during this period.
4) **Adolescence** is a time for education, vocational planning, socialization, independence, and preparation for adult life, when one should correct any residual disabilities caused by deformity.

### Box 13.9.3 Management principles

- **Overall:** retain joint movement
- **Lower limb:**
  - Facilitate standing and walking where possible
  - Plantigrade, stable feet
  - Extended knees
- **Upper limb:**
  - Functional grip
  - Adequate ranges of joint movement at shoulder and elbow to enable activities of daily living.

Children with arthrogryposis can present significant problems for the anaesthetists. It may be extremely difficult to secure venous access and mouth opening may be restricted, making tracheal intubation difficult. An increased risk of malignant hyperpyrexia and aspiration has been reported.

Orthoses are an essential part of the management of arthrogryposis. They are used to maintain correction of deformities and to facilitate standing in cases of muscle weakness and joint contracture. They must fit well and make a significant difference to function otherwise the child is likely to reject the splints. A great deal of parents’ energy can be used trying to get their child to wear splints; these children can be very strong willed! The team must be prepared to offer the families as much support as they need (Figure 13.9.2).

Click to view larger

**Fig. 13.9.2**
Clinical photograph of a child with amyoplasia. He is only able to walk with the aid of KAFOs (knee ankle foot orthoses). Note upper limb involvement which can affect balance and influence gait.
Upper limb involvement is common in amyoplasia. The classic posture is of internal rotation of the shoulders, extension of the elbows, and flexion and ulnar deviation of the wrists and fingers (Figure 13.9.3). The degree of muscle weakness in the upper limbs is variable but may be profound. Generally, the elbow extensors are stronger than the flexors and the wrist flexors are stronger than the extensors. Some children have very little movement in the hands. The management of these deformities should be directed towards independence in adult life. The MDT must promote the skills necessary not only for activities of daily living, such as eating, dressing, and toileting, but also for vocational skills such as the use of a computer keyboard. The child may also need to use crutches for walking, or to use their upper limbs for operating a wheelchair. The aims are to help the child to hold objects with as functional a hand as possible, and also to be able to position that hand in space appropriately. One simple philosophy is that the child should have one hand available for hand-to-mouth activities, such as eating and drinking, and the other able to help with perineal hygiene or with pushing themselves up out of a chair. Others prefer a more individualized treatment programme based on the child’s needs and abilities. There is no doubt that stretching, casting, and the use of orthotics are very effective for upper limb deformities. However, for them to be most effective, they must be started as soon after birth as practically possible, and the involvement of a hand therapist is recommended. Most authors recommend that surgical treatment for upper limb problems should be performed either in infancy or early childhood with later secondary procedures if required.

Shoulders

The shoulders are internally rotated and the profile of the shoulder is down-sloping. It is rare for the fixed internal rotation contracture to cause a functional problem but occasional derotation osteotomies of the humerus have been performed.

Elbows

The elbows may be fixed in flexion or extension but extension is more common. A fixed elbow contracture is the deformity likely to produce most disability. The range of motion is variable and usually the triceps is much stronger than the biceps. It is important to achieve as much passive movement as possible to enable the hand to reach the face, but ideally this should not be at the expense of losing strong elbow extension which is necessary for getting out of a chair or for using crutches. There needs to be a compromise. Stretching and splinting can increase the range of movement in infants. If there is less than 90 degrees of elbow flexion then a posterior release and triceps lengthening will increase the passive range of movement. There is more controversy about the role of muscle transfers to restore active elbow flexion. The pattern of muscle involvement is variable. Triceps transfer is the most widely used but pectoralis major, latissimus dorsi, and proximal transfer of the common flexor origin have also been described. The risk with these procedures is that a fixed flexion contracture may develop and all muscle transfers will result in decreased function elsewhere.

Wrists and hands

In both amyoplasia and distal arthrogryposis, the classic deformities of the hand and wrist are flexion and ulnar deviation of the wrists and curved flexed fingers (Figures 13.9.3 and 13.9.4). The thumb is often tucked in the palm. This posture makes prehension and grip difficult and the problems are compounded by forearm and intrinsic muscle weakness. The use of neonatal serial casting is extremely effective in improving wrist position, particularly in distal arthrogryposis. Casting should be followed by the use of lightweight custom-made orthoses, worn principally at night, to enable the child to use the hand during the day. This splinting regimen is supplemented with a regular stretching programme. The orthoses need to be replaced regularly as the child grows. There does not appear to be a consensus on the indications and timing for wrist surgery but, on average, only one-third of those with upper limb involvement undergo surgical treatment. Surgery can either be performed within the first year of life or at a later age. Those who advocate early surgery do so because they claim that surgery is more difficult after the first year of life: the contractures are more severe in the older child, the joint surfaces will have remodelled with intra-articular adhesions, and the skin has become less elastic. They claim that there is a more rapid recovery with less scarring and a greater remodelling potential when surgery is
performed in infancy. Others suggest that surgery should not be undertaken early but only after the wrist position that will give best function has been identified. This needs to take into account finger flexor power, extension power, and the child’s specific functional requirements (Box 13.9.4). Each child develops their own coping strategies for dealing with the activities of daily living: surgical intervention must be sure to improve the situation rather than simply altering it (Figure 13.9.5). Surgery may involve a volar capsular release, a trapezoidal dorsally-based wedge carpectomy, and tendon transfers to act as check reins.

Fig. 13.9.4
Clinical photograph of a hand/wrist deformity demonstrating the featureless appearance of the soft tissues and the absence of joint creases.

Box 13.9.4 Useful hand function?

Bad prognostic signs at birth:

♦ A complete lack of finger flexion creases
♦ No active motion
♦ Extremely stiff joints.

Fig. 13.9.5
The reverse grip that is used by many children with arthrogryposis looks awkward but functions well.

There can be a significant improvement in finger position and function after the correction of wrist deformities, as the resection of a trapezoidal wedge reduces tension in the contracted finger flexors. Surgical correction of finger deformities is rarely required. When they are refractory to splinting, thumb contractures may be treated by adductor release or, in older children, by metacarpophalangeal fusion and brachioradialis transfer. Web-deepening procedures may also be necessary to improve grasp particularly for the first web space.
Almost 90% of children with amyoplasia will have lower limb deformities. Rigid equinovarus deformities and flexed knees are the commonest pattern accompanied by flexed and abducted hips (see Figure 13.9.1). Sometimes the lower limb deformities at birth can be quite bizarre but these tend to be postural deformities that respond well to careful stretching and splinting. The goals of lower limb management are to provide stability and symmetry to maximize the potential for walking. Surgery for lower limb deformities should be deferred until it is clear whether the child is likely to walk, which can be exceedingly difficult to judge.

Preoperative assessment must take into account not only the degree of joint deformity and muscle strength, particularly of the hip extensors and quadriceps, but also the extent of upper limb involvement. A child who is likely to spend most of their time sitting needs symmetrical lower limbs with plantigrade feet. When surgery is required it is better to do simultaneous procedures on different joints, in order to reduce the immobilization time and the time spent in hospital during childhood.

### Hips

Soft tissue contractures around the hip are common. Most positional deformities respond to careful stretching and splinting. Flexion contractures in excess of 30 degrees are likely to impair walking and those over 45 degrees are likely to require surgical release.

Hip dislocation occurs in almost a half of all children with amyoplasia and is usually bilateral. A unilateral dislocation will affect standing, gait, and sitting balance and should be reduced (Figure 13.9.6). Closed reduction is usually unsuccessful in arthrogryposis. There is still debate about what should be done with bilateral hip dislocations—some believe they should be left untreated, particularly if stiff, but the balance of opinion is tending to swing towards reduction in those who are likely to walk. Reduction of bilateral dislocated hips is said to provide a better-looking and more efficient gait. Some recommend the medial approach for hip reduction because the soft tissue dissection is minimal and there is little blood loss. This is important if the feet and knees are being treated in the same operating session. It is also claimed that there is less stiffness following reduction through a medial approach than after an anterolateral approach but success has been reported with both techniques. In older children concomitant pelvic surgery or femoral shortening may be required. The threshold for treating residual acetabular dysplasia is higher in children with arthrogryposis than without.

![Click to view larger](image.png)

**Fig. 13.9.6**

A) AP radiograph demonstrating a unilateral (left) hip dislocation. The contralateral (right) knee is in fixed extension and there were bilateral severe TEV deformities (B, right foot). The management of the left hip dislocation must take into account the other joint deformities. The hip was reduced and both feet treated with talectomies.

### Knees

Knee involvement is present in 70% children with amyoplasia. The common patterns are fixed flexion, fixed extension, or, less frequently, hyperextension. Fixed flexion of greater than 20 degrees makes standing difficult whilst conversely sitting is difficult with fixed extension (Figure 13.9.6). Patients with extended knees are more likely to be community walkers in the long term but may be at a higher risk of degenerative joint disease. An arc of movement between 15–60 degrees is the ideal. Flexion can be gained with a quadricepsplasty but, in the child with significant quadriceps weakness, this may make it less likely that they will be able to stand. Extension can be achieved by a soft tissue release (with femoral shortening in severe cases), a supracondylar femoral osteotomy, or through the use of a ring fixator. Recurrent deformities are common and splintage is essential after surgery to reduce this risk (Figure 13.9.2). Straightening out flexed knees is the only procedure in paediatric orthopaedics that makes a child walk (Staheli 1993).

### Feet

The vast majority of children with arthrogryposis have foot deformities, most commonly a rigid equinovarus (Figure 13.9.6). Occasionally they may have congenital vertical talus (Figure 13.9.7). Recurrence is the main problem following surgery and many children will require second procedures despite long-term postoperative splinting. The aim of surgery is to produce a rigid plantigrade platform which can be accommodated in normal shoes. Ponseti-style serial casting has been tried and although early reports are favourable, to date, there are no published series available with satisfactory follow-up. More casts are required for
correction compared to the idiopathic foot deformity (see Chapter 13.21) and recurrence is common. The options for surgical treatment of the equinovarus foot are either a radical soft tissue release or primary talectomy (see Figure 13.9.6). Most authors recommend a radical soft tissue release as the primary procedure but the recurrence rate may be up to 73%. Recurrences can respond to serial casting or secondary soft tissue surgery and satisfactory results can be achieved in over 90%. There is no doubt that talectomy is valuable salvage procedure, provided the bone is completely excised and the foot is placed in the correct position after surgery. The Ilizarov method has been used to treat recurrences with good results reported from some specialist centres.

**Fig. 13.9.7**
Clinical photograph of a child with distal arthrogryposis and bilateral vertical tali. The feet demonstrate a ‘rocker-bottom’ deformity with hindfoot equinus and a dorsal subluxation of the talonavicular joint.

### Spine

Approximately 20–30% of children with amyoplasia will develop scoliosis. This may affect sitting balance and interfere with upper limb function. The most common curve pattern is thoracolumbar. Curves that develop in early childhood tend to become the most severe. Some, but not all, curves progress relentlessly even after skeletal maturity. Bracing should be used to contain progression and to treat curves less than 30 degrees. Children with curves greater than 50 degrees should be considered for surgery, with a combined anterior and posterior instrumented correction appearing to produce the most reliable results.

### Summary

Arthrogryposis is uncommon, but needs to be recognized early in life so that treatment can be started, and positional deformities corrected. In the next 5–10 years, there are likely to be great advances in the understanding of the conditions of which multiple congenital contractures are a feature. There are many controversies regarding the timing and nature of surgical treatment and very little evidence upon which to base management. More children are being managed in specialist centres by MDTs and it is to be hoped that collaborative research will lead to better outcomes for these children in the future.

Summary points

- Most torsional or angular deviations are physiological and resolve with time
- Ensure the child has normal growth parameters
- Take care to exclude the rare underlying condition that will require treatment
- Coronal knee deformities may be due to a systemic or local bone dysplasia.

Introduction

Abnormalities of lower-limb alignment, particularly during walking, often cause parental concern and require assessment in the paediatric orthopaedic clinic. Rotational deviations that lead to in-toeing or out-toeing gait, coronal plane knee deformities (genu varum or valgum), and pes planovalgus are the most common causes of parental concern. In the majority of these children, deviations are physiological and of no functional consequence. However, in a small number of children, these abnormalities may be representative of an underlying condition that requires treatment. Therefore, careful clinical assessment of these children is necessary before adequate reassurance can be offered to the parents.

Gait abnormalities

An assessment of gait must include watching the child stand, walk, and run. Many children are on ‘best behaviour’ in the consulting room and parents are frequently concerned that the doctor has not seen their child’s ‘normal’ walk. Every effort must be made to ensure that the child is as relaxed as possible before the assessment is made: often more can be learnt from watching the child leave the room than watching them come in.

Observational (clinical) gait analysis skills must be used to exclude a generalized problem such as a neuromuscular abnormality or skeletal dysplasia before a more specific assessment of their walking pattern is made. Assessment of the child’s torsional profile may help determine where the main deformity lies and reveal the extent of any compensatory deformity (Box 13.10.1 and Figure 13.10.1).

Box 13.10.1 Torsional profile

- Prone hip internal rotation range
- Prone thigh–foot axis
- Foot deformity.

---

**Fig. 13.10.1**
Assessment of torsional profile. A) As the child walks, look at the angle the feet make with the imaginary line of forward
progression. This is the foot progression angle. B) With the patient prone and the knee flexed to 90 degrees place your thumb on the greater trochanter then C) internally rotate the leg. When the trochanter reaches its most lateral position, the angle between the tibia and the vertical is equal to the femoral anteversion. D) With the patient prone and the knee flexed to 90 degrees, allow the hindfoot to be in a relaxed position. The angle between the longitudinal axis of the hindfoot is the thigh–foot angle. Be careful to ‘ignore’ forefoot deformity. E) In the same position, the angle between the transcondylar axis of the proximal tibia and the transmalleolar axis of the ankle is also a measure of tibial torsion.

In-toeing gait

The foot progression angle is defined as the angle between the longitudinal axis of the foot and the line of progression of walking. The average foot progression angle in the adult healthy population is approximately 10 degrees external, with a range between 5 degrees internal and 20 degrees external being considered as normal. Mild deviations from the norm are well tolerated and do not cause functional problems or symptoms. Significant deformities may cause frequent tripping and falling, particularly when children are tired and their compensatory mechanisms are failing. It is not known how significant these deviations need be before they cause abnormal joint loading and moments that may lead to long-term joint degeneration. Measurement of joint moments through instrumented gait analysis may have a role in assessing children with significant deviations who are candidates for treatment. This can establish if these deviations are purely cosmetic or likely to cause long-term clinical problems (Figure 13.10.2).

![Fig. 13.10.2](Click to view larger)

This graph from a gait analysis report demonstrates the internal and external rotation that occurs at thigh level during the stance and swing phases of gait. The light grey band represents the mean and 2 standard deviations either side of the mean values whilst the dashed and black lines represent the right and left legs respectively. Both show significant internal rotation.

Femoral anteversion

Femoral anteversion is the angle between the longitudinal axis of the femoral neck and the frontal plane of the femur defined by the transcondylar axis and the femoral diaphysis. Femoral anteversion is approximately 40 degrees at birth and gradually remodels to the average adult 15 degrees, usually within the first 3–4 years of life. Little remodelling is expected after the age of 8 years. Early remodelling occurs as a result of pressure on the anterior femoral neck by the soft tissues, particularly the ligaments and the joint capsule, which results from the upright human posture. Conditions preventing upright posture or associated with ligament laxity or joint instability are usually associated with failure of remodelling and persistent femoral anteversion. However, persistent femoral anteversion is also present in a significant number of normal children. In addition to their in-toeing gait, children often have a typical running pattern with their lower legs swinging out to the side and they are able to “W” sit comfortably (Figure 13.10.3).

![Click to view larger](Click to view larger)
Clinical assessment of femoral anteversion is performed with the child in the prone position and the knee in 90 degrees of flexion. The hip is rotated until the most prominent part of the greater trochanter is palpated in the mid-lateral position. In this position, the angle between the tibia and the vertical is equal to the femoral anteversion (see Figure 13.10.1B,C). The range of hip rotation is often affected and excessive internal rotation is present, at the expense of external rotation. During walking or running, the knees are facing inwards and, as the tibia flexes, the visual impression of genu valgum is often present. Computed tomography (CT) scan or, preferably, the radiation-free magnetic resonance imaging (MRI) scan can be used for a more accurate measurement of anteversion, particularly when surgical correction is contemplated.

In the absence of any underlying or associated conditions, persistent femoral anteversion rarely requires treatment. Whilst increased femoral anteversion is often present in developmental hip dysplasia, patients with the condition would rarely present with in-toeing as their main complaint. It is important to ensure that examination of the hips is normal in children who present with increased femoral anteversion and, if necessary, a pelvic radiograph should be taken to exclude hip dysplasia. Reassurance can be offered to parents of children under the age of 8 years as in the majority of cases the deformity is likely to remodel spontaneously. Non-surgical treatment does not influence the rate of remodelling. Significant anteversion causing functional problems and persisting beyond the age of 8 years may require surgical correction. Given the potential risks and complications involved in bilateral femoral derotation osteotomies, patients should be carefully selected and treatment indications discussed thoroughly with their families.

**Internal tibial torsion**

Tibial torsion is defined as the angle between the transcondylar axis of the proximal tibia and the transmalleolar axis of the ankle (Figure 13.10.1E). The normal adult average is approximately 20 ±10 degrees of external torsion. Clinically tibial torsion is measured by palpating the above landmarks, defining the axes and using a goniometer to measure the angle. The thigh–foot angle is also used as an estimate of tibial torsion. This is the angle between the longitudinal axis of the foot and the femur assessed in the prone position with the knee flexed at 90 degrees (Figure 13.10.1D). Both clinical measurements can be inaccurate, the former because of the difficulty in defining the transcondylar axis and the latter because of knee rotation and foot deformity compromising the measurement. During walking, the knees are facing forward but the foot progression is internal. In the absence of foot deformity this clinical picture would suggest that internal tibial torsion is present. CT or MRI scan can be used for the accurate measurement of tibial torsion, particularly in surgical candidates.

Internal tibial torsion is probably caused by moulding in utero and resolves spontaneously in the vast majority of infants within the first few years of life. When the deformity is purely torsional, reassurance can be offered to parents of young children. Tibial bowing associated with torsion may require further investigation with radiographs, particularly if it persists after the age 3 years, in order to rule out underlying pathology. If the deformity persists after the age of 6–8 years it is unlikely to remodel spontaneously. Surgical treatment may be appropriate in a small minority of selected cases with significant deformity and functional problems. A supramalleolar tibial derotation osteotomy is undertaken and stabilized, often with internal fixation. A concomitant fibular osteotomy is also used as an estimate of tibial torsion. This is the angle between the longitudinal axis of the foot and the femur assessed in the prone position with the knee flexed at 90 degrees (see Figure 13.10.1D).

**Metatarsus adductus**

Adduction of the forefoot with a normal hindfoot is present in approximately 1:1000 newborn infants and is probably caused by moulding in utero. It can be associated with hip dysplasia and careful assessment of the hips should be undertaken. The deformity is usually observed immediately after birth but a significant number of children present later with parental concerns over in-toeing. Older children may complain of pain from excessive pressure over the lateral plantar area and/or difficulty with shoe fitting.

Clinical examination reveals a curved lateral border of the foot with a normally aligned hindfoot and sometimes a mild degree of forefoot supination. When the deformity is flexible, the forefoot can be manipulated easily to the neutral position or beyond. When the deformity is rigid, further assessment is required to rule out a congenital skeletal abnormality or a varus deformity of the hindfoot that would suggest a mild form of congenital talipes equinovarus.

Dynamic adduction and supination of the forefoot in toddlers with a normal but immature gait pattern can sometimes be confused with metatarsus adductus. This is caused by the predominant use of tibialis anterior tendon for foot dorsiflexion during the swing phase of gait while the peronei are silent. The foot assumes normal alignment at rest and clinical examination is entirely normal. This should be considered as a normal stage of gait maturation that will resolve spontaneously over time.

Flexible metatarsus adductus deformity usually resolves spontaneously within the first 1–2 years of life. Rigid deformity should be treated with early serial above-knee casting. The role of orthotic management and/or splinting in older children is unclear as evidence on the effectiveness of such treatment is lacking. Persistent symptomatic deformity may require surgical treatment in a minority of patients. Relatively mild deformity in younger children responds to soft tissue surgery, including medial capsular release of the appropriate joint(s) at the apex of the deformity (usually navicular–cuneiform or cuneiform–first metatarsal). Lengthening of the abductor hallucis may also be necessary. When forefoot supination is present, lengthening or transfer of tibialis anterior tendon may be appropriate. Rigid deformity in older children requires bony procedures in the form of basal metatarsal or midtarsal osteotomies: this is very rarely necessary and should not be undertaken without considerable thought.

**Out-toeing gait** (Box 13.10.2)

Common causes of external foot progression include external tibial torsion, planovalgus foot deformity (see Chapter 13.22) or more rarely, external hip rotation due to femoral neck retroversion.
External tibial torsion

This may be present at birth or may develop over time as compensation for increased femoral anteversion. Planovalgus foot deformity may further compromise the rotational alignment of the foot in relation to the knee. As a result of this malalignment, the physiological knee extension moment generated by the foot plantarflexors, using the foot as the lever-arm, is compromised. This, in turn, causes excessive strain on the knee and particularly, the patellofemoral joint.

Mild deviations of external tibial torsion are usually asymptomatic, at least during childhood, and cause no functional problems. Significant rotational anomalies may cause symptoms at the knee and/or the foot. Spontaneous correction can only be expected in young infants and toddlers with congenital deviations. Acquired or persistent deformity causing symptoms or functional problems after the age of 5 years is unlikely to remodel and may require surgical treatment. As with deformity due to internal torsion a supramalleolar derotational tibial osteotomy is performed and stabilized with internal fixation. Again, a fibular osteotomy is seldom necessary (Box 13.10.3).

Relative femoral neck retroversion

Predominant external rotation at the hips due to reduced femoral anteversion or retroversion is a rare cause of out-toeing gait. Children with the condition walk with knees facing outwards and an external foot progression. Clinical examination reveals excessive external rotation of the hips at the expense of internal rotation. Usually the condition is idiopathic and of no functional consequence in childhood, therefore no treatment is indicated. Coxa vara can be an underlying cause in younger children while chronic bilateral slipped upper femoral epiphysis should be considered in children of prepubertal age. Radiographic evaluation should be undertaken when these diagnoses are considered.

Toe walking

Walking on tip-toes is a normal stage in the development of a mature gait pattern but by the age of 3 a child should have outgrown this phase. Most children with idiopathic toe walking (ITW) can get their heel to the ground and will do so when standing but when walking or running there is a toe-toe or toe-heel pattern. In both situations there is disturbance of the ankle rockers (Box 13.10.4). The aetiology of ITW is not known but it may be due to an undefined and minor ‘error’ in the central nervous system (CNS).

A full history and examination is required as it is imperative to distinguish ITW from mild cerebral palsy, muscular dystrophy, or other neurological disorders. It is particularly important to clarify if toe walking developed late in children who had previously walked normally as this would suggest a progressive neurological disorder. The foot may be triangular in shape with a splayed forefoot and a relatively under-developed heel. Neurological examination is essentially normal but there may be some symmetrical loss of ankle dorsiflexion. Formal gait analysis distinguishes ITW from mild cerebral palsy but this is rarely necessary.

Many children stop toe walking spontaneously over time and perhaps with an increase in body mass and compensatory external tibial torsion. Persistent ITW with maintenance of 5 degrees of dorsiflexion is unlikely to cause any functional problems. Treatment with Achilles tendon stretches and dorsiflexion strengthening exercises may help improve gait pattern. Serial casting and/or botulinum toxin injections may be successful but if there is significant tightness of the Achilles tendon a surgical lengthening will

---

**Surgical correction:**

- Supramalleolar osteotomy
- Internal fixation
- Fibula osteotomy rarely necessary

**Box 13.10.2 Out-toeing gait**

- External tibial torsion
- Planovalgus (flat foot) deformity
- Femoral neck retroversion.

**Box 13.10.4 Three ankle rockers of normal gait**

- 1st—plantarflexion in early stance between heel strike and foot flat
- 2nd—dorsiflexion in mid stance as the leg moves over the foot
- 3rd—plantarflexion in terminal stance for push off.
be necessary. Although the operation itself is simple and reliable, the procedure changes the gait pattern dramatically and the parents must be forewarned. The gait improves in the rehabilitation phase as the plantar flexors regain their strength. Recurrent toe walking is not uncommon perhaps because the cause lies in the CNS. Toe walking in children with behavioural problems or autistic syndrome disorders should be distinguished from ITW as it is rarely associated with tightness of the Achilles tendon and responds less well to surgical treatment (Box 13.10.5).

**Box 13.10.5 Unilateral toe walking**

Is not ITW—so look for another cause:

♦ A late diagnosed developmental dysplasia of the hip or other hip pathology
♦ A leg length discrepancy
♦ Neurological problem.

---

### Angular deformity

#### Genu varum and valgum

The coronal alignment of the knee changes in the first 6–7 years of life. These changes can cause parental concerns, particularly at times of development when they reach peak values. Knowledge of the physiological evolution of the coronal knee alignment is therefore important when advising parents about the natural history of the deformity.

At birth and during the first year of life the knee alignment is 15 degrees (±5 degrees) varus. It remodels to neutral alignment during the second year of life, presumably as the result of weight bearing. After the age of 2 years the knee progresses to valgus alignment to reach a maximum of 10 degrees (±5 degrees) valgus at the age of 3–4 years. From there it gradually remodels to the average adult value of 7 degrees valgus by the age of 6–7 years (Figure 13.10.4).

A wide variety of conditions, including metabolic bone diseases, bone dysplasias, and Blount’s disease, can lead to coronal plane knee deformity. Consideration should be given to those conditions if knee alignment deviates from the pattern described earlier. While varus knee alignment at the age of 18 months is likely to be physiological, if it deteriorates overtime or persists after the age of 3 years it may require further investigation. Similarly, the combination of significant tibial torsion with a varus deformity raises concern regarding underlying pathology.

Persistent varus or valgus alignment of the knee after the age of 8 years is unlikely to remodel spontaneously. Although there are no long-term studies to substantiate this, it is logical to assume that significant coronal knee deviations will lead to degenerative arthropathy, particularly if the mechanical axis lies outside the joint. Therefore, severe deformity may be an indication for surgical correction, particularly if symptomatic. It is essential to establish the level of the deformity with appropriate radiographs: is it in the distal femur or the proximal tibia? Furthermore, it is important to confirm that the deformity is truly and entirely in the coronal plane as increased femoral anteverision combined with external tibial torsion may give the false impression of genu valgum. During growth, coronal knee alignment can be corrected with temporary hemiepiphyseodesis at the appropriate level (Figure 13.10.5). After the end of growth, osteotomy of the distal femur or proximal tibia would be necessary.
Fig. 13.10.5
A) Leg alignment radiographs showing bilateral genu valgum. The mechanical axis of the right leg has been drawn and shows the line passing through the lateral aspect of the knee. The patient was treated by temporary hemiepiphysiodesis of the medial distal femoral physis. B) 13 months later the axis had improved significantly. (At 18 months, the axes were normal and the plates were removed.)

Summary points

- Anomalies are common but often minor and of little functional concern
- Often associated with other manifestations that are of greater clinical significance
- A knowledge of embryological development allows a better understanding of the clinical picture and informs management plans.

Incidence and aetiology

The term congenital upper limb anomaly is used to describe all hand and upper limb abnormalities that arise as a result of an error of normal embryological development. This error can either be environmental or genetic in aetiology.

A good knowledge of these anomalies is important as not only can they have a profound impact on the functional and cosmetic condition of the child affected but they may also have important psychological consequences for both the child and parents. It is often the position of the surgeon to relay information regarding the aetiological and embryological basis for these disorders to the parents as well as to discuss the prognosis and possible management strategies.

These anomalies are common: they may be obvious at birth if severe or they may present when the child is older, becoming more apparent with growth. They are often very visible and identifiable as a result of this but equally many anomalies are minor and interfere little with upper limb function.

Most epidemiological studies regarding upper limb anomalies are based on relative frequency, as opposed to true incidence and prevalence rates. In a recent study in Western Australia, upper limb anomalies were reported in 1:506 live births but this reduced to 1:610 at the time of presentation due to neonatal or infant deaths perhaps with conditions related to the upper limb anomaly. Previous studies have reported an overall incidence of any congenital anomaly as 1:100–200 live births and as 10% of these were upper limb abnormalities, the incidence for upper limb anomalies was given as 1:1000–2000. Many upper limb problems are associated with non-musculoskeletal problems. There is no evidence that anomaly rates are higher in monozygotic rather than dizygotic twins but rates are higher in mothers who are either old or young and babies born both pre- and post-term (Box 13.11.1).

Upper limb anomalies can be the result of either a malformation or a deformation. A malformation is described as an abnormality of primary structural development whereas deformation is the result of secondary change in a part which was previously developing normally.

Whilst upper limb anomalies do occur in isolation, they may well be associated with other systemic disorders or syndromes. These associated conditions are often of more clinical importance to the health of the child than the musculoskeletal abnormality. It is therefore important to be aware of these disorders so that the patient is evaluated properly.

The aetiology of congenital upper limb anomalies is incompletely understood. The accepted classification of this group of anomalies is based on clinical diagnosis and according to our understanding of where and when the failure took place during fetal development. There is no good evidence to link congenital upper limb anomalies to specific environmental agents although the use
of thalidomide was associated with phocomelia. Some studies have shown an association with the use of antiepileptic agents in the early gestational period. The causative environmental agent or genetic abnormality can impact upon development at various stages of fetal development and a specific insult may have a very different effect if it is given at different stages of development. Similarly, seemingly very different insults given at a specific stage of development can cause the same anomaly.

**Box 13.11.1 Associations with congenital upper limb anomalies**

- Males = females
- 20%* have an identifiable syndrome
- 50%* have non musculoskeletal anomalies
- 50%* have bilateral upper limb anomalies
- 15%* have another anomaly elsewhere
- 15%* have multiple separate hand anomalies.

* approximate percentages

Overall, duplications and failures of differentiation and formation account for the majority of the upper limb anomalies identified.

**Embryology**

The upper limb bud appears on the lateral aspect of the embryo 24h before the lower limb bud around 26 days postfertilization. There is then rapid progress with upper limb development and the process is complete by 8 weeks (Figure 13.11.1). Therefore it holds that congenital upper limb anomalies are most likely to occur during this short time period of development.

Three areas of signalling have been discovered which guide the development of the embryonic upper limb. Firstly, the apical ectodermal ridge (AER) which overlies the limb bud, guides the mesoderm to differentiate by the medium of fibroblast growth factors. Differentiation occurs in a proximal to distal direction; thereby the upper arm will differentiate prior to the forearm which develops prior to the hand. It is this mechanism that allows the webbed hand to develop by way of dorsal grooving and interdigital necrosis regulated by apoptosis (programmed cell death) separates the digits between weeks 7–8.

The second mechanism is the zone of polarizing activity (ZPA), located on the posterior aspect of the limb bud. This activity is mediated by the Sonic hedgehog (SHH) protein and its function is to signal radio–ulnar development and orientate the limb.

The final mechanism of upper limb embryonic development is through the Wingless-type (Wnt) signalling centre. This centre is located in the dorsal ectoderm and it controls dorsoventral differentiation and limb rotation by secreting factors that influence mesodermal development around week 7.

The HOX (homeobox containing) genes also play an important role in limb development as their genetic expression controls growth by regulating mesenchymal cell function.

Thus, any abnormality in the function of any of these mechanisms could result in a specific and possibly predictable upper limb anomaly; for example, failure of the AER can lead to a failure of distal limb development including syndactyly. In experimental situations, transplantation of the AER has led to duplication of the limb or the development of supernumerary digits.

By the end of week 5, the majority of the skeletal limb has differentiated, as well as the brachial plexus. More distal neurological branches are complete at the end of week 6, with musculature defined at the end of week 8.

Other systems are also developing between weeks 4–8 and therefore a more general embryological insult, genetic or environmental, can result in abnormalities elsewhere in the developing embryo. Specifically the gastrointestinal, cardiovascular, and neurological systems are all also developing rapidly at this time. Therefore it is important for the clinician to consider the possibility of a wider and potentially more clinically serious disorder than the musculoskeletal anomaly alone and to investigate and refer as appropriate.

**Classification**

Currently the most widely accepted classification for congenital upper limb anomalies is the Swanson classification which has been adopted by the International Federation of Surgical Societies of the Hand and known now as the IFSSH classification (see Table 13.11.1, and Chapter 13.13). It is based on the specific developmental failure and relies on clinical diagnosis of the anomaly.
Table 13.11.1 Classification of Spence’s deformity

<table>
<thead>
<tr>
<th>Grade</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>Mild deformity where shoulder girdles are at the same level. The deformity is not visible in the dressed patient</td>
</tr>
<tr>
<td>II</td>
<td>Slight deformity still present, where shoulder joints are almost level, but superomedial portion of scapula visible as a lump</td>
</tr>
<tr>
<td>III</td>
<td>Moderate shoulder joint deformity with scapula visibly elevated 2–5 cm</td>
</tr>
<tr>
<td>IV</td>
<td>Severe deformity with scapula angle close to the occiput with webbing of the neck</td>
</tr>
</tbody>
</table>

Often, as shown in epidemiological studies, more than one anomaly may be present in more than one area of the limb and with this current embryological classification of upper limb anomalies, it is not possible to classify all hand anomalies. For example, brachysyndactyly may fit in either of two categories, failure of formation and failure of differentiation.

Anomalies of the shoulder

Congenital pseudarthrosis of the clavicle

Congenital pseudarthrosis of the clavicle is a rare condition. Less than 200 cases have been reported in the English literature. The majority of cases are right sided and the common presentation is that of a painless, non-tender, and mobile mass at the centre of the clavicle identified soon after birth. The clavicle begins to ossify at 8 weeks and is the first bone to do so. It normally develops from two separate intramembranous centres of ossification which go on to unite. In pseudarthrosis of the clavicle, this process fails due either to a mechanical or an environmental insult: it may be caused by an intrinsic primary failure of development or because of external compression. The two parts of the clavicle form a fibrous bridge which then goes on to develop into a true pseudarthrosis. Histologically, each clavicular end is capped with cartilage tissue and they are joined by dense fibrous or fibrocartilaginous tissue. Generally, radiographs show that the medial part of the clavicle sits anteriorly and superior to the lateral acromial section of the pseudarthrosis (Figure 13.11.2). A birth fracture is the most common differential diagnosis but the lack of callus formation over time excludes this diagnosis. Occasionally neurofibromatosis or cleidocranial dysostosis may be considered.

It is postulated that pressure from the subclavian artery which runs posterior to the clavicle on the right accounts for the fact that the right clavicle is much more commonly affected. In accordance with this theory, left-sided cases are found almost exclusively in individuals with dextrocardia or situs inversus.

There is usually no significant functional deficit of the shoulder. The natural history is not known as most reported cases have undergone operative treatment. The aesthetic appearance worsens with time as the pseudarthrosis becomes more prominent, tenting the skin on movement. There may be pain on certain activities or with compression.

The indications for treatment are often aesthetic and surgical treatment is usually advocated between the ages of 3–5 years. Treatment involves surgical excision of the pseudarthrosis, remembering that approximation of the bone ends followed by bone grafting and stable internal fixation is essential if union is to be achieved. Some authors emphasize the importance of maintaining the periosteal sleeve. Currently, plate and screw fixation is recommended. The major complication of this surgery is non-union but overall, reported union rates are high and the cosmetic appearance is improved.

Cleidocranial dysostosis

This skeletal dysplasia affects the development of many bones, primarily those of membranous origin. As the name implies, the bones most significantly affected are the clavicles and the skull although there is also delayed ossification and underdevelopment of the pelvis (including the hips) and the spine. The clavicles can be hypoplastic or absent and in the skull, there is delayed closure of the cranial sutures and the fontanelles with maxillary hypoplasia and dental abnormalities (Figures 13.11.3 and 13.11.4).

Fig. 13.11.4
A) Frontal and B) superior views of a three-dimensional CT reconstruction of the skull of a 12-year-old child with cleidocranial dysostosis showing that the sutures and fontanelles remain open.

Recently, genetic studies have concluded that the disorder is inherited in an autosomal dominant fashion with an increase in mutations of the CBFA1 gene located on the short arm of chromosome 6.

Clinically the patient has bilateral ‘drooping’ shoulders, often with the ability to oppose the shoulders anteriorly, due to the profound hypoplasia or absence of the clavicles. This can lead to difficulty with coordination of arm movements and a theoretical potential for brachial plexus injury. Abnormalities of the musculature can also occur depending on which part of the clavicle is deficient. If lateral, deltoid and trapezius muscles can be affected but if the medial end is affected problems with the pectoralis major and sternocleidomastoid muscles can occur.

Other associations include hypoplastic scapulae, hypoplasia of the iliac wings, joint laxity, and dislocations and abnormalities of hands and feet. The patient is often of short stature and he may walk with a Trendelenburg gait secondary to the associated coxa vara.

Management involves genetic testing and counselling. Specific orthopaedic intervention at the shoulder is only indicated if the hypoplastic ends of the clavicles compress the subclavian vessels or the brachial plexus or to prevent secondary complications of pressure on the overlying skin. Treatment is usually by excision of the hypoplastic clavicle. Craniofacial surgery and surgical correction of the concomitant coxa vara or scoliosis may be required.

Sprengel deformity

A Sprengel deformity is the most common congenital malformation of the shoulder girdle. During normal embryological development the scapula arises opposite the lower cervical spine and in the third month of gestation it descends caudally to the thorax. Failure of this normal migration leads to a hypoplastic, undescended, and hence malpositioned scapula. Associated with this bony abnormality are abnormalities of the surrounding musculature: pectoralis major, trapezius, rhomboids, and latissimus dorsi may be hypoplastic, absent, or weak. A weak serratus anterior can lead to a winged scapula.

The condition is three times more common in males than females but it affects both left and right sides equally. It can occur sporadically but sometimes there is an autosomal dominant inheritance pattern.

Clinically there is an asymmetrical shoulder line (Figure 13.11.5). The scapula can sit up to 10cm more superiorly than normal as well as more medially. The inferior pole is medially rotated which in turn points the glenoid fossa inferiorly. Patients often complain most about a ‘lump’ in the web of the neck where the superior pole of the scapula bends anteriorly over the top of the thorax (Figure 13.11.6).
Fig. 13.11.5
Clinical photograph of a child with a unilateral Sprengel deformity.

Fig. 13.11.6
Three-dimensional CT scan showing a left Sprengel shoulder and highlighting the abnormal shape, position, and orientation of the scapula. It resembles an ‘equilateral triangle’ and there is no long medial border. No bony omovertebral bar is seen and there are no anomalies of the cervical spine. Excision of the superomedial corner of the scapula in the base of the neck can improve the cosmetic appearance.

Movements of the glenohumeral joint are often normal but scapulothoracic movement is limited and thus there is a restriction of shoulder abduction (Figure 13.11.7). Rotation and forward flexion may also be limited.

Fig. 13.11.7
Clinical photograph of an adolescent with bilateral Sprengel deformities. He was a talented badminton player but had an unorthodox service action perhaps because of the limited shoulder abduction. Only 10–30% of cases are bilateral.

The deformity can be classified in rudimentary terms (Table 13.11.1) and the more severe the deformity the greater the restriction in joint movement and the more likely there are to be associated developmental anomalies (Box 13.11.2).
Musculoskeletal:
- Klippel–Feil syndrome
- Scoliosis
- Absent/fused ribs
- Cervical spina bifida
- Omovertebral bar

Systemic: renal and pulmonary disorders.

An omovertebral connection is present in up to 50% of cases: this may consist of a fibrous, cartilaginous, or bony bar and it may contribute adversely to the cosmetic appearance.

Treatment for a Sprengel deformity is based on the severity of the functional loss and to some extent cosmesis. Passive stretching exercises are recommended in less severe cases to increase the range of movement and strengthen the surrounding muscles. If surgery is required it should be carried out before 8 years of age to reduce the risk of complications such as a brachial plexus neuropathy. Many of the operations described can leave an unsightly scar and therefore careful consideration should be given to the cosmetic benefits of such surgery. In mild cases, an extraperiosteal resection of the superior pole of the scapula and any associated omovertebral tissue may provide significant cosmetic improvement with little risk of morbidity.

In more severe cases, the aim of surgical treatment is to improve the range of functional abduction by relocating and repositioning the scapula and hence the glenoid. Several surgical options are essentially soft tissue releases involving resection of the omovertebral bone with division of the trapezius, rhomboids, levator scapula, and parascapular muscles from either their spinal or scapular origins. The muscles are then reattached via various suture techniques once the scapula has been brought distally. Another popular technique involves a vertical scapular osteotomy.

Other developmental anomalies of the shoulder region

Phocomelia

Phocomelia is rare but in such cases there is often glenoid aplasia as there is in amelia. The management is non-operative. Prosthetic limbs are not often a good functional solution.

Glenoid dysplasia

In this uncommon condition, the glenoid is flat and shallow. It can be found in association with a malformed proximal humerus (which may be an aetiological factor) and may develop secondary to a neonatal brachial plexus lesion (see Chapter 13.12). Clinically the patient may complain of instability and/or dysfunction but often the condition is entirely asymptomatic. If the deformity is severe enough to cause loss of function, operative management involves a glenoplasty using iliac crest graft.

Glenoid dysplasia is often an isolated condition but it can be part of other more general conditions (Box 13.11.3).

Box 13.11.3 Conditions associated with glenoid dysplasia

- Apert’s syndrome
- Mucopolysaccharidoses such as Hurler’s syndrome
- Holt–Oram syndrome

Holt–Oram syndrome is an autosomal dominant condition resulting in a complex of cardiac defects and skeletal malformations. The genetic defect is in a transcription factor TBX5. All cases have abnormalities of the carpal bones and the most severe cases will have a phocomelia. In between, manifestations include a rotated, hypoplastic scapula with associated wrist and forearm problems (see Chapter 13.13).

Os acromiale is a disorder where there is a non-union between one, two, or all of the three normal ossification centres of the acromium with the rest of the scapula. The condition is not inherited (Box 13.11.4). It is often an incidental finding on plain radiographs but symptoms may be similar to those of subacromial impingement syndrome. Initial treatment is conservative but occasionally, surgical excision or fixation of the fragment is required and subacromial decompression may be necessary.

Box 13.11.4 The bipartite acromium

- Failure of fusion of the three ossification centres
- Present in 1–15% of patients
- Approximately 50% are bilateral
Humeral dysplasia

*Congenital humerus varus* is analogous to coxa vara. It may be due to medial epiphyseal damage of the humeral head. Often it is asymptomatic but severe cases demonstrate a limitation of abduction.

*Humeral head retroversion* develops in response to abnormal pressures on the shoulder: it is commonly associated with a neonatal brachial plexus palsy. Movements of abduction, external rotation, and adduction are limited. Treatment, if necessary, is by anterior capsular release. If the deformity and decreased function are severe, a proximal derotation osteotomy can be performed but only after careful assessment of shoulder congruity.

Poland’s syndrome (Box 13.11.5)

Poland’s syndrome is a sporadic, uncommon, unilateral congenital disorder characterized by underdevelopment or absence of the chest wall and scapula muscles and the breast tissue with associated rib cage defects and hand anomalies (see Chapter 13.13). Not all features need be present to constitute a diagnosis of Poland’s syndrome and subtle cases may be missed. Girls may present in puberty due to the unilateral failure of breast development.

Like congenital pseudarthrosis of the clavicle it is thought to arise from an abnormality in the development of the subclavian artery. Non-musculoskeletal manifestations of Poland’s syndrome include dextrocardia, diaphragmatic hernia, and gastrointestinal abnormalities.

Functional impairment in Poland’s syndrome is rare and surgical management is often primarily to improve appearance. Syndactyly is usually treated prior to school age.

Anomalies around the elbow

Abnormalities of the elbow joint can be overlooked particularly in the patient with normal function in the joints above and below (the shoulder and wrist/hand) and when the elbow is essentially asymptomatic. Congenital disorders of the elbow can involve bone and joint or soft tissues.

**Box 13.11.5 Poland’s syndrome**

- Males 3:1 females
- Right 2:1 left
- Incidence 1:10–50 000.

Radial head subluxation and dislocation

Radial head subluxation or dislocation is the most frequently occurring congenital abnormality of the elbow; 60% of cases are bilateral. The pathology is thought to be due to a hypoplastic capitellum allowing the radius to dislocate. In about one-third of patients, there will be another anomaly elsewhere in the upper limb. The forearm is often hypoplastic, and the ulna may be short with a negative variance at the distal radioulnar joint. Acquired dislocations can occur in infancy. It is, however, the hypoplastic nature of the capitellum on radiography or arthrography or other imaging that help distinguish a congenitally dislocated radial head from an acquired one (Figure 13.11.8).
Lateral radiograph of the forearm of a 4.5-year-old child. There was no history of trauma, simply a lump in the antecubital fossa. The ulna is bowed and the direction of radial head dislocation is anterior: usually traumatic rather than congenital in origin.

Congenital radial head dislocation often presents at ages 3–5 years. There is usually no functional loss of movement but clinically the patient may have reduced supination with an inability to achieve full extension. Pain or clicking is not usually a major feature but many patients or their parents notice a lump on the lateral side of the elbow.

Three types of isolated congenital dislocation are described: type 1 is the least frequently occurring, but is associated with pain (Table 13.11.2). Radial head dislocations can also be classified according to the direction of dislocation (Table 13.11.3). Radial head dislocation is associated with a variety of conditions: in some such as diaphyseal aclasis, the dislocation develops over time as a result of the abnormal forces that growth places on the developing forearm structures (Figure 13.11.9 and Box 13.11.6).

Treatment

Management in most cases is to reassure and observe. Analgesia may be required. Surgical treatment is indicated when the patient has significant symptoms of pain. Occasionally, surgery is advised for deformity (with growth the dislocated radial head may become more obvious) and to try and improve movement if there is severe restriction.

Due to the hypoplastic capitellum and reciprocal changes in the radial head, relocation of the congenitally dislocated radial head is not a very successful option. For acquired dislocations, most frequently seen secondary to a missed or late diagnosis of a
Monteggia fracture dislocation of the forearm, relocation of the radial head is advisable and usually successful. This involves an open reduction of the joint in combination with a reconstruction of the annular ligament with a triceps fascial sling and an ulnar osteotomy to restore length and correct the bowing deformity.

Excision of the congenitally dislocated radial head invariably reduces symptoms of pain but it is less likely to improve the patient’s range of movement. This can be performed safely at any age if symptoms are severe (Box 13.11.7).

**Box 13.11.7 Radial head excision**

- For congenital dislocations: at any age if symptomatic
- Following trauma: delay until skeletal maturity to reduce complication rate.

**Prevention of dislocation/subluxation**

**Diaphyseal aclasis (hereditary multiple exostoses)**

Classically, the exostoses around the distal ulna lead to differential growth rates in the forearm bones. The ulna is short and the radius becomes progressively bowed leading to radial head dislocation in a significant number of cases (see Figure 13.11.9). Surgery designed to prevent this complication has been advised. This involves excision of the prominent exostoses, correction of the radial deformity and lengthening of the short ulna. Whilst this approach may keep the radial head in joint, it risks decreased function due to an increase in forearm stiffness with further limitation of pronation/supination.

**Congenital radioulnar synostosis**

This abnormality is a congenital osseous or fibrous union between the radius and ulna. It is generally sporadic but occasionally autosomal dominant inheritance can occur with incomplete penetrance and variable expression. It is a rare disorder demonstrating an equal sex distribution.

During the sixth week of gestation, the cartilage anlage of the humerus, ulna, and radius starts to separate. An abnormality in this separation can cause a synostosis to occur. The union may be complete or more commonly partial. Over half of patients will have bilateral synostoses. The most common site for partial synostosis is the proximal radius and ulna and the proximal radius is often hypoplastic. Radioulnar synostosis is associated with a large range of limb and other congenital anomalies and some syndromes.

The clinical problem is loss of forearm rotation but presentation may not be until late childhood. There is usually a fixed pronation position that most patients adapt to by extending their range of movement at the radiocarpal joint so that, overall, there is little functional loss. There is no association between forearm position and level of the synostosis or between forearm position and function. The condition has been classified into four types (Table 13.11.4 and Figure 13.11.10).

Treatment

Indications for operative treatment usually include bilateral synostoses with a severe degree of functional loss and fixed pronation deformity of both forearms. The shoulder and wrist joints can compensate, to a certain extent, for loss of forearm supination and pronation. If required, a derotational osteotomy is performed designed to improve the fixed forearm position: attempts to restore range of movement by excision of the synostosis and/or silastic or tissue interposition have been unsuccessful. Even in bilateral cases, a position of 10–20 degrees pronation is usually preferred although an individual decision may be required to take into account particular cultural or social requirements. Although various osteotomy levels have been described, some have a high complication rate and simple methods are often the most reliable. Vascular compromise is a particular risk if the correction is greater than 45 degrees.

Pseudarthrosis of the forearm

Congenital pseudarthrosis most commonly affects the tibia but it has been documented in all the long bones. In the forearm, the ulna is more frequently affected. The reported incidence of associated neurofibromatosis is higher with forearm pseudarthrosis than with tibial pseudarthrosis. As with tibial pseudarthrosis, surgical management is often required but frequently fraught with difficulties. The use of a vascularized fibula graft is perhaps the most popular and successful technique reported but in severe cases the creation of a single bone forearm may be most realistic solution.

Further reading

Congenital brachial plexus palsy (CBPP) is very different from the adult injury. The main difference between the two is that the neonatal nervous system is still immature and capable of repair. In the immature system, the position and form of the ‘transitional zone’, the interface between central nervous system (CNS) and peripheral nervous system (PNS), oscillates. In neonatal nerves, there is a greater density of neural fibres with a relative paucity of collagen fibres and this might contribute to their mechanical vulnerability. The nerve blood flow is also highest in the first weeks of life and then declines so that during this time, the immature nervous system might be more susceptible to ischaemia and anoxic conduction block. Once axonotomy occurs, chromatolysis starts and this can lead to neuronal death. Moreover, the developing neuron does depend upon neurotrophic factors produced by the target tissues.

It is therefore clear that a CBPP does not inevitably undergo a spontaneous recovery and equally clear, that such a vulnerable system might be susceptible to a ‘second injury’ such as occurs with a surgical resection of the neuroma and subsequent nerve graft.

Incidence

The reported incidence of CBPP varies from 0.6–2.6 per 1000 live births and there has been one study from an area of Sweden that has documented an increasing incidence of CBPP (from 1.4 per 1000 live births in 1980 to 2.3 in 1994).

Risk factors

In almost all cases the mechanism of injury is traction pulling the upper limb away from the axial skeleton as delivery of the baby is ‘obstructed’ at the narrowest point of the birth canal. This trauma is not necessarily excessive or inappropriate. Intrauterine causes have also been described such as oligohydramnios and the umbilical cord wrapped around the neck. Muscular denervation has been reported within days of birth implying intrauterine development of the lesion.

A strong relationship between birth weight and CBPP has been noted and there is an associated shoulder dystocia in more than 60%. Breech presentation with vaginal delivery is another risk factor and associated with more severe, and often bilateral, lesions with a high percentage of avulsions. Delivery by Caesarean section appears to be protective against the development of CBPP with the incidence of Caesarean section delivery being only 2% in patients with a CBPP compared to 18% in the general population.

Natural history

The study of the natural history of these lesions must start with the classification proposed by Narakas in 1987 as it offers a good guide to management. It should be used 1–2 weeks after birth by which time a simple conduction block should be showing signs of recovery.

Group 1

There is paralysis of the shoulder muscles specifically deltoid, supra- and infraspinatus, and of biceps (which influences elbow function). This implies a lesion of C5/C6 only. Complete recovery is seen in 90% of cases. Hand activity is not affected directly but the degree of shoulder recovery can influence hand function.

Group 2

One more nerve, C7, is affected and thus a lack of wrist extension on top of shoulder and elbow impairment. Full recovery is still possible in about 70% of children but the process is much slower than in group I.
This is a complete brachial plexus lesion involving all nerve roots. At birth, paralysis of shoulder, elbow, wrist, and hand is complete. Within a few days some recovery in finger flexion may be apparent but less than 50% of cases show a good functional recovery and 25% do not recover finger and wrist extension.

**Group 4**

This is the most severe lesion with a Bernard–Horner syndrome (damage to the cervical sympathetic trunk) accompanying the complete brachial plexus palsy. Few children demonstrate good spontaneous functional recovery but, surprisingly, many do show a satisfying degree of recovery in the hand—a fact that must be remembered when considering surgical repair of the lower trunk lesion. In most children, shoulder and elbow function does not recover as well as forearm pronation/supination. Sometimes even after many years the Bernard–Horner signs are still present. In all these children the nerve lesion affects growth and development of the upper limb. This is particularly evident at the shoulder and elbow level where the degree of growth inhibition is related to the severity of the lesion at birth.

**Clinical evaluation**

After a difficult delivery or a shoulder dystocia, difficulty in moving the affected limb may be obvious straight away but sometimes it is not noticed for several days and the possibility of trauma or joint infection must be considered (Box 13.12.1). Depending on the severity of the injury the child’s arm movement may be simply limited or completely absent. The characteristic posture of Narakas group 1 and 2 with the shoulder adducted and medially rotated, the elbow extended, forearm pronated, and wrist and fingers flexed compares with a completely flaccid arm in group 3 which is associated with a Bernard–Horner syndrome in group 4. In some, the phrenic nerve is paralyzed with obvious breathing problems.

**Box 13.12.1 Differential diagnosis of a CBPP**

- Clavicular fracture
- Physeal separation of the proximal humerus
- Sepsis of the glenohumeral joint
- Ischaemic cord injury
- Arthrogryposis.

On first assessment, a complete history of risk factors, mode of delivery, and progress to date is taken. As a matter of simplicity it is better to think of the different roots in terms of their main muscle innervation. The clinical examination must focus on evaluation of shoulder function, particularly active abduction and lateral rotation, because pectoralis major can supply forward flexion; elbow function, examining biceps and triceps; and wrist function looking at wrist extensors and hand function looking at finger flexors. In this way the recovery of individual nerve roots can be assessed more accurately allowing a management plan to be instigated promptly. In many children the recovery starts within a few days of birth and by the time they are seen in the specialist clinic, considerable improvement in upper limb function is obvious. Nevertheless, it is important to ask what muscle activity was at one week of age (Box 13.12.2).

**Box 13.12.2 Nerve roots related to muscle innervation.**

- C5: shoulder activity
- C6: elbow flexion
- C7: wrist extension
- C8-T1: hand function.

With early recovery, physiotherapy must be started as soon as possible to avoid the development of contractures and to maximize functional recovery. If there is no recovery in any nerve root at 1 month then electrophysiological assessment is required urgently. If there is some recovery in some muscles, the investigation focuses on the roots which do not show recovery and can be performed between 2–3 months. Records are made of active and passive ranges at glenohumeral, thoracoscapular, and radioulnar joints: the difference between passive and active ranges defines the presence of contractures in muscles, capsules, and ligaments. These records and the modified Mallett score for shoulder, the Raimondi score for the hand, and Raimondi and Gilbert for the elbow, quantify recovery, progression of deformities, and response to treatment.

**Investigations**

**Neurophysiology**

Neurophysiological tests are important in defining the prognosis of a CBPP and thus help the surgeon to identify which cases would be helped by a surgical procedure. Nerve action potentials (NAPs) are measured from the median and ulnar nerves by
stimulating at the wrist and recording at the elbow. The deltoid for C5, biceps for C6, wrist extensors and triceps for C7, wrist flexors for C8 and first interosseous for T1 are sampled by electromyography (EMG). For each nerve root, the lesion is then graded according to the degree of reduction of the NAP and amount of spontaneous and volitional activity in the muscles:

- Grade A: NAP normal or near normal. EMG normal units, no spontaneous activity
- Grade B favourable: NAP ≥50% of normal. EMG mild axonal injury with copious recruitment
- Grade B unfavourable: NAP absent or ≤50%. EMG limited recruitment, moderate axonal injury. Collateral reinnervation present
- Grade C: NAP present in some cases (predictive of avulsion), but more often absent. EMG poor recruitment, fibrillations, nascent units. Severe axonal injury.

Neurophysiological evaluation of a slowly recovering CBPP lesion can predict correctly the nature of the lesion and help in defining the indication for brachial plexus exploration. The importance of identifying the cases of prolonged conduction block has been emphasized as, clinically, these babies may be indistinguishable from those with more severe lesions. At the Peripheral Nerve Injury Unit at the Royal National Orthopaedic Hospital, 56% of patients who had no/minimal recovery at 3 months had favourable neurophysiological investigations and therefore no operative procedure was performed even when there was no recognizable clinical activity in biceps. Outcomes based on this neurophysiological prediction were found reliable in 92% for C6 and 96% for C7. Predictions for C5 were confirmed in only 76%. The inability to record NAP for C5 and the high incidence of posterior dislocation of the shoulder probably accounts for this.

**Imaging**

Magnetic resonance imaging is useful in severe cases of CBPP to identify nerve root avulsion and is preferred to contrast computed tomography or myelography.

**Management**

**Physiotherapy/occupational therapy**

These treatment methods are the mainstays of CBPP management. Parents play a major role in caring for their child as regular, gentle stretching exercises are essential to prevent fixed deformity and should be started within a few weeks of birth. Specific stretches for medial and lateral shoulder rotation are required with the arm at their side (elbow flexed) and at 90 degrees of abduction. Holding the scapula fixed to the chest wall whilst the arm is abducted, stretches the inferior scapulohumeral angle abduction of the arm and with forward flexion and medial rotation of the arm, the stretch is to the posterior glenohumeral angle.

**Surgical management**

**Indication for surgical treatment of a nerve lesion**

Surgical exploration is reserved for:

1) Group 4 lesions where neurophysiology and radiological evidence suggest avulsion
2) Lesions secondary to breech position when the complete lesion of the plexus is associated with phrenic nerve palsy. With both these indications, an operation is performed early, ideally by 8 weeks of age.
3) Group 1, 2, and 3 patients in whom there is failure of recovery of shoulder abduction and lateral rotation and elbow flexion by 3 months of age or even later.

**Operations on the brachial plexus**

After induction of anaesthesia, recording electrodes are placed on the neck and scalp and sensory evoked potentials (SEPs) are recorded from median and ulnar nerves bilaterally. After a suitable exposure, the brachial plexus lesion can be dissected and neurophysiological assessment performed to identify the type of the lesion (Table 13.12.1).

</table>

Good shoulder function is essential for a useful upper limb—poor shoulder recovery is thus more of a concern than poor elbow flexion. Muscle transfers around the shoulder are less useful than those around the elbow and hand, so every effort must be made to define prognosis for the C5 nerve root and particularly for the suprascapular nerve. At shoulder level, the author prefers to leave the upper trunk neuroma alone and perform a spinal accessory to suprascapular nerve transfer. At times it is impossible to say how much lack of function in the shoulder is due to the nerve injury itself and how much is due to subluxation or even dislocation of the glenohumeral joint and it is very important that the mechanical status of the joint is known. When indicated, relocation of the shoulder joint should accompany nerve repair/transfer.

To restore elbow function, a graft can be used to reconstruct the nerve root rupture but fascicles from the ulnar nerve can be implanted on to the nerve to biceps and selective reinnervation of the avulsed ventral root are very valuable procedures particularly for group 4 lesions.

To restore partial hand activity, repair of the nerve root rupture is not the only possibility. With avulsion of C7, C8, and T1, the hand can be reinnervated using the proximal stumps of the ruptured C5 and C6 roots or with selective reinnervation of the ventral roots of the avulsed nerves by transfer of the spinal accessory. It is important to remember that good functional recovery is observed in about one half of the group 4 lesions without surgical intervention.

Postoperative care

Following nerve repair, a 3–4-week period of immobilization is necessary and after that gentle stretching of joints can be resumed.

Results from repair

Recovery is very slow and in the hand may take many years. The PNI unit results show that only one-third of C5 lesions had a good result with a worse mean Mallett score in children who had shoulder relocation performed at a later stage. C6 repair was associated with a good result in just over 50% and C7 repair was disappointing with less than one in three children regaining wrist and finger extension. Results for reinnervation of proven avulsion of C8 and T1 were good in 57%. Table 13.12.2 reports these results.

**Deformity**

The main causes of deformity associated with CBPP are direct damage to the shoulder and proximal humerus, occurring at the time of the difficult delivery but unrecognized and hence untreated. Atrophy of denervated target organs and persisting muscular imbalance from incomplete neurological recovery are also common. Muscle imbalance is the underlying cause of many shoulder dislocations. Supination and ulnar deviation deformities of the forearm and hand are often present. Deformity can be induced by over stretching incongruent joints and/or by performing muscle transfers on them.

**Shoulder**

Shoulder deformity is frequent and if not recognized leads to a progressive deterioration in function not only of the joint itself but of the whole upper limb. Whilst the deformity can be observed as a progression from medial contracture to subluxation and then dislocation, it is present in the perinatal period in 25% of patients referred to our unit (Figure 13.12.1). These cases showed extreme glenoid dysplasia, muscular fibrosis and humeral head retroversion. A further 21% subluxed/dislocated by 12 months and the remaining 54% presented later. The shoulder subluxation/dislocation occurred after neurological recovery was established in approximately 25%. The incidence of shoulder problems is higher in the Narakas group 3 and 4 where muscular imbalance around the shoulder is greater. Altered muscle pull also affects growth and development and it is likely that the shortening of the clavicle is implicated in abnormal shoulder growth.

![Fig. 13.12.1 Radiograph showing a dislocated shoulder with a retroverted glenoid and a deformed humeral head.](Click to view larger)

**Diagnosis**

To the experienced clinician, diagnosis is straightforward. The posture of the arm with fixed internal rotation and limited elevation associated with a humeral head palpable posterior to the glenoid and a forearm lying in full pronation is indicative of a dislocated shoulder. The diagnosis of subluxation is based on the same findings but is more subtle and relies more on the restriction of passive external rotation beyond 10 degrees and on the prominent head of the humerus.

**Surgical treatment**

Surgical treatment used to be delayed until the child was of walking age but recently early relocation is advised and may, if indicated, take place at the time of nerve repair. Early relocation facilitates greater remodelling of both the glenoid and the humeral retroversion. Subscapularis recession has been associated with a high recurrence rate and has therefore been abandoned. Whilst some surgeons favour a lateral rotation osteotomy, this does increase humeral head retroversion which is a major contribution to the recurrence of shoulder dislocation.

Two relatively minor procedures are useful in the treatment of contractures in congruent shoulders: release of the coracoacromial and coracohumeral ligaments and shortening of the coracoid process increase lateral rotation whilst release of the tight axillary fascia improves abduction.
The procedure to deal with an incongruent shoulder is more complex and it is defined by several sequential steps (Box 13.12.3). At the end of each step the passive lateral rotation and the position of the head of the humerus are checked. The shoulder joint is always inspected even in those cases where a complete elongation of the subscapularis muscle is not performed.

**Box 13.12.3 Steps in surgical management of an incongruent shoulder**

After each step check passive lateral rotation and the position of the humeral head:

1. Expose the coracoid process and section the ligaments with basal osteotomy of coracoid process if necessary
2. Z-lengthening of the subscapularis muscle with preservation of the capsule
3. Correct humeral head retroversion
4. Correct glenoid dysplasia with a glenoplasty (not a posterior bone block).

**Postoperative care**

The child is immobilized in a full plaster jacket with the arm abducted 30 degrees and externally rotated 2–30 degrees for a period of time: 6 weeks (simple cases of medial contracture) to 12 weeks (complex dislocation). Physiotherapy is recommenced after the cast is removed.

**Elbow and forearm**

Flexion deformity of the elbow is common and may be minimized by gentle, continuous stretching exercises and splinting and occasionally by serial casting. Surgical release provides only a modest improvement and recurrent contracture is common. Forearm rotation is usually reduced if not completely lost when the shoulder is dislocated—treatment of the latter improves supination. Supination deformity is associated with ulnar deviation of the hand and can be treated by rotation osteotomy of the radius repeated as necessary as the child grows.

**Hand**

The recovery of hand function is very slow and can continue until the age of 5 years. Careful and prolonged functional splinting of wrist and thumb is essential in order to maximize neurological improvement. All candidates for a muscle transfer must use a functional splint for 1 year and in many cases, at the end of this period, the operation is not required because of significant improvement in function. In a few selected patients flexor to extensor transfers are performed. Thumb abduction is essential for hand function.

**Conclusion**

The treatment of CBBP does not end with neurological repair/reconstruction. The deformities during growth, particularly around the shoulder, can downgrade a potentially excellent neurological recovery. Recognition and treatment of a shoulder dislocation is of primary importance and a greater understanding of the deformities and their development is required. Further advances in the performance and interpretation of intraoperative neurophysiology will help the surgeon choose the most appropriate treatment for the nerve lesion.

**Further reading**

Summary points

♦ Malformations of the upper limb are amongst the most common anomalies seen in surgical practice
♦ Recognition and awareness of the varied diagnoses, their significance, and their impact on the child and family are vital to help these children and improve their function.

Introduction

Congenital upper limb anomalies are common with an incidence of 1:506 live births but the variety of anomalies is huge and many are subtle. Approximately 25% of anomalies are syndromic and the variation in hand anomalies helps geneticists identify individual syndromes. The child usually adapts easily to the problem but the impact of anomalies on the parents can be more significant. Despite this adaptation, the surgeon has much to offer in terms of diagnosis, advice, and treatment to improve the function and aesthetics of the hand and upper limb. This chapter gives some general information, a classification of anomalies, and a brief description of the commoner conditions and their treatment. See also Chapter 13.11.

Knowledge of the general principles of upper limb embryology helps in understanding the pattern of some anomalies. Males are more affected than females and although 50% of problems are bilateral, the severity of the condition may differ from side to side. The aetiology is unknown in most cases but in the isolated anomaly genetic causes are unlikely. Often, it is difficult to determine the cause as several aetiologies may result in a similar appearance. Gene defects have been identified for some conditions.

Antenatal diagnosis of some defects, particularly failure of formation, is now common and the surgeon may be called upon for advice at this early stage.

Assessment of the child is based mainly on observation: paying particular attention to features like flexion creases that indicate joint movement. Observe the child’s hand movement and correlate it to normal development. Feel for the presence of bones and move joints to assess passive mobility. Take a family history and assess the whole child and their family to detect inherited conditions.

The timing of surgery in congenital hand anomalies is controversial and as good evidence is lacking, decisions are based on personal preference. Generally, the earlier the reconstruction the better the cortical integration of the reconstructed part and the better the anatomical adaptation. Growth potential is maximized and physical and psychological scarring is minimized.

It is important to emphasize to the parents that they were not responsible for the anomaly and explain briefly why such anomalies have occurred. Reassure the parents that even with the most severe anomalies children adapt amazingly well. Offer psychological and genetic counselling, if you feel it is appropriate. For complex conditions it is wise to watch development over several consultations, to help decide the appropriate intervention and prepare the parents for surgery. Treatment is designed to improve function and allow growth and development. Dysfunction often draws attention to the hand anomaly and conversely improved function often renders the anomaly less noticeable. Functional requirements generally centre on thumb function and its ability to oppose with stability and strength (Box 13.13.1).

Box 13.13.1 Hand development

♦ 0–3 months: ulnar sided grasp
♦ 3–6 months: palmar grasp
♦ 6–9 months: extends wrist
♦ 9–12 months: palmar pinch, pinch, uses thumb for adduction.

Classification

The classification of congenital upper limb anomalies is based on current beliefs of their embryological derivation. It was adopted by the International Federation of Surgical Societies of the Hand and is called the IFSSH or Swanson classification. The main categories are divided further according to descriptive or site characteristics (Table 13.13.1).

### Failure of formation

This group shows arrested limb development. The pattern can be transverse, or longitudinal (Figure 13.13.1). The longitudinal patterns are named according to the affected side.

![Click to view larger](image_url)

**Fig. 13.13.1**
Radiograph showing a transverse arrest of the upper limb.
Radial dysplasia

Radial dysplasia (radial club hand) is the congenital failure of formation in a longitudinal distribution affecting all preaxial or radial structures, resulting most obviously in radial deviation of the wrist. It is defined by the most obvious skeletal deficiency.

The incidence of radial dysplasia is 1:30,000–100,000 live births. Fifty to sixty-six per cent of cases are bilateral but the dysplasia is usually not symmetrical. Right-sided involvement is most frequent and males are twice as commonly affected as females. Radial anomalies are always associated with thumb hypoplasia (except in TAR (thrombocytopenia with absent radius) syndrome) but only 50% of thumb hypoplasia cases are associated with an anomaly of radius.

The aetiology is unknown, and most cases are sporadic. Some are syndromal and some linked to teratogens such as thalidomide, valproic acid, or radiation. Due to the presumed timing of the congenital insult (the cardiac septum and radius both form in the fifth week), there are many associated disorders (Box 13.13.2).

Box 13.13.2 Disorders commonly associated with radial dysplasia

- VACTERL or VATER: vertebral, anal, cardiac, tracheo-oesophageal, renal and limb anomalies
- Cardiac: Holt–Oram syndrome (familial, with atrial septal defect)
- Gastrointestinal
- Haemopoietic:
  - Thrombocytopenia (TAR syndrome)
  - Fanconi anaemia (with renal anomalies and pancytopenia)
- Skeletal:
  - Syndactyly
  - Scoliosis
  - Sprengel’s
  - Knee deformity (tibia)

Pathology

The pathology of radial dysplasia is well described. The humerus is shorter than normal with distal defects of coronoid, capitellum, and medial condyle that reduce elbow flexion. Most commonly there is complete absence or absence of the distal third of the radius. The fibrous anlage or mesenchymal ‘scar’ that replaces the deficient radius tethers growth producing progressive deformity that includes curvature of the ulna and forearm shortening. The radial carpal bones are absent, hypoplastic or coalesced, especially the scaphoid and trapezium.

The soft tissues are as severely affected as the skeleton with hypoplastic, fused, or absent radial wrist and thumb, extensors, and flexors. In severe cases, the finger flexors/extensors are also affected. The fingers are stiff and this determines the outcome of thumb reconstruction by pollicization. The ulnar digits are less affected.

The radial artery is absent as are several nerves (superficial radial, musculocutaneous, lateral cutaneous nerve of forearm). The median nerve is abnormal, lying quite radial and supplying areas normally supplied by the radial and musculocutaneous nerves.

Classification

The classification of radial dysplasia relates to the severity of skeletal involvement but the soft tissue deficiencies are correlated, for example, the absent radius is usually associated with a Blauth type 4 or 5 hypoplastic thumb (except in TAR syndrome). (Table 13.13.2 and Figure 13.13.2).

</tbody>
</table>
Clinical photograph of a child with radial dysplasia: there are four digits, the wrist is radially deviated and the distal ulnar is prominent.

Presentation

The clinical presentation is usually obvious at birth: ‘isolated’ thumb anomalies may alert the surgeon to look at the forearm. The hand and wrist are flexed, pronated, palmar subluxed, and radially displaced. The thumb is hypoplastic or absent and the radial digits absent or stiff.

Management

Initial management consists of careful evaluation of the whole child and a passive stretching and splintage regime for the wrist/hand. At this age most postural deformity can be corrected and maintained providing the wrist is splinted continuously. This makes subsequent surgery easier. In all but type 1 and mild type 2 cases, surgery is indicated to stabilize the wrist and later to reconstruct the thumb. Wrist stabilization improves hand position, allows more effective use of the thumb and improves finger flexion strength. There is the additional benefit of improved aesthetics, easier care, and potentially improved ulnar physeal growth. Thumb reconstruction depends on the exact anomaly. Contraindications to surgery include bilateral radial dysplasia, lack of elbow flexion, a very short forearm, severe systemic illness (or an adult who has adjusted to the deformity).

Surgical (Box 13.13.3)

Understandably there are variations in operative technique: some surgeons believe in soft tissue distraction prior to operative reduction and this may be necessary if operative reduction is delayed. If soft tissue distraction is used, apply the distractor at 6–9 months, distract slowly over 2 months, stabilize and then proceed with the definitive operation.

The two definitive wrist procedures are: centralization or radialization.

- **In centralization** the wrist is reduced and stabilized by placing the distal ulna into a surgically created carpal slot, avoiding injury to the ulnar physis. This results in a well-aligned but stiffer and shorter limb.
- **In radialization**, no carpal bones are excised. Full passive correction is a prerequisite for surgery. Tendons are released and the ulna is placed radial to carpus, overcorrecting the wrist. Tendon transfers maximize their lever arm and create an ulnar force. The position is maintained by temporary pin fixation for 2–12 months. Radialization results in better motion and possibly less disturbance to growth.

Correction of the ulna bow may be performed simultaneously or later with forearm lengthening (if required).

The outcome of these procedures should be a short forearm with a neutral stable wrist and prehensile grasp (Figures 13.13.3 and 13.13.4). Complications are common including skin necrosis, pin breakage or infection, recurrent deformity especially carpal subluxation, premature distal ulnar physeal closure, wrist stiffness.
Cleft hand (Box 13.13.4)

Cleft hand is defined as a congenital longitudinal failure of formation of the central portion of the hand and forearm. It has a very variable presentation from the classic V-shaped central cleft to a single ulnar digit hand (Figure 13.13.5). The incidence is estimated at 1:30,000–100,000 live births. Fifty per cent are bilateral and involve the feet as well. These bilateral cases are familial: autosomal dominant with high penetrance. The aetiology of cleft hand is unknown. The interdigital spaces should form between days 39–50. When this process fails osseous syndactyly occurs whereas if necrosis occurs in the middle of a digit, there is polydactyly and if excess necrosis occurs then a cleft results. Thus cleft hands are frequently seen with syndactyly, polydactyly, osseous fusions, as well as cleft feet (Box 13.13.5).

Box 13.13.3 Management of radial dysplasia: surgical principles

- Before 6-9 months:
  - Correct wrist alignment and stabilise the joint
  - Rebalance deforming forces with tendon transfers
  - Correct ulnar bow
- At 9-18 months: thumb reconstruction
- Later:
  - Oppensplasty
  - Ulna osteotomy ± distraction lengthening.

**Presentation**

Cleft hand presents with absence of the middle finger and to varying degrees the middle metacarpal. Adjacent digits may be absent or present: if present they are often large, frequently syndactylized, and with camptodactyly. With increasing severity the radial side of the cleft becomes absent eventually leaving only the single little finger (Figure 13.13.5B), or in worst cases no digits at all (peromelia). Fusions are often present in the palm but usually there are no carpal anomalies. The intrinsic muscles and long tendons are present but insert anomalously.

**Management**
Cleft hands are often described as having good function but poor aesthetics. Function can be improved by increasing the first web space, releasing any syndactyly, improving motion at metacarpophalangeal (MCP) joints by excision or release of cross bones, releasing proximal interphalangeal (PIP) joint contractures, performing osteotomies of the metacarpals to align the digits, improving abduction and opposition of the thumb, and providing opposition posts or digits when these are absent. Occasionally straightening and covering a cross bone can create a digit. Aesthetics are improved by the closure of the cleft.

Several techniques exist to create a first web space and close the cleft simultaneously by transposing the cleft skin to the first web and the border digit into the cleft. The Snow–Littler technique uses a palmar-based flap from the cleft transposed to widen the first web space and simultaneously transposing the index finger at the metacarpal base onto the middle finger metacarpal base. The Miura–Komada technique uses the same index transposition but with an incision along the web space and around the digit, and a dorsal extension for access to the metacarpal base minimizing wound problems. The Ueba technique uses the same digit transposition but the flaps lie transverse with the dorsal flap from one side of the cleft and the palmar flap from the other side of the cleft.

**Ulnar dysplasia**

Ulnar dysplasia is a longitudinal failure of formation of the ulnar portion of the hand and forearm. It is less common than radial dysplasia occurring in 1:100,000 live births. Most are unilateral with no sex preponderance. It is more common on the left. Half are associated with other musculoskeletal anomalies but unlike radial dysplasia, ulnar dysplasia is not normally associated with systemic anomalies (Box 13.13.6).

Table 13.13.6 Classification of the hand anomalies in ulna dysplasia

Ulnar dysplasia is thought to be due to an injury to the zone of polarizing activity (ZPA). The forearm anomalies are classified according to the ulna and elbow anomalies (Bayne or Baur). Whereas the hand is defined by the Cole and Mansky (1997) classification based on the thumb and first web space (Tables 13.13.5 and 13.13.6) (Figure 13.13.6).

</tr>
<tr>
<td>IV</td>
<td>Humeroradial synostosis</td>
</tr>
</tbody>
</table>
Presentation

Ulnar dysplasia affects the whole upper limb but the deformity is less obvious and function better when compared with radial dysplasia. The limb is hypoplastic, the ulna possibly absent, the radius bowed, and the elbow unstable. The radial head is dislocated or fused to the humerus (radioulnar synostosis, Figure 13.13.7). In the hand, the digits are hypoplastic or absent and syndactyly occurs in 30%. Seventy per cent have some thumb or first web anomaly.

Management

Splinting and stretches help improve or maintain the wrist position; wrist surgery is rarely indicated. Most surgery is performed to release syndactyly, treat the thumb hypoplasia and first web space deficiency to provide prehension. A rotational humeral osteotomy can help the marked internal rotation deformity and radial osteotomy/lengthening can improve radial curvature if required. Early excision of the fibrous ulnar anlage can prevent progressive bowing of the radius and may result in better growth.

II Failure of differentiation

Radioulnar synostosis

See Chapter 13.11.
Syndactyly

Syndactyly is one of the two most common hand anomalies. The term is usually used to describe conjoined digits due to a congenital failure of separation (but it can apply to post-burn or post-trauma 'fusion'). It occurs in 1:650–2000 births and is twice as common in men as women. Half affect the third web space and only 5% involve the first web space (Figure 13.13.8).

Fig. 13.13.8
Clinical photograph of a complete type 2 syndactyly affecting the middle/ring fingers.

The aetiology is unknown, but 20% are familial usually displaying autosomal dominant inheritance with incomplete penetration and variable expression.

Failure of separation is linked to steroid use in early pregnancy and also fibroblast growth factor receptor deficiency. Some congenital cases are due to trauma and healing as in amniotic band/constriction ring syndrome. Many cases of syndactyly are associated with other syndromes and chromosomal disorders such as Apert’s, Poland’s, symbrachydactyly, and Aarskog’s.

Syndactyly is classified according to site and degree (Table 13.13.7 and Box 13.13.7).

Box 13.13.7 Classification of syndactyly

- Complete (extends to tips) or incomplete
- Simple (soft tissues only) or complex (bone involved)
- Acrosyndactyly (digit tips fused, bases free)
- Single or multiple
- Unilateral or bilateral
- Hand or foot or both
- Isolated anomaly or part of a syndrome.

Presentation

Syndactyly is present at birth although occasionally not noticed until later in life. Assess the web involved: does the failure of separation involve soft tissue, nail, and/or bone. Is the syndactyly causing a deformity?
Hand development occurs rapidly between 6–24 months so it can be important to separate the syndactyly before this period especially if the involved digits are of different lengths.

Management

Surgery involves separation of the digits, creation of a web space and resurfacing of the digits: the circumference of two separate digits is 22% greater than the circumference of conjoined fingers. Problems may arise from the fascial, neurovascular, or tendinous connections running transversely between the digits. The aim is to create a web space sloping at 45 degrees from dorsal to palmar, with a free transverse distal edge, and an aesthetic shape, with minimal scarring on the dorsum of the hand and fingers, no scar contracture, and no longitudinal scars on the digits. In general, avoid separating an adjacent syndactyly simultaneously: staged procedures pose less risk to the vascular supply.

Digital separation is by a zig-zag design, creating interdigitating triangular skin flaps of varying width from the dorsum and palmar aspects of the digits to cover the sides of the separated digits. These flaps avoid longitudinal digital scars that may cause flexion contracture. In digits with symphalangism (such as in Apert’s syndrome) simple longitudinal division is permissible, as flexion contractures cannot occur.

Web reconstruction has many more surgical options: most require full thickness skin grafts to fill the defect created by formation of the web. Most surgeons use a modification of the Bauer design (1956), which creates a dorsal rectangular flap to recreate the web space, or opposing palmar and dorsal triangles, or an omega and anchor design. There are also techniques that avoid skin grafts by redistributing the dorsal digital skin. For complicated syndactyly some surgeons have attempted using distraction of the digital skeleton laterally from the involved web or tissue expansion of the dorsal skin but neither technique is popular due to the high complication rate. Reconstruction of the lateral nail folds is by Buck–Gramcko triangular pulp flaps (Figure 13.13.9).

Complications

Injury to digital neurovascular bundles leading to an inability to separate the digits or digital necrosis is the most feared but also the rarest complication.

Distal web creep due to digital scarring and growth is more common in complex syndactyly.

Deformity of the digit usually a flexion and lateral curvature due to scarring and growth disturbance from the length inequality between the syndactylized digits is common particularly in border digit involvement.

When skin grafts are used there is the risk of hyperpigmentation or hair growth of the skin graft. Skin graft loss or flap necrosis can lead to delayed healing and scarring.

Camptodactyly

Camptodactyly is defined as a congenital flexion deformity of the PIP joint. It affects 1% of the population but is under-reported. It can be subtle and is sometimes only noticed late, giving two peaks of presentation: early childhood and adolescence. In adolescence it often presents after trauma although this is not the cause. There is a female preponderance in the adolescent group. Camptodactyly is most frequent in the little finger. Some cases are familial (autosomal dominant).

Camptodactyly results from a congenital imbalance of the flexion and extension forces at the PIP joint. The theories of causation include abnormal intrinsics, anomalous finger flexors or extensors.

Presentation

Camptodactyly presents with a flexion deformity at the PIP joint but from this position, full flexion is possible. Rarely the deformity is fixed. A history of preceding trauma is common but unrelated. Lateral x-rays in adolescents show characteristic changes at the PIP joint (Figure 13.13.10). In addition on the anteroposterior view the PIP joint slopes to the ulnar aspect and clinically a ‘ulnar drift’ of the middle and distal phalanges is noted. Though rarely found, always check for dysfunction of the ulnar nerve, intrinsic
muscles, and the flexor digitorum superficialis (FDS).

Fig. 13.13.10
Lateral radiograph of a camptodactyly showing abnormalities at the PIPJ: an anvil or wedged shaped head of the proximal phalanx with a divot in the articular base of the middle phalanx and an exaggerated subcondylar recess (Drucker’s space).

Management

Splinting and stretches are used first. In most cases this improves the contracture sufficiently. If conservative therapy fails and the contracture is greater than 50–70 degrees then surgery can be considered. The principles of surgery involve release of the skin, soft tissues, and joint, an attempt to rebalance flexor and extensor forces, and reconstruction of the skin defect. The options are: exploration for specific anomalies, resection and/or release of the anomaly and then splintage, or tendon transfers to augment extension at the central slip utilizing the lumbrical, FDS, extensor indicis profundus (EIP), or extensor plication. Alternatively the FDS lasso procedure can increase MCP flexion, helping transfer some of the extensor pull to the central slip.

In older patients with established PIP joint changes not amenable to soft tissue correction an osteotomy can be performed at the proximal phalangeal neck to correct flexion and inclination.

Congenital trigger digit

A discrepancy between the size of the pulley and the size of the flexor tendon leads to a flexion contracture of the digit or less commonly triggering as seen in adults. Thumbs are most commonly affected. The aetiology is unknown.

It is not usually apparent at birth but becomes noticeable in the first year of age, or occasionally later.

The child presents with a digit locked in flexion or extension and a palpable nodule on the flexor tendon may be felt called Notta’s node.

Reports suggest that 33% of trigger thumbs resolve with stretches and splinting if the tendon is mobile (triggering) on presentation but they do not improve sufficiently to allow normal interphalangeal (IP) joint hyperextension. Operative release of the A1 pulley should be performed. Finger triggering does not resolve spontaneously and should be treated operatively. Steroid injections are not indicated unless there is other pathology such as diabetes or inflammatory arthritis.

Clasp thumb

An anomaly where the thumb is flexed into the palm and no active extension is seen. The clasp thumb can be passively extended. This is normal behaviour in babies under 6 weeks and should not be confused with the fixed thumb-in-palm deformity.

The incidence is unknown as is the aetiology. Some cases are due to hypoplasia of extensor pollicis longus (EPL). It can occur in association with Digitotalar syndrome, Freeman–Sheldon ‘whistling face syndrome’ and arthrogryposis or it may be the first presentation of thumb hypoplasia or mild radial club hand.

Clasp thumb was classified by Weckesser according to severity or clumped together by McCarroll into supple (having an absent EPL) or complex (an absent EPL with a flexion contracture of the MCP joint and thumb hypoplasia) (Table 13.13.8).

</tr>
</tbody>
</table>

**Management**

If the child is young, reassure the parents that this is probably normal and reflects a mild imbalance of flexor and extensor development. Initially it is treated by splinting the thumb in extension. This is usually successful. In resistant or complex cases surgical management may be needed with tendon transfer to reconstruct the absent EPL. The EIP is often absent and cannot be used. Complex thumbs may need extensive palmar skin release, and thumb hypoplasia reconstruction as well.

### Ill Duplication

#### Polydactyly

Polydactyly is the formation of all or a part of an extra digit. It is the commonest congenital upper limb anomaly (Figure 13.13.11). The aetiology is unknown. It can be hereditary especially when the little finger is involved. Polydactyly is associated with many syndromes (Table 13.13.9 and Box 13.13.8).

![Click to view larger](Fig. 13.13.11 Clinical photograph of ulnar sided polydactyly.)

**Box 13.13.8 Polydactyly associated syndromes**

- Ellis van Creveld
- Lawrence–Moon–Bardet–Biedl
- Trisomy 13.

**Management**
Type A: sometimes the polydactyly is ‘strangulated’ by ligating the base with a suture. This may leave a tender nodule on the ulnar border of the little finger due to the underlying neuroma. Alternatively, excision, under local or general anaesthesia, can be done soon after childbirth. Dissect out and divide the neurovascular bundle deep to avoid a neuroma.

Type B polydactyly cannot be excised under local anaesthetic due to the bone reduction required. Leave more skin than first appearances suggests, as the resulting defect is often large. In central polydactyly, correction of adjacent bone or soft tissue anomalies may avoid problems with further growth.

Type C polydactyly requires excision of the whole ray, closure of the space, and creation of the intermetacarpal ligament. Try to excise a central rather than a border ray if there is no obvious choice, as the result will be more stable but may leave some widening of the interdigital space and scissoring (Figure 13.13.12).

![Click to view larger](Fig. 13.13.12 Radiograph showing a central polydactyly with partial duplication of the metacarpal.)

**Thumb duplication**

Thumb duplication is common, it differs from other digital polydactyly in the complexity of the duplication, the functional importance of the thumb, and hence the reconstruction.

Wassel based his classification of thumb duplication on the most proximal extent of the duplication (Table 13.13.10 and Figure 13.13.13). The commonest type is type 4, next commonest is type 2, then type 6. Note that types with even numbers are duplications which extend to joint level. A Stelling A polydactyly-type duplication of the thumb where there is a small nubbin of a thumb connected by a thin soft tissue pedicle (usually at the level of the metacarpophalangeal joint) is not covered adequately by this classification, but is sometimes described as a rudimentary thumb.

Management

Treatment does not consist of simple excision of the extra thumb. Prior to excision assess the level of the duplication, the development and stability of the joints, and the degree of axial deviation of each element. Excision of the most hypoplastic thumb is combined with osteotomies, and reconstruction of the collateral ligaments. Osteotomies are needed to align the joint surfaces, the axis of the phalanges and to thin the widened metacarpal or phalangeal head. Division of intertendinous connections and realignment of the flexor and extensor tendon may also be needed.

In many cases the remaining thumb is smaller than the opposite thumb, and stiffer. This does not substantially affect function, but should be pointed out to the parents pre-operatively. It is common to reoperate for a subsequent zigzag deformity if initial osteotomies are not performed.

IV Undergrowth (hypoplasia)

Brachydactyly

Brachydactyly describes short fingers usually due to an autosomally dominant inherited condition. These are sometimes syndromic such as in achondroplasia, or part of a systemic condition like pseudohyoparathyroidism (with short metacarpals), but most commonly are asymptomatic and often unnoticed such as little finger clinodactyly.

Management

Good function means intervention is usually not required. Associated conditions such as syndactyly will need treatment. Occasionally a functional problem such as a palpable and painful short metacarpal head in palmar grip or a finger deformity that impacts on function will require surgery. Longitudinally bracketed epiphyses in delta phalanges may benefit from epiphyseolysis. Mature deformities causing functional problems can be corrected by osteotomies. Lengthening is rarely indicated.

Symbrachydactyly

Symbrachydactyly, translated as short fingers joined together, represents a spectrum of failure of digital development with a tendency to preserve the thumb (in contrast to a similar spectrum of cleft hand which preserves the little finger).

The incidence of symbrachydactyly is 1:10 000. The inheritance is mostly sporadic. The etiology is unknown but thought to be a mesodermal defect of vascular origin leaving ectodermal remnants such as skin and nails as nubbins. It usually affects the left side but when associated with Poland’s syndrome affects the right.

Presentation

Symbrachydactyly has a spectrum of severity: the best cases have all digits and all phalanges present but the fingers are slightly shorter and stiffer whilst at the other extreme, in essence there is a transverse failure of formation that may be through the level of the forearm. The rudimentary digital remnants suggest a symbrachydactyly rather than a reduction defect.

In between these two extremes there are reducing patterns of digital loss described as a teratologic sequence starting with loss of the middle phalanges, then the distal phalanges, then the metacarpals as well. The pattern of loss tends to be more severe on the ulnar side sparing the thumb initially. The pattern with short/absent middle fingers preserving the thumb and little finger was called an atypical or U-shaped cleft hand, as compared to the classical V-shaped cleft pattern (Figure 13.13.14).
Fig. 13.13.14
Clinical examples of symbrachydactyly. A) atypical cleft type B) adactylous type.

Management

In symbrachydactyly with short fingers no intervention is indicated, as function is good. Where digits are absent, the number of remaining digits and their function determines treatment. The quality of the thumb and first web space determine the final functional outcome.

Operatively consider whether the hand would benefit from first web space release/deepening, would lengthening of the thumb or other digits improve grasp and pinch? Methods of achieving the latter include vascularized or non-vascularized toe transplant and distraction lengthening of existing parts.

Non-vascularized toe phalanx transfer is very much a second choice option. The donor site leaves an ugly defect once growth occurs as the growth in the remaining middle and distal phalanx is reduced by 50%. The donor defect can be minimized by suturing the flexor to extensor tendons or by bone graft from iliac crest. One expects growth of approximately 1mm per year, eventually achieving approximately 78% of the length of contralateral toe phalanx, or 52% of opposite digital phalanx. This type of transfer results in better growth if performed before 15 months of age.

Thumb hypoplasia

Congenital hypoplasia or aplasia of the thumb may be categorized either in the failure of formation or in the hypoplasia category of the IFSSH classification. It is common and may be an isolated phenomenon or part of a radial dysplasia, cleft hand, or symbrachydactyly. The aetiology is unknown but has been linked to fetal neurogenic injury and thalidomide.

Thumb hypoplasia presents with a very predictable pattern and is classified according to Blauth (1967). This classification does not cover transverse absences of the thumb due to different pathologies (Figure 13.13.15 and Table 13.13.11).

Management

Surgery aims to increase function and appearance of the hand. Try to reconstruct all the deficiencies in one operation and do this before 1 year of age to encourage full thumb function (Box 13.13.9).

Box 13.13.9 Thumb reconstruction

- First web space—improve width and depth
- MCP joint stabilization (occasionally fusion)
- UCL reconstruction
- Oppensplasty
- EIP or EDM transfer for thumb extension/flexion or
- Pollicization

The MCP joint stabilization and UCL reconstruction is achieved by UCL plication or soft tissue gubinsoplasty where tissue allows or, if necessary, with a tendon graft (palmaris longus or extensor digiti minimi) or use the end of the tendon used for the opponensplasty.

Pollicization creates a thumb by the transposition, stabilizing and shortening of a finger ray (usually the index). The index MCP joint becomes the basal joint of the new thumb, the PIP joint becomes the new MCP joint, and the DIP joint becomes the new IP joint. A first web space must also be created.

The outcome of pollicization depends more on the quality of the index finger and the presence of intrinsics and other musculotendinous structures than the surgical procedure. Complications include overgrowth of the trapeziun due to persistence of the physis, stiffness, instability usually due to hyperextension of the new carpometacarpal (CMC) joint, lack of flexion or extension due to tendon imbalance, poor opposition either due to inadequate rotation or poor intrinsics, poor position of thumb and skin flap necrosis.

Poland’s syndrome
Pectoral and hand anomalies were described in 1841 by Alfred Poland, a medical student at Guy’s Hospital, London. With an incidence of 1:20 000–30 000 the condition is rare but well known. The sex ratio is equal but the right side is affected twice as commonly as the left. The aetiology is unknown but there are a few families identified with an inherited form. Left-sided Poland’s syndrome is also linked with leukaemia, non-Hodgkin’s lymphoma, and dextrocardia. The current theory is that the musculoskeletal malformations seen in Poland’s and symbrachydactyly stem from a disrupted subclavian artery occurring in the sixth week of gestation as the ribs grow forward and medially causing a subclavian artery kink and the subclavian artery supply disruption sequence.

In Poland’s syndrome the hand anomaly is the most obvious defect. It varies from syndactyly and symbrachydactyly to amputation. The upper limb girdle and chest anomalies are less obvious but consist of a hypoplastic forearm or arm, an absent sternal (and sometimes clavicular) head of pectoralis major, deficiency or absence of pectoralis minor, latissimus dorsi, serratus anterior and other shoulder muscles, hypoplastic breast and nipple, abnormal ribs and costal cartilages with deficient subcutaneous fat and axillary hair, and the sternum may rotate to the involved side causing a contralateral carinatum deformity.

The hand conditions are treated appropriately by syndactyly correction or by deepening the webs to create the illusion of longer fingers. The first web often needs a flap to deepen and widen it. The deformity of the rib cage occasionally requires surgical correction. The anterior axillary fold is reconstructed by using a latissimus dorsi transposition by detaching its insertion and transferring it forward on the humerus or by contralateral latissimus dorsi free flap transfer if the muscle is absent.

Females may need tissue expansion of their breast through puberty, followed by a permanent implant. The thin chest subcutaneous tissue will need simultaneous latissimus dorsi transfer. There are autologous tissue alternatives.

**V Overgrowth**

**Macrodactyly**

Congenital overgrowth of a digit is rare (2:100 000 live births, 1% of all congenital anomalies). It may be a component of other hypertrophic conditions or gigantism. Ninety per cent are unilateral but involving more than one digit. The index and middle digits are most commonly affected: distally more than proximally (Figure 13.13.16). The cause is unknown but probably varies with the type of overgrowth. There is a theory that the commonest type ‘progressively growing lipofibromatous nerve overgrowth’ is related to neural growth factors (Box 13.13.10).

![Click to view larger](Fig. 13.13.16)

Macroductyly of the thumb and index finger in an adult.

**Box 13.13.10 Macrodactyly**

- Primary (non-syndromic)
- Secondary (associated conditions), e.g.:
  - Neurofibromatosis
  - Vascular malformations
  - Proteus syndrome
  - Ollier’s enchondromatosis
  - Albright’s polyostotic fibrous dysplasia
- Static or progressive.

Primary macroductyly has generalized soft tissue enlargement of lipofibromatous tissue. This follows a nerve-like distribution and so often affects one side of a digit or ray, frequently following the median nene.
Secondary macrodactyly may occur with a variety of conditions. Pathologically four types have been described: lipofibromatous, neurofibromatous, hyperostotic, hemihypertrophy or Proteus syndrome.

**Management**

Surgery is indicated for poor function or cosmetic concerns. Surgery aims to create a relatively normal sized digit with some function. The operative options are amputation; reduction (by combination of bone excision, osteotomies to correct angulation and soft tissue excision perhaps including the nerve); epiphysiodesis (if at age 10 the digit is already the size of the parents). Reduction of a macrodactyly is performed through a midlateral incision on the convex side of the digit, extending in an L-shaped pattern at the pulp. Excise the fat, enlarged digital nerve, and the overlying skin. Perform a closing wedge osteotomy of the proximal phalanx and excise sufficient middle and distal phalanx to shorten the digit and fuse the DIP joint. A nail partial excision to reduce the length and width of the nail will complete the procedure. Secondary surgery is often required.

### VI Amniotic band syndrome/constriction ring

Amniotic band syndrome (also known as constriction ring syndrome)

Amniotic band syndrome is a congenital disorder mostly affecting the limbs but occasionally seen around the trunk and face. It is thought to be caused by amniotic bands that wind around extremities, possibly related to perforation of the amniotic sac but alternative theories do exist. Interestingly 50% have more than one limb affected. It occurs in 1:2000–15 000 births. There is an association with oligohydramnios, cleft lip and palate, and talipes. The central digits and the hands are most commonly affected (Table 13.13.12).

<table>

</tr>
<tr>
<td>4</td>
<td>With intrauterine amputation</td>
</tr>
</tbody>
</table>

Clinically, the appearances are diagnostic for types 1, 2, and 3. With amputation the diagnosis is more difficult, though unlike symbrachydactyly there is tapering of the stumps and there are no nail remnants. X-rays show amputation occurring through bone or joint and the remaining part is not hypoplastic. The proximal soft tissue structures are all present, influencing reconstruction. The band if deep may involve or divide major nerves or vessels resulting in altered sensibility or a temperature difference below the band even after treatment.

Treatment involves multiple Z-plasties around the band releasing the constriction and flattening the depression by re-distribution of periband fat. Release of any acro syndactyly should be done before any growth disturbance occurs. In cases with amputation consider lengthening the thumb by distraction, toe transfer or on-top plasty (extending the length of the thumb by moving the index stump on top).

Surgery should be performed very early if there is any vascular compromise, severe lymphoedema or acro syndactyly affecting development. Late treatment of distal lymphoedema or macrodactyly may be needed.

### VII Generalized conditions

**Arthrogryposis (see Chapter 13.9)**

The management of arthrogryposis is multidisciplinary. Initially stretches and splinting aim to maintain joint movement with the ultimate goal for the hands to be used at the desk top rather than the traditional aim of one hand extended for toileting and the other flexed for feeding. Management is influenced by the fact that sensation is normal and the patient is usually well motivated.

**Madelung’s deformity**

In 1878, Madelung described a congenital ‘dinner-fork’ deformity of the distal radius and wrist but credited Dupuytren. This is an inheritable, autosomal dominant condition with incomplete penetrance. It is usually bilateral affecting females more than males. The anomaly occurs on the ulnar palmar aspect of the distal radial growth plate such that the radial side grows but an abnormal bone bar on the ulnar side tethers growth. This leads to early closure of ulnar aspect of distal radial physis. The tether is thought to be an abnormal radiolunate ligament. Madelung’s deformity is associated with achondroplasia, Turner’s, nail-patella syndrome, Leri-
Weill mesomelic dwarfism, dyschondrostosis, and with the SHOX (short stature homeobox) gene. This gene affects the mid portion of the limbs, so sitting height is near normal.

Presentation

Madelung's presents usually at age 8–12 years with a spontaneous palmar subluxation of the wrist with increasing radiopalmar and ulnar tilt due to abnormal growth forces, producing a dinner fork-like deformity. Radiographically there is a short bowed radius whose articular surface is inclined in a palmar and ulnar direction. The ulna head is prominent dorsally and a triangular-shaped proximal carpus has the lunate apparently retracted in between the radius and ulna leading to ulna carpal impingement (Figure 13.13.17).

Management

Observation and reassurance is the main method of management as most patients have excellent function. Surgery is considered if there is pain secondary to impingement, degeneration, or gross deformity.

If the patient presents before skeletal maturity consider an epiphysiolysis and release of the tight tethering radiolunate ligament. After skeletal maturity consider a volar approach releasing the pronator quadratus and radiolunate ligament, followed by a dome osteotomy of the radius to rotate the distal radius into a better position. An ulnar shortening may also be necessary.

Management of the limb deficient child

DOI: 10.1093/med/978019550947.003.013014

Summary points

♦ The majority of congenital limb defects are sporadic and unilateral
♦ The skeletal deficiency is described as transverse or longitudinal
♦ A multidisciplinary approach to management is required
♦ The balance between surgical reconstruction of the limb vs primary amputation is difficult to find.

Introduction

Congenital limb deficiency is rare, with an overall incidence of 1:2000 live births. In 2005/2006, there were 95 new upper limb and 68 new lower limb referrals to United Kingdom Prosthetic Rehabilitation Centres. Upper limb congenital absence is commoner than lower limb absence with fingers, hands, and forearms most affected. The majority of children will develop coping strategies to deal with their deficiency with many benefiting from prostheses or appliances and a few from surgical intervention. In 2005/2006, only 17% of congenital abnormalities required a surgical amputation, the majority of which involved the lower limb. These procedures usually aid prosthetic fitting or improve cosmetic appearance. Sometimes limb lengthening and/or reconstruction procedures must be considered.

Normal limb development

Limb development begins during the fourth week after fertilization. Thickening of the lateral plate mesoderm occurs opposite the cervicothoracic and lumbosacral segments. The overlying ectoderm differentiates into a ridge known as the apical ectodermal ridge (AER). This controls the proximodistal limb growth by keeping the cells beneath the ridge in a continuous proliferating state. As the limb grows away from the trunk these cells stabilize and differentiate. The femur and humerus are both patterned before cell differentiation; however, formation of the remaining bones and digits depends upon the AER. The lower limb lags behind the upper limb by 1–2 days.

Further control of development in an anteroposterior direction (radial to ulnar) is by the zone of polarizing activity (ZPA), a small area of mesoderm along the posterior border of the limb. The limb development from the dorsal to ventral surface is controlled by the dorsal ectoderm. Ossification begins around the seventh week with vascular invasion and creation of the primary ossification centres within the cartilage anlage model by the process of endochondral ossification.

Control of limb development involves factors such as fibroblast growth factors (FGF)-4 and -8. FGF-4 is present after the AER has been induced; FGF-8 is present before and therefore may be involved in the initiation process. Overexpression of FGF-8 in chick embryos has resulted in limb anomalies: truncations, deletions, and extra digits. The action of the ZPA is related to a protein produced by the sonic hedgehog gene (SHH). Other genes involved include the Wnt-7a, that controls dorsoventral development, and the Hox (homeobox containing) genes that influence proximodistal and anteroposterior patterning.

Aetiology of congenital limb deficiency

The majority of limb defects are unilateral and sporadic. In 60–70% of cases the cause is unknown. Some are associated with known genetic changes resulting in specific syndromes (Table 13.14.1). Chromosomal abnormalities can lead to limb deficiency, for example, trisomy 18 may be associated with a central ray deficiency. Maternal drug ingestion, including both alcohol and smoking, during the first trimester can lead to limb anomalies. In the recent past, thalidomide, prescribed as an antiemetic, resulted in severe multiple limb deficiencies.

Vascular disruption at a critical stage of limb development can result in birth defects. Poland’s syndrome presents with unilateral absence of the sternocostal head of pectoralis major muscle, ipsilateral hypoplasia (or absence) of the breast with absence or hypoplasia of the fingers, hand, and occasionally the forearm. It is hypothesized that these deficiencies occur following an interruption of the early embryonic blood supply in the subclavian, vertebral, and/or branch arteries.

True intrauterine amputation in association with amniotic bands is very uncommon. The amnion becomes disrupted resulting in mesenchymal tissue developing fine hair-like structures that wrap around the limbs resulting in amputation or a constriction requiring emergency release soon after delivery.

**Classification**

Traditionally surgical classifications describe the affected bone and its deficiency, for example fibula hemimelia and proximal femoral focal deficiency (PFFD). While these remain convenient terms for clinical practice, the accepted classification is the International Standards Organization’s *Method of Describing Limb Deficiencies at Birth* (ISO 8548-1, 1989). The system describes the skeletal element deficiency as either transverse or longitudinal.

- **Transverse deficiencies** resemble surgical amputations and are described by the level at which the limb ends. If a long bone is partially deficient the level is quantified, for example, ‘transverse deficiency, forearm, upper third’. If the deficiency is at the elbow level the classification is ‘transverse deficiency, forearm total’. Vestigial digital buds may be present (Figure 13.14.1).

- **Longitudinal deficiencies** are described by naming the absent or deficient bones. The description passes proximal to distal describing partial or complete absence. For example, PFFD is ‘longitudinal deficiency femur, partial upper third’ (Figure 13.14.2).

![Click to view larger](image)

**Fig. 13.14.1**

A) Child with a right transverse deficiency of the forearm, upper third. B) Radiograph of an infant’s left upper limb demonstrating the same type of transverse upper limb deficiency as in (A).
Principles of management

The birth of a child with congenital limb deficiency is a cause of great anxiety to the family. They require support along with adequate explanation of the condition and its management and with reassurance that experts are available for advice and assistance. Information given to parents and family should be accurate and avoid unrealistic expectations and if an antenatal diagnosis has been made on fetal ultrasound, an early referral to a Prosthetic Rehabilitation Centre could be considered.

Provided there are no associated congenital abnormalities, these children are expected to develop normally until they are old enough to compare themselves to their peers. The lifelong management of patients with congenital limb deficiencies may involve different professional disciplines at different stages. The emphasis of management is on the needs of the child and thus as the needs change with growth from childhood to adulthood so does the management. Good liaison between the Paediatric Services, Limb Deficiency and Prosthetic Clinics, and the orthopaedic or plastic surgeons is vital. Combined clinics are recommended to facilitate management plans.

The child with a limb deficiency requires a multidisciplinary approach for both the child’s clinical condition and the psychological support for the family. In the lower limb, our treatment algorithm (Figure 13.14.3) always raises the question of possible limb reconstruction. For the lower limb, the aim is that at skeletal maturity, the legs will be of equal length with a stable foot and good, pain-free function. Upper limb reconstruction may involve procedures such as pollicization in cases of absent thumbs, carpal centralization in radial hemimelia, or ulna lengthening in ulna hemimelia to provide support for the carpus. (For further details see Chapter 13.13.)

In cases where limb reconstruction is considered unachievable, treatment concentrates on providing support and improving function. This may consist of simple advice, appliances (e.g. to hold cutlery), orthotics, or prostheses. Surgical intervention is indicated in only a minority of cases. Procedures are performed for cosmesis or to improve prosthetic fitting, the latter by removal of obstructing appendages (Syme’s disarticulation) or correction of deformity (lateral femoral hypoplasia creating genu valgum or significant tibial bowing in complete fibula absence).

In the growing child, the optimal level for a surgical amputation is a disarticulation (or a ‘through joint’ amputation). This reduces the risk of bone overgrowth: a common complication of diaphyseal amputations particularly with transtibial or transhumeral levels where the growing end of the bone is retained in the residual limb. The overgrowth can result in pain, bursa formation, and skin ulceration.
often requiring surgical revision. Through joint amputation or disarticulation also offers a larger end-bearing surface and better proprioreceptive properties. The malleolar or condylar flare also aids suspension and rotational control of the prosthesis.

### Specific treatments

#### Upper limb deficiencies

**Transverse**

Transverse radial deficiency is the commonest level of congenital limb loss in children (see Figure 13.14.1). The management is prosthetic replacement, as part of an overall rehabilitation programme, with virtually no place for surgical intervention. As children are generally likely to benefit from prostheses, they should be introduced to them early. This allows the child to learn and make valid choices, based on personal experience. However, many children prefer not to use any prostheses at all, or opt to use it part time for specific tasks or for cosmetic purposes.

The rehabilitation programme starts with a simple cosmetic arm (Figure 13.14.4) first provided when independent sitting balance is achieved at 6 months. A functioning prosthesis, either body powered (Figure 13.14.5) or with electric controls (Figure 13.14.6) can be introduced at 18–24 months of age, when the child is better established with walking. The first powered prostheses use switch controls incorporated in a shoulder loop. Later, surface electrodes are used to pick up signals from extensor and flexor muscles for opening and closing myoelectric hands. The increased weight of these prostheses may limit their use in younger children. With increasing maturity (and as required) more complicated control mechanisms and additional tasks can be added to the limb. A specialist occupational therapist is crucial in training the patient how to use the limb and for advice on the use of other appliances, aids or ‘gadgets’ and how to manage one-handed activities.

---

**Fig. 13.14.4**

A simple cosmetic infant arm, often termed a ‘crawling hand’ prosthesis.

**Fig. 13.14.5**

Exoskeletal prosthesis for transverse deficiency of the forearm with a split hoot ‘hand’ and an operating cord.
Prostheses for more proximal levels of limb deficiencies (through elbow or transhumeral) are appreciably more difficult to use because of the need to control the prosthetic elbow. A figure-of-eight harness is required for suspension and control and the electric prostheses are heavy. ‘Hybrid’ prostheses may be required. Many patients opt for a passive function or cosmetic prosthesis and even those who have a functioning prosthesis often use them simply as a cosmetic arm. A comprehensive review of the literature over the past 25 years showed that there is a rejection rate of 45% in body-powered and 35% in myoelectric prostheses in children, although, worldwide, a wide variance is reported.

Children with distal limb loss (partial hand or transcarpal), if unilateral, generally function very well without active prosthetic intervention. However ‘appliances’ or orthoses in the form of simple leather gauntlets with pockets to hold cutlery or cup sockets for cycle handle bars or other activities need to be considered as part of the rehabilitation and management. Recently, myoelectric prostheses have been made available for transcarpal or partial hand levels of limb loss.

Longitudinal (see Chapter 13.13)

These deficiencies are less common and tend to be bilateral. They sometimes occur as part of various syndromes, for example VATER (vertebral defects, imperforate anus, tracheo-oesophageal fistula, radial and renal dysplasia), Holt–Oram syndrome, Fanconi syndrome, TAR (thrombocytopenia and absent radius) syndrome, etc. (see Table 13.14.1).

Unlike transverse deficiencies, surgical reconstruction has a major role in maintaining optimum hand function in longitudinal limb deficiencies (Box 13.14.1). Radial longitudinal deficiency is commoner than ulnar longitudinal deficiency. Centralization of the hand or ‘radialization’ have been recommended but results are not always encouraging in the long term. Pollicization is generally recommended after these procedures to establish pinch grip. However these procedures are contraindicated in the presence of severe restriction of elbow function because the repositioned hand is unable to reach the face.

Box 13.14.1 Surgical options (see Chapter 13.13)

- Absent thumb—consider pollicization
- Cleft hand—consider closure
- Syndactyly—consider release
- Finger deficiencies—reconstruction for pinch grip.

Longitudinal ulnar deficiency is associated with variable degrees of deficiencies in the hand on the ulnar side. The radius is short and associated with a functionless elbow and possible fusion of the radius with the humerus. Function is often better than expected. Various surgical procedures have been attempted but radical surgery is best avoided. Function is assisted by use of various aids, appliances, and other forms of orthoses.

Congenital deficiencies in the hand may be an absence of the thumb, central hand deficiency (cleft hand), syndactyly, or absence of a number of digits.

Cleft hand function is usually good without surgery and syndactyly can be released if felt appropriate. With severe finger deficiencies, reconstruction or rarely finger prostheses are used to provide a pinch grip.

Lower limb deficiencies

Transverse

Transverse lower limb deficiencies are rare and surgical intervention is usually unnecessary. This type of limb loss is managed with a prosthesis, just like an acquired amputation at the same level. When limb loss is unilateral, they are well tolerated with good function.
For forefoot absence or complete metatarsal loss, a total contact silicone prosthetic foot may be provided. If the residual limb is hypoplastic or there is a Chopart-type amputation (partial tarsal) additional support will be required above the ankle such as a plastic or leather booted with an ankle-foot orthosis. Alternatively, a Syme’s disarticulation may be indicated with an appropriate appliance and later the possibility of revising this to a standard transtibial prosthesis. Total absence of the foot will require similar prostheses. A Syme’s appliance in children does not have the same problem of poor cosmesis as for adults, because as the child grows, the malleoli tend to be hypoplastic and a standard below knee prostheses can be used.

Transverse limb loss at a higher level requires a standard lower limb prosthesis to compensate for the partial or complete tibial deficiency or the partial femoral loss (Figure 13.14.7). Treatment should start when the child begins to show signs of standing independently. For above knee levels, the introduction of a flexible knee unit may need to be delayed. Unilateral complete absence of the lower limb is worth treating with a prosthesis but the prosthetic socket encompasses both hips and presents practical problems in daily living. Regular follow-up is essential to allow modifications or replacement to the prostheses to accommodate for growth.

**Longitudinal**

**Fibula hemimelia (Box 13.14.2)**

This is the most common congenital lower limb deficiency. The diagnosis covers a spectrum of limb deformities often involving proximal and distal anomalies both in the femur and in the foot, such as tarsal coalition and absence of the lateral ray. The fibula itself can simply be smaller in size but in the most severe cases it may be completely absent (Table 13.14.2).

Treatment guidelines were highlighted by Birch et al. (1998) in their ‘Functional classification of fibular deficiency’ (Table 13.14.3). Patients are divided by possessing a functional foot or a non-functional foot, and further divided by leg length discrepancy: minor discrepancies may be considered for equalization but a discrepancy of 30% or more would require multiple lengthenings and could be considered for amputation (Box 13.14.3).

Box 13.14.3 Functional classification of fibular deficiency

- How good is the foot?
- How big is the limb length discrepancy?

Our preferred amputation for a severe Type I is the modified Syme’s disarticulation (Figure 13.14.8). The remaining stump acts as a below-knee level amputation at skeletal maturity and is fitted with the corresponding type of prosthesis. The Boyd type amputation may be considered but difficulties in placing the calcaneum below the tibia can be encountered as the calcaneum is often in significant equinus and adherent to the posterior cortex of the tibial shaft.

Box 13.14.2 Fibula hemimelia

May include some or all of the following features:

- Absent lateral rays of the foot
- Tarsal coalition
- Ball and socket ankle joint
- Short, absent fibula with short and bowed tibia
- Absent cruciate ligaments
- Deficient lateral femoral condyle
- Short, externally rotated femur.

Fig. 13.14.8
A) Child with a Syme’s amputation for longitudinal deficiency of fibula, total, tarsus partial, rays 4 and 5 total (Type 1d fibula hemimelia, Table 13.14.2). B) Same child wearing her prosthesis. Note genu valgum which is part of the anomaly.
Type II cases with a non-functional foot are further subdivided into IIA with a functional proximal component of the limb, treated with amputation as described earlier and IIB with a non-functional proximal part. In these cases salvage procedures are considered as the foot may become important for function.

Other surgical interventions may be necessary for associated femoral deformity such as the genu valgum secondary to lateral femoral hypoplasia (Figure 13.14.8B).

**Tibial hemimelia**

This uncommon condition is characterized by complete or partial loss of the tibia but usually with the presence of a normal fibula. Clinically, there is anterolateral bowing of the lower leg with equinovarus position of the foot. There may be duplication of the toes and associated hand anomalies. Jones classified tibial deficiency into four types (Table 13.14.4 and Figure 13.14.9).

Classic recommendations dictate knee disarticulation for types 1a and 3, and below-knee amputation for types 1b and 2. Reconstruction may be considered in types 1b, 2, and 4 either by limb lengthening or consideration of ipsilateral fibula transfer using Brown’s procedure.

**Femoral deficiency**

Femoral deficiency may present with subtotal absence of the femur, true PFFD (see Figure 13.14.2), or simple femoral hypoplasia, with a femur that is normal anatomically but simply smaller than the contralateral bone. There are several classifications in the literature describing the spectrum of radiological appearances that can be seen.

Radiographs alone may, however, be misleading of the actual femoral length, especially if the film is taken with the limb in its characteristic resting posture of hip flexion, abduction, and external rotation. Although radiographs obviously aid in management decisions, they should be used in conjunction with a full clinical assessment of the limb. The function and possible fixed contractures of the hip and knee joints will impact on surgical intervention (see Figure 13.14.2B).

Gillespie and Torode initially recognized two broad groups—true PFFD and congenital short femur. Later a change was proposed that would take into account the clinical features. Group A consist of congenital short femur with no hip instability and minimal fixed flexion of hip and knee. By extending the limb the foot lies opposite the mid part of the contralateral tibia or lower. The
shortening will be 20% or less. Group B are an exaggeration of group A, the thigh is short and bulbous with the hip in flexion, abduction and external rotation. There is a sense of proximal instability with ‘pistoning’ of the proximal femur. When the limb is pulled down into extension the foot lies at the level of the opposite knee or shorter, the knee fixed flexion persists. Group C represents those patients with a subtotal loss of the femur. There is marked proximal instability with a similar clinical appearance to group B.

In group B the proximal femur tends to flex anteriorly during weight bearing. This makes prosthetic fitting difficult: treatment options include performing an arthrodesis of the knee in combination with an ankle disarticulation. This produces a single lever arm with the aim of leaving the end of the limb slightly proximal to the opposite knee and allowing an above knee prosthesis to be fitted.

In group C patients, due to the femur being so much shorter, anterior displacement of the thigh segment does not occur and therefore knee fusion may not be required as an ischial bearing prosthesis can be fitted more easily.

An alternative procedure is the van Nes rotationplasty, described in 1950. The aim with this procedure is to fuse the knee as above whilst rotating the foot 180 degrees to leave the ankle lying at the level of the opposite knee. The gastrocnemius and soleus muscles then act as ‘knee’ extensors and a below-knee type prosthesis may be fitted. We have no experience of this technique. A comparison between the two procedures emphasized the need for individual treatment plans. With a good hip and adequate ankle function then the rotationplasty allows more ‘normal’ function as judged clinically, but there can be a psychological price to pay due to the abnormal cosmetic appearance.

Recently, authors have emphasized again the importance of knee mobility and knee deficiency in patient management and some feel that knee function is of greater importance than hip stability (Table 13.14.5).

The strategy of Paley’s treatment algorithm is for reconstruction from proximal to distal thus ultimately reconstructing a functional limb of equal length. He does accept that amputation may be the preferred option in type 3 cases.

Finally, the Steel femoropelvic fusion is a procedure that may be considered in those severe cases of significant diaphyseal femoral loss (Gillespie Group C, Paley Type 3). The femur is fused to the pelvis in a flexed position to allow the knee to act as the ‘hip’. A good result allows the patient to function as an above-knee amputee.

Prostheses for longitudinal lower limb deficiencies

Prosthetic replacement forms an important and integral part of the management of PFFD. Because of the inevitable limb shortening on the affected side, the aim of treatment is to equalize limb length for effective gait. This can be achieved by simple devices like heel or shoe raises if the shortening is minimal. If the shortening is significant and greater than that which can be managed reasonably with a shoe raise, an ‘extension prostheses’ is used. This is essentially a prostheses accommodated distally to the end of the short limb, effectively ‘extending’ it to the ground level and attached proximally to the short limb by enclosing it in the prosthetic socket. The design and construction varies, dependant on the deformity including shape and size of the residual limb and joint function and understandably they are not particularly aesthetic (Figure 13.14.10). Sometimes, surgical intervention may be advisable, to improve function and appearance by facilitating use of standard below or above-knee prostheses. Thus, a Syme’s disarticulation in a child with fibular hemimelia or PFFD with a stable hip joint may allow use of a cosmetically more acceptable, standard transfibial or transfemoral prosthesis (Figure 13.14.11).
A) Exoskeletal extension prosthesis for young child with longitudinal deficiency of femur, partial, upper third (PFFD) with external knee hinges and knee lock and an ischial bearing socket. B) Same prosthesis flexed in the sitting position: the lower part of the socket which accommodates the natural foot, projects awkwardly.

Fig. 13.14.10

A) Child with a right longitudinal deficiency of the femur, partial upper third (PFFD) following a Syme’s amputation. The end of the stump approximates to the level of the contralateral knee. B) Same child wearing an endoskeletal prosthesis at fitting stage with polycentric knee. She walks with a free knee gait. C) Same child sitting, wearing her completed prosthesis. Foot amputation and the use of a polycentric prosthetic knee has much improved the cosmesis compared with an extension prosthesis as seen in Figure 13.14.9.

All categories of patients with femoral shortening should initially be treated with extension prostheses to allow them to stand up when they are ready to do so, generally around the ages of 12–18 months. In patients with a severe form of PFFD with no true hip joint and the knee virtually at the hip level and with associated fixed contracture, the prostheses needs to be ischial tuberosity bearing. Rarely, they may need to enclose the whole pelvis. If the foot is a significant cosmetic problem, a Syme’s disarticulation should be recommended. With an intermediate degree of PFFD and minor loss of hip extension, an arthrodeses of the knee joint and Syme’s amputation may allow the use of standard transfemoral prostheses if the resultant stump length is approximately equal to the contralateral femur. In practice, this is most effective and appropriate in those patients who have associated distal limb deficiencies in the fibula and foot.

The principles for prosthetic prescription for distal deficiencies are similar. An extension prosthesis is provided for limb shortening, if it is too great to be overcome conveniently with an orthosis or shoe raise. However, the extension prostheses may not need to extend proximal to the knee joint. If a Syme’s disarticulation has been performed, a standard transtibial prosthesis will be appropriate, and cosmetically preferred. Good function is achieved. If a knee disarticulation has been performed, a standard prosthesis for the appropriate level is prescribed. It should be noted that a transfemoral prosthesis is often appropriate for a knee disarticulation because of the associated minor femoral shortening and knee clearance available.

Prosthetic management for longitudinal lower limb deficiencies is challenging. Each case has to be assessed on individual circumstances and management planned jointly with the surgical and medical rehabilitation teams.

Acquired limb deficiency

Discussion of this topic is outside the remit of this chapter but many of the principles that govern management of the congenital limb deficiency are applied to patients with acquired limb deficiency: in both groups, consideration must always be given to
possible problems with the opposite lower limb (Figure 13.14.12).

Fig. 13.14.12

Further reading

The management of limb length inequality

Summary points

- Limb length inequality is common: prediction of the final discrepancy at skeletal maturity is important to allow appropriate management plans to be made
- Knowledge of the underlying cause helps with prognosis
- Management is influenced by various factors including age and height and often involves a combination of treatment methods.

Introduction

Limb length inequality occurs as a result of a spectrum of musculoskeletal conditions. The degree of asymmetry ranges from a subtle difference without functional consequence, to major congenital reduction deformities (see Chapter 13.14). These patients present in general orthopaedic practice and a robust knowledge of the natural history and an appreciation of the likely short- and long-term functional consequences of each condition is essential for sensible management. This chapter discusses diagnosis, clinical and radiological assessment, including methods of prediction of final discrepancy, and management strategies that include various treatment options.

Aetiology

Length discrepancy occurs acutely due to fracture malunion or because of retardation or stimulation of limb growth in childhood. Growth retardation may be secondary to congenital reduction syndromes, growth plate injury or neurological abnormality. Shapiro et al. recognized that specific patterns of retardation were a function of the causative pathology. Identification of the cause allows prediction of final discrepancy, particularly in conditions where this evolves at a constant rate. Growth stimulation may be a feature of conditions such as juvenile idiopathic arthritis, trauma, vascular malformation syndromes, and neurofibromatosis.

In the major congenital reduction syndromes, the discrepancy increases in proportion to longitudinal limb growth. The evolution of the discrepancy has been demonstrated using antenatal ultrasonography and with serial radiographs in childhood. It remains constant from the time of fetal limb formation until skeletal maturity.

Physeal injury following acute fracture, local infection or generalized sepsicaemia has a profound affect on growth, particularly around the knee. As the rate of growth at each site is known, the limb length discrepancy at skeletal maturity can be predicted. These growth plate injuries, when incomplete, are often associated with additional sagittal, coronal, and rotational deformities. Neurological conditions including hemiplegic cerebral palsy and poliomyelitis also cause a predictable reduction in leg length related to the degree of involvement in cerebral palsy and the age of onset and extent of involvement in poliomyelitis. Variable overgrowth related to age of onset, extent of synovial involvement, and response to therapy complicates inflammatory conditions such as juvenile idiopathic arthritis. Other conditions that cause a discrepancy by stimulation include some vascular malformation syndromes and neurofibromatosis. All tend to increase in proportion to normal growth. Overgrowth following fracture does occur but unpredictably. The common causes of limb length inequality are outlined in Table 13.15.1.

### Clinical assessment

Initial clinical assessment involves visual analysis of the pattern of walking, barefoot and with shoes/orthotics, to identify compensatory strategies. Long-standing minor discrepancies may produce no more than a subtle abnormality in the gait pattern.

The patient is examined standing comfortably to attention and features such as dipping of the short side pelvis, flexion of the long side knee, and equinus of the short side ankle noted (Box 13.15.1). Active and passive joint ranges of movement are assessed for all lower limb joints and fixed deformity and contractures identified.

### Box 13.15.1 Leg length discrepancy

In stance:
- Dipping of the short side pelvis
- Flexion of the long leg knee
- Equinus of the short side ankle
- Are there fixed contractures or deformity?
Clinical measurement of limb length discrepancy is imprecise, particularly in the presence of long bone deformity and joint contracture, although measurement between bony points can help document an evolving discrepancy. A simple and reasonably accurate method of assessment uses graduated wooden blocks under the short limb to balance the pelvis until the anterior superior iliac spines are on the same horizontal line. Clinical assessment must include the spine to identify a coexisting postural or structural scoliosis and the upper limbs to identify involvement in congenital reduction and hemiasymmetry syndromes.

It can be surprisingly difficult to define the degree of leg length discrepancy accurately and investigations including plain x-rays may be necessary.

Radiological investigations

The benchmark of limb length discrepancy assessment is clinical, with radiographs as necessary to ensure an appropriate degree of accuracy.

The most useful radiograph is the standing long leg alignment view (Figure 13.15.1). The patient is positioned with blocks to accommodate the limb length discrepancy and the limb is aligned with the patella facing anteriorly to produce a reproducible radiograph that allows comparison over time. This is also useful for assessing associated sagittal plane malalignment. With this technique, there is the disadvantage of parallax error due to the single beam.

Prediction of final discrepancy

Accurate prediction of the discrepancy at skeletal maturity is of fundamental importance in planning the type and timing of corrective surgery. A number of popular methods of assessment rely on historical growth data. This data was used by Paley to calculate the proportion of final growth of the femur and tibia and he produced the multiplier method of assessment for children of all ages. The product of the measured difference in bone length and the relevant multiplier for age, sex, and site determined the maturity discrepancy for that segment. The information is presented in tabular form and allows straightforward, accurate prediction of leg length discrepancy at maturity.

Estimation of skeletal age

Conventional methods of skeletal maturity assessment use the Greulich and Pyle radiographic atlas and more recently the method of assessment described by Dimeglio (see Chapter 13.23). Recent studies demonstrate that skeletal and chronological ages do not diverge significantly until the later part of skeletal growth. This allows prediction of final discrepancy to be conducted with some confidence without a radiological assessment of skeletal maturity.

The patient’s height must be related to that of their parents and an estimation of their pubertal stage made. A simple, additional question as part of the history asks whether the child is tall or short compared to their classmates. For those at the extremes, more care needs to be taken but those in the middle can be assumed to fall within two standard deviations of normal with concordant skeletal and chronological age up until the age of 13 years in girls and 14 years in boys.

Consequences of limb length discrepancy
Conventional wisdom dictates that limb length inequality up to 2.0cm is tolerated without compensatory mechanisms, symptoms or long-term disability. Greater discrepancies lead to secondary compensation and in the short term, the functional leg length is equalized with an equinus posture of the short leg/ankle, a flexion posture of the long leg knee, or a combination of both.

In the longer term, this leads to an oblique pelvis with the potential for ‘long leg acetabular dysplasia’ and an increased incidence of low back pain and a non-progressive scoliosis. This eventually leads to a loss of spinal mobility with a fixed scoliosis and later radiological abnormalities that include disc space asymmetry, marginal osteophyte formation, and wedging of the vertebral bodies. There is, however, no good statistical correlation between the degree of limb length discrepancy and the incidence of low back pain.

Management

The initial management involves reassurance and a cogent treatment plan made soon after diagnosis. The parents of children born with congenital abnormalities are often distraught. The initial consultation frequently includes questions about the cause, the role of avoidable factors, and the risk to future pregnancies. Unfounded statements at this stage often cause long-standing management difficulties.

It is possible to estimate the final discrepancy in the major congenital abnormalities and this determines whether long-term management should involve surgical or prosthetic reconstruction (Box 13.15.2). The decision is difficult, particularly with recent advances in surgical reconstruction techniques, but in general, a reduction deformity greater than 20–30% with instability of the adjacent joints signifies a very difficult reconstruction with the potential for a functionally poor result in the longer term. Following a decision to manage the deformity with a prosthesis, the purpose of surgery is to improve prosthetic wear and function: procedures include hip reconstruction and amputation of the foot to allow for a more cosmetic prosthesis (see Chapter 13.14).

Box 13.15.2 An example strategy for 20cm predicted leg length discrepancy

- Age 1 year: Femoral valgus/derotation osteotomy, Millis acetabuloplasty
- Age 5 years: soft tissue knee reconstruction
- Age 6 years: lengthen 5cm
- Age 8 years: lengthen 5cm
- Age 10–15 years: lengthen 5cm
- Age 12 years: contralateral epiphysiodesis.

For less significant reduction deformities, surgical limb lengthening is often appropriate but must be embarked upon with caution and it is often only part of the overall operative strategy.

In a long-standing minor discrepancy, surgical correction should be prefaced with a shoe raise to simulate the post operative result. Continuing low back pain after a period of 3–6 months of functional limb equality implies that surgical equalization may not relieve this symptom. The options for treatment in the skeletally immature patient are dependant on the degree of growth remaining and predicted final discrepancy. Epiphysiodesis is relevant for correction of differences up to 5cm. After skeletal maturity, diaphyseal resection of bone with internal fixation allows equalization of between 3–5cm. More aggressive shortening leads to long-standing muscle weakness particularly in the quadriceps and hamstrings with an associated extensor leg which may not recover.

In patients with a congenital deformity, an early decision needs to be made regarding whether it is in the patients’ best interest to consider surgical reconstruction or if long term, prosthetic management is the preferred option.

Surgery

Epiphysiodesis

Epiphysiodesis is the conventional approach for equalization of a discrepancy of up to 5cm. There are numerous descriptions of the technique but the Canale percutaneous approach is technically straightforward and should be within the remit of the general orthopaedic surgeon.

The distal femoral and proximal tibial physes are visualized using an image intensifier. A lateral stab incision is made at the level of the physeis and using a single entry point in the perichondral ring, a hemiepiphysiodesis is performed with a 3.5mm drill with multiple passes, fanning towards the mid line (Figure 13.15.2).
The target area is the resting zone of the physis and therefore the drill should pass close to the epiphyseal/physseal junction to increase the likelihood of growth arrest: the epiphysiodesis is completed with a curette. The procedure is repeated from the medial side in an identical fashion. The fibula is approached under direct vision using a hand held burr, due to the proximity of the common peroneal nerve.

Postoperatively, full weight bearing is encouraged but contact sports prohibited for 6 weeks. Clinical and radiographic follow-up is to ensure that there has been successful, symmetrical growth arrest. Any signs of differential growth mean the procedure must be redone.

Timing

Determination of the optimum time for surgery is crucial. The author’s preferred method involves prediction of the final discrepancy using the Paley multiplier method and timing of surgery using the Eastwood-Cole chart. This chart is a graphic representation of a simple arithmetic method for predicting future growth and hence the timing of an epiphysiodesis described by Menalaus and Westh. It relies on the assumption that the distal femoral and proximal tibial growth plates make a predictable contribution (10mm femur, 6mm tibia) to longitudinal growth with boys reaching skeletal maturity at 16 and girls at 14 years of age.

Shortening

After skeletal maturity, segmental shortening of up to 5cm can be performed using a step-cut osteotomy of the proximal femur, stabilized with a blade plate or similar device. Alternatively, closed shortening over an intramedullary nail affords the most rapid return to normal activity with a limited approach and more cosmetically acceptable scarring (Figure 13.15.3).

Lengthening

Modified Ilizarov technique for femoral lengthening

The following description is the author’s preferred method of lengthening the femur and combines the classic technique described...
by Ilizarov (1992) with techniques modified by Catagni and others (1998). This description is of the technique used to lengthen the femur but it can be modified to address any three-dimensional long bone deformity. Recent advances in computerized hexapod external fixators have simplified femoral lengthening and deformity correction but this description highlights the essential mechanical principles that need to be understood, irrespective of the hardware used.

This procedure is suitable for patients in whom the predicted length discrepancy is 20–30% of the uninvolved side and assumes that the hip and knee are intrinsically stable. The assessment of current length discrepancy and prediction of final discrepancy described above are essential for accurate pre-operative planning. Coexisting coronal and sagittal deformities are identified using the methods popularized by Paley and colleagues to ensure that in addition to limb lengthening there is accurate deformity correction.

The soft tissue dimensions of the thigh are measured using commercially available templates and this allows the fixator to be constructed prior to the operation, simplifying the surgical exercise. The basic construct involves a distal fixation segment composed of two complete rings. The proximal fixation segment is composed of an arch support and these are connected using a floating or force transmission ring (Figure 13.15.4).

**Procedure**

The procedure is performed under general anaesthesia, without neuromuscular blockade or non-steroidal anti-inflammatory medication. The patient is supine on a radiolucent operating table; the entire limb is draped after skin preparation from the toes to above the iliac crest. The ipsilateral buttock and flank are raised with a pillow or large sandbag to enhance access to the proximal femur and allow flexion of the hip and knee during wire and pin placement. An operating table with a detachable segment also allows satisfactory access to the leg, with the tibia supported on a Mayo table.

Using an image intensifier, a 1.8-mm reference wire is inserted into the distal femur, parallel to the joint line from lateral to medial, at the level of the distal metaphyseal flare. The fixator must be placed parallel to the mechanical axis of the femur to prevent medialization of the knee during lengthening. The joint line is approximately perpendicular with the mechanical axis and therefore provides a good point of reference (Box 13.15.3).

**Box 13.15.3 Fixator ‘rules’ for femoral lengthening**

- Fixator parallel to mechanical (not anatomical) axis
- Adequate soft tissue clearance around all rings/arches
- Transfix muscles at their maximal length
- Ensure that the bone is in the middle of the frame
- Precise technique for the insertion/placement of pins/wires.

Careful attention to detail is required during wire placement to minimize subsequent pin site infection and allow maximum excursion of the knee and hip joints.
The knee is passively flexed and extended, and the skin over the lateral aspect of distal femur is observed. There is a consistent area of skin that does not move during knee excursion and this is the optimum entry point for the wire. The knee is fully flexed before the wire penetrates the lateral quadriceps and this transfixes the muscle at its maximum length, preventing a tether that will restrict knee motion. The wire is inserted into the femur at its maximum diameter, avoiding high-speed insertion, which will generate intense heat, causing a ring sequestrum and early loosening. The wire can be cooled, sterilized, and controlled using an alcohol-soaked swab. The knee is fully extended and the wire advanced through the medial hamstrings muscles using a mallet. Power insertion is to be avoided on the distant side to minimize the risk of neurovascular damage. At this point, the range of knee movement is checked and any skin tethering is released with a scalpel.

A 6-mm hydroxyapatite (HA) coated half pin is inserted into the proximal femur at the level of the lesser trochanter. The image intensifier is used to insert this pin parallel to the line that joins the tip of the greater trochanter to the centre of the femoral head, provided the morphology of the proximal femur is normal. If there is a significant abnormality, the pin is inserted 7 degrees to the anatomical axis of the femur, perpendicular to the mechanical axis.

The fixator is attached to the proximal pin and distal wire, ensuring that the femoral diaphysis is centred in the rings in the anteroposterior and mediolateral planes, with adequate soft tissue clearance. The fixator has now been positioned parallel to the mechanical axis of the femur, with the femur in the centre of the frame.

The distal wire is tensioned to 110–130kg and the proximal pin is attached to the arch using the appropriate pin holder. Distal fixation is secured using two further tensioned wires or HA coated half pins, with the greatest possible crossing angle that does not jeopardize other structures. Again a careful insertion technique is required for each wire or pin.

Proximal fixation is completed using two further 6-mm HA coated half pins, inserted above and below the reference pin, with the maximum crossing angle that is allowed by the dimensions of the arch.

The method and site of femoral osteotomy is a controversial subject. In general there is agreement that the femur should be divided in the metaphyseal region using a low energy technique: the author prefers a distal osteotomy.

A 2-cm longitudinal incision is made in the mid lateral line. The iliotibial band is identified and its anterior and posterior limits dissected. It is then divided transversely under direct vision. The vastus lateralis muscle is defined and reflected anteriorly using a bone lever placed over the anterior surface of the femoral shaft. The periosteum is identified and incised longitudinally. Periosteal stripping has a negative effect on bone formation and should be avoided. Using a sharp osteotome, the anterior and posterior cortices are divided completely, leaving the posteromedial corner undivided. The osteotome is rotated 45 degrees in either direction, completing the osteotomy.

Usually the peristeum can not be closed but a careful, layered wound closure is performed. The pin and wires are dressed with alcohol-soaked sponges and stoppers.

Femoral lengthening using a computerized hexapod fixator is more straightforward and can be accomplished with a two-ring fixator. The ring placement is not as critical, but the position of the rings in relation to the bone must be accurately determined with postoperative radiographs.

Postoperative management

The patient is encouraged to put 25% body weight through the limb as soon as comfort allows, graduating to full weight over a period of several weeks. Distraction commences after a latent period of 5–7 days depending on the age of the patient and the bone pathology. It continues at a rate of 0.25mm every 6h or according to the computer-generated prescription, until the target length and deformity correction has been achieved.

The patient attends for follow-up on a regular basis, with radiographs to assess the quality and quantity of new bone formation. The rate of distraction may be altered to prevent premature consolidation or incomplete regenerate formation.

Complications

Surgical limb lengthening is associated with a high, but not necessarily prohibitive, complication rate. The knowledge that complication rates can approach 100% should not lead to a feeling of inevitability or complacency. The detailed description of wire/pin insertion techniques, pin-site care, and postoperative management is deliberate and leads to a substantial reduction of the frequency and severity of these complications.

Infection.

Pin site infection is a common consequence of prolonged external fixation. Careful attention to detail during pin and wire insertion and good postoperative pin-site care reduces but does not abolish this complication. Pain and erythema usually herald infection. The use of broad-spectrum antibiotics, in appropriate doses for patient body weight is often effective. If rapid resolution does not occur, hospital admission may be necessary for parenteral antibiotics, according to microbiological culture. The majority of infections will resolve if treated promptly but it is occasionally necessary to remove the infected fixation and very rarely to abandon the procedure.

Pain.

Pain is often associated with infection. Neurogenic pain may be associated with the lengthening process and may limit the rate of lengthening. Instability due to improper fixator construction or loosening must also be considered and appropriate adjustments made.
Problems with the regenerate bone.

The quality of the new bone depends on a number of mechanical and biological factors. An excessive rate of distraction may lead to deficient regenerate whilst premature consolidation is associated with slow distraction. Bone formation is monitored with frequent radiographs and, in some centres, with ultrasound and computed tomography. There is poor correlation between radiological and mechanical parameters of bone 'strength' and decisions relating to consolidation of the regenerate are usually based on plain radiographs in two planes. The optimum time for fixator removal is difficult to predict. Premature removal is complicated by regenerate failure, with deformity or fracture.

Joint subluxation/contracture.

The joint laxity that is commonly encountered in congenital femoral deficiency or fibular hemimelia predisposes to joint subluxation and dislocation. An early sign is a loss of joint movement with a flexion adduction deformity at the hip or a flexion contracture at the knee causing concern. If joint subluxation does occur, the lengthening and deformity correction may have to be stopped and the fixator extended to incorporate the knee before the programme can be continued. Careful preoperative assessment, surgical reconstruction of the joints before lengthening and aggressive physical therapy during lengthening is important to prevent this complication.

Summary

Discrimination between conditions that are due to overgrowth or reduction in growth and an estimation of the compounding effect of future growth during childhood allows a rational approach to limb equalization. Whilst the current enthusiasm for surgical limb lengthening is appropriate in carefully assessed patients, the importance of shortening by acute resection or epiphysiodesis should not be underrated. The aim should be for limb equalization by the simplest and most appropriate method (Box 13.15.4).

Box 13.15.4 Before lengthening

- Careful assessment of the problem and the child/family
- Plan and agree aims of treatment
- Reconstruct unstable joints first
- Consider spanning the neighbouring joint
- Ensure that the need for a postoperative rehabilitation programme is understood.

Further reading

Summary points

- Some rare angular deformities of the lower limbs must be recognized early
- Most deteriorate with time and cause significant functional problems
- With tibial bowing, description of the apex of the bow determines prognosis and management
- Surgical management of these conditions can be difficult: multiple procedures may be required during the growth period.

Introduction

There are a group of rare angular deformities of the lower limbs such as coxa vara, congenital dislocation of the knee, tibia vara, and two types of tibial bowing, posteromedial and anterolateral, that may present at birth or at walking age. All can lead to problems with function in the long term; and all but one (posteromedial bow) deteriorate without intervention.

Coxa vara

Infantile coxa vara is a rare condition that causes the femoral neck-shaft angle to be reduced (<125 degrees), associated with a characteristic defect in the femoral neck (Figure 13.16.1).

Fig. 13.16.1
AP radiograph of the pelvis showing bilateral coxa vara. Both femoral necks show the characteristic Fairbanks triangle at the inferomedial corner of the metaphysis where there is defective ossification.

Incidence

The quoted incidence is 1:25,000 births. However, the condition is not evident at birth and although often noticed when the child begins walking, in half of the cases it is not recognized until age 5 years. There is an equal sex distribution, little geographical variation and, in up to a third of cases, both hips are affected.

Anatomy

Normal

Radiographically, the normal neck-shaft angle increases from 130 degrees in the newborn to 145 degrees by 1 year of age. It then decreases to 125 degrees by adulthood. Microscopically, the femoral neck physis is typical of other long bone growth plates.

Pathological

Radiographs show a decreased neck-shaft angle (typically 85–115 degrees initially) and a short femoral neck but with a normal head and a straight shaft. In 25% hips the neck-shaft angle worsens with time. There is a characteristic triangular osseous fragment (Fairbanks’ triangle) at the inferomedial corner of the metaphysis (Figure 13.16.1) and abnormal irregular ossification of the femoral neck metaphysis. The physis is wide and vertical with disturbance of the normal cellular organization. The affected growth plate closes early, usually at the age of 10 years.

Classification
Infantile coxa vara should be differentiated from other causes of coxa vara, including congenital dysplasias and acquired abnormalities (Box 13.16.1).

**Box 13.16.1 Causes of a radiological coxa vara**

- **Congenital/developmental:**
  - Infantile
  - Congenital dysplasia–PFFD

- **Acquired:**
  - Post-traumatic
  - Osteomyelitis
  - Avascular necrosis
  - Osteogenesis imperfecta/other bone softening disorders.

**Clinical History**

A limp is noticed as the child begins to walk or in early childhood. Children may complain of stiffness after resting and pain after walking.

**Physical examination**

Examination identifies a short leg with a high trochanter. Hip abduction is significantly reduced but the adduction range is maintained. There is often a fixed flexion deformity of the hip associated with a lumbar lordosis. The poor lever-arm of the hip abductors leads to a Trendelenburg gait.

**Investigation**

Pelvic x-rays show the characteristic features outlined earlier. Imaging of other bones may be needed to rule out a generalized skeletal dysplasia. Two radiographic lines are commonly used to assess the deformity the neck–shaft angle and the Hilgenreiner–epiphyseal (HE) angle (Figure 13.16.2). Both angles may be affected by lower limb rotation.

---

**Fig. 13.16.2**

The Hilgenreiner–epiphyseal (HE) angle lies on the medial side from a horizontal line that joins the triradiate cartilages, and line that runs through the proximal femoral physis.

In some cases of isolated coxa vara, computed tomography (CT) studies have shown a decrease in the physeal–femoral neck angle (as seen in adolescent slipped capital femoral epiphysis). The epiphysis and attached triangular fragment slip from the normal superanterior portion of the neck in an inferioposterior direction. Often, in severe congenital coxa vara, there is a marked femoral retroversion.

Magnetic resonance imaging (MRI) studies in patients with congenital coxa vara reveal a widened growth plate with expansion of cartilage mediadistantly between the capital femoral epiphysis and metaphysis but do not identify a true slip.

Histological studies have found the growth plate is made of few irregularly distributed germinal cells. Similar changes found in the growth zone of the iliac bone seem to indicate that the ossification disturbances are multifocal.
Natural history

If the neck-shaft angle is less than 110 degrees, coxa vara tends to worsen with time. Hips with HE angles less than 45 degrees will usually correct spontaneously without surgery. Those with HE angles of 45–60 degrees represent a ‘grey zone’ and should be observed. However, progression of deformity is the rule if the HE angle is greater than 60 degrees. Progression is often accompanied by other problems such as a pseudarthrosis at the site of the defect, leg length differences, mechanical axis deviation, and rotational deformity. There are associated dysplastic changes in the acetabulum.

Management

Operative

The indications for surgery are a Trendelenburg gait and a HE angle greater than 60 degrees, or evidence of progressive deformity. The conventional operative procedure is a valgus extension proximal femoral osteotomy, as described by Pauwels. The aim of surgery is to correct varus to a HE angle less than 45 degrees, equalize leg lengths, and normalize abductor muscle length. However, these operations are often technically difficult and may lead to joint stiffness without sufficient correction of the coxa vara or associated deformities.

The valgus osteotomy may be combined with a greater trochanter epiphysiodesis or trochanteric advancement if the trochanter is high. Circular fixators can also be used to correct the deformity.

Results/complications

In some series recurrence rates of up to 50% are seen following a valgus extension osteotomy. However, when the HE angle is well-corrected (<38 degrees), the recurrence rate is only 5%. If deformity correction is achieved and maintained before age 10 years, 87% of children have excellent acetabular depth, spherical congruency, no pain, and a correction of Trendelenburg gait in the short to medium term. The triangular defect closes within 6 months of surgery.

Premature capital femoral physeal closure is frequent, leading to relative overgrowth of the greater trochanter and, in unilateral cases, unequal leg lengths. The leg length discrepancy is sufficient to require treatment in 40% of cases, usually with contralateral epiphysiodesis.

Congenital dislocation of the knee

This spectrum of hyperextension disorders of the knee includes congenital genu recurvatum (CGR) and congenital dislocation of the knee (CDK) (Figure 13.16.3).

Incidence

The incidence is estimated to be 2:100 000 with equal sex distribution.

Anatomy

Normal
Cadaver studies of neonatal knees demonstrate that 5–15 degrees of hyperextension is normal which could be increased by 10 degrees with prolonged pressure. By 3 months, fixed flexion of 5 degrees develops. Extension can be achieved with prolonged pressure but at this age, hyperextension does not occur.

**Pathological**

Knee hyperextension greater than 30 degrees is demonstrated with associated limited flexion. There are two groups: those involving anomalies of the elastic tissues and those with a postural deformity secondary to intrauterine problems. In 60% of children with CGR/CDK there are other anomalies, including hip dysplasia, foot deformities, cleft lip and palate, chest wall deformities, and elbow dislocation. CDK is commonly seen in conditions such as arthrogryposis, spina bifida, and syndromes associated with joint laxity, such as Down syndrome. The combination of CDK or joint laxity with other malformations should raise the possibility of a chromosomal abnormality.

At operation, an absent cruciate ligament is a common finding. Other aetiological theories include fetal molding or quadriceps contracture.

**Classification**

The classification system by Leveuf and Pais (1946) has been used to determine management. Essentially these types are: hyperextension of the knee, anterior subluxation of the tibia, or anterior dislocation of the tibia (Table 13.16.1) (Figure 13.16.3).

</tr>
</tbody>
</table>

**Clinical**

The diagnosis is usually obvious at birth: 30% are associated with a breech delivery.

**Physical examination**

The knee appears “back to front” (Figure 13.16.4). There is a deep anterior skin fold and the femoral condyles are easily palpable in the popliteal fossa. The patella is deep and often difficult to feel. As the child lies flat, the hyperextension tends to externally rotate the leg giving an impression of valgus.

**Investigation**

The diagnosis may be made on antenatal ultrasound. After birth, ultrasound can be used to follow the progress of the condition; radiographs are less helpful due to the cartilaginous nature of the neonatal knee joint.

**Management**

**Initial**
As the deformity is often very striking in the newborn, the parents need prompt reassurance that most children can be treated successfully by conservative means. The aim of treatment is to gain a range of movement adequate for activities of daily living. Other associated conditions such as developmental dysplasia of the hip and talipes equinovarus should be treated as appropriate: most authors suggest that the knee be treated first. The presence of associated deformities, delay in treatment, and generalized joint laxity adversely affect the prognosis.

Non-operative

Immediate reduction or serial casting should be tried when the patient is seen within the first week or so of life. In the infant, it is important to ensure that the manipulation and casting is performed in the correct direction: the limb lies in external rotation and there is a tendency to ‘flex’ the knee into valgus. The deep anterior skin crease helps in orientation of the limb. Flattening of the tibial plateau and anterior bowing of the tibia is common after prolonged conservative treatment but remodels eventually. If the patient is seen late and serial casting proves to be unsuccessful, traction in the Bryant position or in a prone position should be used for 1–2 weeks, and then gentle closed reduction of the CDK can be tried with or without anaesthesia.

Operative

Not all children respond to serial casting. Those with fibrous changes in the quadriceps muscles often require operative treatment, (10–50%). This is performed with an arthrogram to assess the knee, a V–Y plasty of the quadriceps and anterior release of the adherent capsule. This allows the collaterals, the iliotibial band, and the hamstrings to return from the extensor to the flexor side of the knee axis. Intraoperatively the aim is to achieve 90 degrees of flexion and this is maintained with a cast in 90 degrees of flexion for 6 weeks. An operation at age 9 months appears to be optimal, enabling the children to walk and function normally.

Results

Non-operative correction appears to be most effective if it starts immediately after birth. This may restore complete function and joint range, although some children may lack full flexion.

In patients with valgus alignment and hyperlaxity, ongoing bracing or even a corrective osteotomy may be required. Selected patients may benefit from transposition of the pes anserinus and the tibial insertion of the medial collateral ligament to reinforce the medial aspect of the knee joint.

Good results are more difficult to achieve in children with Larsen’s syndrome and arthrogryposis: conservative treatment usually fails and operative treatment may need to be more aggressive. Indications for surgery need to be considered carefully.

Tibia vara

Infantile tibia vara is characterized by an acute varus angulation of the tibia just below the knee joint, secondary to disturbance of the posteromedial proximal tibial physis (Figure 13.16.5). This is a multiplanar deformity with proximal tibial varus, procurvatum, and internal torsion (Figure 13.16.6).

Fig. 13.16.5
Clinical photograph of a heavy child with bilateral tibia vara.
The condition is most commonly known as Blount’s disease as Blount described the first series of cases, although he acknowledged that Erlacher described it first in 1922. He also described a similar deformity in adolescence that is considered a different disorder (as are two other types: late onset tibia vara and fibrocartilagenous dysplasia).

Incidence

This condition is rare and never seen until walking age. It is more common in girls, early walkers, and children with obesity. There is a significant relationship between the magnitude of obesity and biaxial radiographic deformities especially those children with a body mass index higher than 40. The two population groups who appear to be particularly susceptible are African Americans and Scandinavians.

Anatomy

Normal

The normal lower limb alignment of a child under the age of 2 years is of knee varus (‘bow-legs’) that normally progresses to maximum knee valgus (‘knock-knees’) by the age of 5 years see (Chapter 13.10).

Pathological

If a child walks early, whilst they are in varus alignment, their mechanical axis will fall medial to the knee and put pressure on the medial growth plate. If there is excessive varus or excessive force (related to body mass) going through the medial growth plate then this may damage the growth plate. There is also tension on the convex side. According to the principles of Heuter, Volkmann, and Delpech, this encourages increased growth laterally. In turn this leads to a positive feedback phenomenon of worsening varus deformity, leading to even further force medially.

Histological examination of tibia vara in 6–7-year-olds shows widening and depression of the medial growth plate, small and deep intrusions of cartilage into the metaphysis, oedema of the medial tibial epiphysis, medial and lateral metaphysis; widening of the lateral growth plate, hypertrophy of the medial meniscus and focal bone bridging. Patients with infantile tibia vara have normal alignment of the distal femur unlike adolescent tibia vara.

Classification

Langenskiöld described a classification system that is based on stages of progression with age, not prognosis. The stages, from I to VI, show progressively increasing deformity with bone bridge formation between the tibial epiphysis and metaphysis (see Figure 13.16.6).

Clinical

History

Many young children are referred to orthopaedic clinics with bowlegs. Predicting whether these deformities will progress can be challenging. There is no consensus as to whether children with radiographic medial tibial beaking should all be classified as having Blount’s disease.

Physical examination

As noted earlier these children have varus alignment of one or both knees, and are often obese. A differential diagnosis must be considered (Box 13.16.2).
Box 13.16.2 Differential diagnosis of Blount’s disease

- Physiological bowing
- Congenital bowing
- Rickets
- Trauma
- Osteomyelitis
- Skeletal dysplasia:
  - Metaphyseal chondrodysplasia
  - Ollier’s disease.

Investigation

Imaging

Radiographs of the knees show the deformity with medial tibial depression and beaking progressing onto physeal bridging, as described by Langenskiöld.

Levine and Drennan described the tibial metaphyseal-diaphyseal angle (TMDA) (Figure 13.16.7). An angle greater than 11 degrees can distinguish between physiological and pathological varus. Subsequent work shows that there is a grey area between 9–16 degrees, where there is some overlap between physiological and pathological. The epiphyseal–metaphyseal angle (EMA) is also helpful under the age of 3 years. Children with TMDA above 9 degrees and EMA over 20 degrees are at greater risk for Blount’s disease and should be followed closely. A combination of a body mass index higher than 22 and a TMDA greater than 10 degrees has a high predictive value for tibia vara in children between 2–4 years.

Fig. 13.16.7
A) shows the anatomical femoro-tibial angle and B) demonstrates the TMDA (with the dotted line being perpendicular to the long axis of the tibia shaft). The Levine and Drennan tibial metaphyseal–diaphyseal angle (TMDA) is created by the intersection of a line perpendicular to the longitudinal axis of the tibial diaphysis and another line drawn through the transverse axis of the tibial metaphysis.

MRI has been used to confirm the pathological changes and to plan surgical management (Figure 13.16.8B).

Fig. 13.16.8
A) AP radiograph of a knee showing the changes associated with tibia vara (Blount’s disease). B) Corresponding MR image highlighting the changes in the physeal cartilage. C) Long-leg radiographs of the same child. She has bilateral disease. The
mechanical axis of her right leg lies medial to the joint. There is significant deformity of the right tibial plateau and ‘compensatory’ distal femoral valgus. The left leg shows a lesser deformity: there is evidence of previous treatment (hemiplateau elevation and a distal fibula osteotomy).

Management

Initial

Bracing (knee–ankle–foot–orthoses, KAFOs) has been used for children with a significant degree of varus before the age of 3 years. There is an overlap between toddlers with a marked physiological varus and those with a mild tibia vara and thus debate as to whether bracing works. It is agreed that bracing is only effective in Langenskiöld stages I and II, and in half of those treated.

Operative

The conventional operation that has been used for tibia vara is a proximal tibial valgus osteotomy often combined with external rotation. It is important to avoid damaging the apophysis, and to aim for some overcorrection into overall valgus alignment. Such surgery, performed early (under 4 years of age) may prevent recurrence of varus deformity in Blount’s disease at long-term follow-up. On its own, a lateral staple physeodesis does not seem to be effective although recently, encouraging results have been seen following the use of a physeal plate that acts as a tension band tether to physeal growth.

Elevation of the medial hemi-plateau of the tibia for correction of severe varus deformity secondary to Blount’s disease produces satisfactory results but a tibial osteotomy may also be required for full correction (Figure 13.16.8C). On the basis of knee arthrograms and MRIs, there is some disagreement as to whether the medial tibial plateau is truly depressed or simply filled with unossified cartilage (Figure 13.16.8B).

Circular frames have been used effectively to treat the combined problem of a complex tibial deformity and leg length difference in older children.

Results and complications

The most significant early complication of a proximal tibial osteotomy is compartment syndrome or neurological damage and close postoperative monitoring is essential.

Recurrence of deformity requiring repeated osteotomy occurred more frequently in children who underwent a late (>4 years of age) initial osteotomy and/or were Langenskiöld stage III or more. Patients who underwent a single osteotomy for correction of their deformity had significantly decreased pain in the affected knee at maturity. All patients who were symptomatic or who had significant knee instability or both had abnormal ligamentous, meniscal, or bony changes on MRI, confirmed by arthroscopy.

Congenital pseudarthrosis of the tibia

Congenital pseudarthrosis of the tibia is characterized by an apex anterolateral angulation of the lower leg through an area of abnormal tissue. It continues to pose one of the most difficult problems in paediatric orthopaedic surgery.

Incidence

Congenital pseudarthrosis of the tibia is rare with an incidence of 1:250,000 live births.

The pseudarthrosis is usually not present at birth (and therefore not truly congenital) but develops during the first decade of life. The male:female ratio is 3:2, left and right sides are equally affected, but only 1% of cases are bilateral.

Anatomy

Pathological

Most of the lesions are initially found in the middle or distal third of the tibia. In 29% the localization changes during the course of the disease. The fibula is also affected.

Associated pathology

Signs and symptoms of neurofibromatosis (NF) are present in 55%. It has also been noted that many have curly or overlapping toes on the affected leg. Screening for the NF gene is advised.

Classification

Various morphologic classification systems have been proposed but because the appearance changes during the course of the disease, all classification systems have some limitation. The most common classification is that by Boyd (Table 13.16.2).
Table 13.16.2 Boyd classification of congenital pseudarthrosis of the tibia

</tr>
</tbody>
</table>

Clinical History

Presentation depends on degree of tibial deformity and the presence of a fracture.

Physical examination

Typically there is bowing of the tibia, apex anterolateral. This must be differentiated from posteromedial bowing (see later). The affected segment is short and there may be the scars of previous operations (Figure 13.16.9). Stigmata of NF should be sought.

![Click to view larger](Fig. 13.16.9 AP view left tibia. An expanding intramedullary nail has been used to treat the tibial pseudarthrosis. The pseudarthrosis has healed but the nail has broken. There is residual ankle deformity. The fibula is also involved.)

Investigation

Imaging

X-ray changes as described previously are seen depending on type (see Table 13.16.2). MRI of congenital pseudarthrosis allows assessment of the type and extent of the disease. It is especially recommended for the evaluation of periosteal and soft tissue changes near the pseudarthrosis.

Histopathology

Histological examination shows a non-specific fibrous appearance in 45%; in 16% the ultrastructure resembles fibrous dysplasia; and in 39% there is evidence of NF1.

Histological comparison of the pathologic samples of patients with and without NF reveals no significant differences. The pseudarthrosis gap is continuous with periosteal soft tissues and filled by fibrous tissue, fibrocartilage, and hyaline cartilage with features of enchondral ossification.
A single pathologic process appears to occur in all cases: growth of an abnormal, fibromatosis-like tissue either within the periosteum or within the endosteal or marrow tissues. This may represent a skeletal expression of NF, either within the fully expressed syndrome (patients with known NF) or as isolated lesion (patients with unknown/cryptic NF). Fibrous hamartoma cells maintain some of the mesenchymal lineage cell phenotypes but do not undergo osteoblastic differentiation in response to bone morphogenic protein.

**Management**

**Initial**

Once the condition has been diagnosed, protective bracing should be started usually with a KAFO or clamshell orthosis. If the tibia remains intact surgery may be avoided.

**Operative**

There is debate about surgical intervention; in particular regarding the age at first operation, whether the resection should be conservative or radical and whether reconstruction or amputation would be the better option.

**Reconstructive**

The aim of reconstructive surgery is to manage the biological and mechanical abnormality by:

- Resecting the pseudarthrosis to provide stability, the basic requirement for bony consolidation
- Correcting length discrepancy and axial deformity (including consideration of the hind foot)
- Achieving fusion/fracture union.

The surgical techniques most frequently used for treating congenital pseudarthrosis of the tibia are intramedullary nailing associated with bone grafting, vascularized fibular grafting, and the Ilizarov circular external fixator device for stabilization and correction of deformity.

Recent studies using an intramedullary rod suggest that the best results are seen in children under 3 years of age at surgery: this contradicts the previous belief that surgery should be deferred until after 3 years.

Ipsilateral or contralateral vascularized fibular grafts are effective treatments and can be considered as a primary option. Both techniques involve resection of the abnormal tissue with transfer of normal living tissue into the defect and stabilization of the bone and the ankle joint.

Circular frames have become increasingly popular in the management of this condition. The technique may be used in various ways: for acute compression and stabilization after resection, for simple longitudinal compression of the ‘non-union’, side to side compression of over-riding atrophic bone ends or segmental bone transport to fill a bone defect.

For all of these techniques, a brace is advocated until the end of growth and often beyond.

**Amputation**

An alternative approach to reconstruction is amputation. Following Syme’s amputation, a solid union may be seen across the pseudarthrosis site, even without internal fixation or bone grafting. Healing is achieved by vertical alignment of the limb in a total contact prosthesis, along with the compressive forces of weight bearing (Box 13.16.3).

**Box 13.16.3 Indications for amputation**

- Failure to achieve bony union after 3 surgical attempts
- Limb length discrepancy > 5cm
- Development of a significant foot deformity distal to the pseudarthrosis
- Concerns regarding the functional loss due to prolonged medical care and hospitalization.

**Results**

A multicentre study by the European Paediatric Orthopaedic Society found that the Ilizarov technique had the highest rate of fusion (75.5%) of the pseudarthrosis and the best success in correcting the associated deformities. The Japanese multicentre study showed that the Ilizarov method with a vascularized fibular graft provided the best results. The worst outcomes seem to occur in patients with an associated fibular pseudarthrosis.

Despite good anatomical results, gait and muscle strength of patients with ‘healed’ congenital pseudarthrosis of the tibia are markedly disturbed. Early onset of disease, early surgery, and transankle fixation lead to an inefficient gait, comparable to that of amputees.

**Complications**
Even when union is achieved, the residual deformities in the affected limb often result in significant disability. These deformities include leg-length discrepancy, angular tibial deformities, ankle valgus and fibular non-union. Refracture is common. Factors predisposing to non-union/refracture are distal location of the tibial pseudarthrosis and the presence of concomitant pseudarthrosis of the fibula (Figures 13.16.9 and 13.16.10).

Future directions

Various adjuvant treatments such as bone morphogenic protein and bisphosphonates have been tried and although early results suggest that bone healing may be enhanced, none have yet documented a reduction in the refracture rate.

Congenital posteromedial tibial bow

This variety of bowed tibia is usually associated with a dimple at the apex and with a calcaneovalgus foot (Figure 13.16.11A).

Incidence

The deformity is very rare and much less common than an anterolateral bow. There is equal sex distribution.

Clinical

History/physical examination

This is alarming to parents as the acute angular deformity of the lower leg is obvious at birth. There is usually a skin dimple at the site of the bow and an associated calcaneovalgus foot deformity.

Investigation

It may be detected on the antenatal ultrasound scan and spontaneous correction starting before birth has been noted. X-rays show
sclerosis at the site of the bow with the deformity as seen clinically (Figure 13.16.11B).

Histology has been performed in one case of an aborted fetus and this demonstrated evidence of amniotic perforation, abnormal pericostal ossification, and remodeling.

Management

Initial

The natural history is of resolution but this may be incomplete (Box 13.16.4).

Box 13.16.4 Tibial bowing?

Direction determines prognosis and management:

- Posteromedial: benign with spontaneous improvement
- Anteromedial: consider fibular hemimelia
- Anterolateral:
  - Associated with congenital
  - Pseudarthrosis of the tibia.

Non-operative

Serial casting is often advocated but there are no studies of the effectiveness of this compared to the natural history. The process of spontaneous resolution may continue for several years and a conservative approach to treatment is recommended.

Operative

Tibial osteotomy to correct deformity is not usually required but there is always an associated leg length discrepancy which averages 3cm (2–6cm) at maturity. The degree of leg length difference and difference in calf size appears to be related to the degree of deformity. Operative techniques described elsewhere may be needed to correct this leg length discrepancy.

Complications

The degree of limitation of ankle movement is related directly to the severity of the initial deformity and the subsequent leg length discrepancy. It is probably due to a contracture of the heel cord and posterior capsule resulting from chronic use of an abnormally short limb.

Posteromedial bowing
Summary points

- Developmental dysplasia of the hip represents a spectrum of hip pathology with or without hip instability
- Controversy continues regarding the relative roles of clinical and ultrasound screening programmes
- Early diagnosis and prompt, appropriate treatment is important
- All treatment methods risk compromising the vascularity of the developing femoral head
- Residual dysplasia may require an aggressive surgical approach.

Introduction

Developmental dysplasia of the hip (DDH) is an umbrella term encompassing many different clinical presentations of disordered hip development, ranging from a deficiency in acetabular coverage of the femoral head (dysplasia), through instability of the femoral head (dislocatable hip), to displacement of the femoral head from the acetabulum. This displacement may be partial (subluxation) or complete (dislocation) and either reversible or irreversible on examination. Whilst gross hip instability is found only in the neonate and infant, dysplasia and complete dislocations present at any age.

Anatomical dysplasia is defined as inadequate development of the acetabulum and/or the proximal femur. Radiographically, the integrity of Shenton’s line distinguishes between dysplasia and subluxation: it is intact in dysplasia and disrupted with subluxation (Figure 13.17.1).

Embryology and pathoanatomy

An understanding of normal hip development, the pathological processes that affect it, and the resultant anatomical malformations helps explain the clinical presentation and the rationale for management.

At 8 weeks postfertilization, a cleft develops between the femoral head and the acetabulum, the joint forms, and the labrum can be distinguished as a distinct entity.

Normal hip development occurs with balanced growth of the proximal femoral and triradiate cartilages. An imbalance in this system may be a genetically determined cause for DDH but, at the outset, the only anatomical abnormalities identified are an elongation of the hip capsule and ligamentum teres, the acetabulum, labrum, and femur are usually normal.

The relative capacity of the normally developing acetabulum decreases over the last 3 months of gestation becoming smallest.
The relative capacity of the normally developing acetabulum decreases over the last 3 months of gestation becoming smallest around birth. Neonates of African origin have deeper acetabulae: a possible explanation for their significantly lower incidence of DDH.

DDH may, therefore, be the result of capsular laxity that allows the femoral head to escape from a normal acetabulum that happens to be at its shallowest around birth. Coexistent adverse intrauterine factors and the hormonal changes during birth may promote this pathological process.

An unstable hip at birth may either stabilize spontaneously and continue normal development or, if instability persists, develop progressive subluxation or complete dislocation with predictable secondary anatomical changes. Initially, these abnormalities are reversible but with time, the anatomic malformations become irreversible. Unfortunately, the fate of any individual hip is unpredictable.

Femoral head instability results in a ridge of hypertrophied acetabular cartilage on the posterior wall that Ortolani referred to as the neolimbus. It is the movement of the femoral head over this ridge that produces the ‘clunk’ of the Ortolani sign.

The primary stimulus for acetabular development is the presence of a spherical femoral head. In its absence, the acetabular floor becomes thickened and the acetabulum aspherical, shallow, and antverted as the anterosuperior wall fails to develop. Over time, a pseudacetabulum forms in response to the abnormal femoral head position either within the superior portion of the true acetabulum or above it.

The predominantly cartilaginous proximal femur may undergo compressive ischaemic injury as a consequence of its displacement, resulting in segmental flattening or increased anteverision. The greater trochanteric region is unaffected and may demonstrate relative overgrowth.

As well as osseous abnormalities, DDH is associated with specific soft tissue changes. The labrum together with its capsular attachment and adjacent acetabular ring epiphysis (the ‘limbus’) becomes distorted. The fibrofatty tissue in the acetabular floor ('pulvinar'), the ligamentum teres and the transverse acetabular ligament all hypertrophy and encroach into the empty acetabulum. The capsule is pulled upwards by the femoral head, causing the inferior capsule to cover the mouth of the acetabulum. Muscles spanning the hip joint shorten, most significantly the iliopsoas whose tendon crosses the anterior aspect of the capsule leading to an hourglass capsular constriction that keeps the femoral head in its displaced position.

Incidence, epidemiology, and aetiology

Given the different clinical pictures and detection methods, an accurate determination of the incidence and prevalence of the DDH spectrum is difficult: estimates have ranged from 1:1000 to 1:50 live births. The incidence of actual hip dislocation is 1–1.5:1000. Several risk factors have well-recognized associations with DDH but it is unlikely that any single factor is responsible.

The incidence of DDH varies considerably with both location and race; the former Yugoslavia had an incidence 50 times greater than other parts of Europe. The incidence in North American Indians has been reported to be as high as 1:50, whilst it is 0.1:1000 in the Hong Kong Chinese and essentially not seen in African Bantu babies. Eighty per cent of cases are female.

Twin studies have demonstrated a tenfold increased incidence of DDH in identical twins compared to fraternal twins suggesting that there is a genetic basis for the familial tendency (Box 13.17.1).

Box 13.17.1 Familial incidence suggests genetic link

- Identical twins: 34% concordance
- Fraternal twins: 3%
- Parents of patients: 5–10× increased incidence
- Siblings: 7× increased incidence.

The intrauterine environment has also been implicated as a risk factor. There are associations with increased birth weight, oligohydramnios, and the other ‘packaging disorders’ (metatarsus adductus, torticollis), suggesting that intrauterine crowding may be involved in the pathogenesis. The risk of DDH in a child with metatarsus adductus is approximately 10% and double this with torticollis. The left hip is more frequently affected than the right, perhaps because in the most common fetal position, the left hip is adducted by pressure against the sacrum. Over half of all DDH cases are in firstborn children, related to the increased abdominal and uterine muscle tone of the nulliparous woman restricting fetal movement.

There is a strong association between breech presentation in the last month of pregnancy and DDH: the incidence is 20% with the extended breech position. Although overall, less than 5% of babies are breech, 15% of DDH cases were breech. It is the prolonged effect of the intrauterine environment that is responsible for DDH, thus the method of delivery (vaginal or Caesarean) may have no significant independent effect.

Neonatal positioning also influences the incidence of DDH. Swaddling babies with their hips extended increases the incidence whilst carrying babies with hips abducted is protective.

Capsular laxity is a key finding in DDH and a unifying hypothesis that explains many of the epidemiological characteristics of the condition is a connective tissue abnormality resulting in generalized ligamentous laxity. Studies have demonstrated higher ratios of
type III to type I collagen and increased laxity of the symphysis pubis in neonates with DDH. Joint laxity can be inherited and so could account for the recognized familial tendency of DDH. Laxity also follows the same racial predilections that DDH does. Maternal relaxin hormone crosses the placenta and induces laxity in the fetus. The effect is greater in the female explaining the gender association. However, there is no increased incidence of DDH in some of the conditions characterized by hyperlaxity such as Ehlers–Danlos or Marfan syndrome (Box 13.17.2).

### Natural history

#### Course in newborns

In his classic paper, Barlow reported that 1:60 infants have unilateral or bilateral hip instability. Untreated, more than 60% stabilized during the first week and 88% within the first 2 months. Other studies have also demonstrated that a significant proportion of unstable hips, including Ortolani-positive hips, will become normal over time.

#### Course in adults

The outlook differs between the subluxed hip and the dislocated hip. Counterintuitively, patients with subluxed hips usually experience symptoms of degenerative disease at a younger age than those with untreated dislocations. Degenerative disease is related to increased point-loading and contact stresses between the articular surfaces of the dysplastic hip, and is an inevitable consequence of subluxation. Radiographic parameters of dysplasia, such as the centre-edge angle (CEA) of Wiberg and the acetabular angle of Sharp do not act as predictors of degenerative disease. The rate of degeneration is related to the severity of subluxation, with the most severe cases developing symptoms in the second decade of life and those with minimal subluxation affected during the fifth decade.

The prognosis for a dislocated hip depends on the formation of a false acetabulum: in its absence, the hip maintains a good range of movement and a better chance of a good clinical outcome (52% vs 24%). In addition to osteoarthritis, unilateral dislocations are associated with limb length discrepancy, valgus knee deformity and scoliosis whilst bilateral dislocation causes hyperlordosis of the spine and back pain.

### Clinical presentation

The presentation of DDH depends on the age of the child. It is important to identify the unstable hip before irreversible anatomical changes develop, as these reduce the likelihood of success with non-operative measures.

In early life, there are few clinical signs, all of which may be subtle. Most cases are diagnosed through clinical screening but parental concerns regarding hip movements should always be taken seriously.

The second peak for presentation is significantly later, after the child begins to walk. Contrary to popular belief there is no significant delay in walking age but the family may notice an abnormal gait, classically described as ‘waddling’: a combination of a Trendelenburg and short-leg gait. The child with bilateral hip dislocations will walk with a bilateral Trendelenburg gait and a hyperlordosis secondary to hip flexion contractures. Unfortunately, as gait abnormalities are common in the toddler, unsuspecting physicians often falsely reassure parents.

Neonatal hip examination should follow a systematic approach, adhering to Apley’s basic tenets of ‘look, feel, move’. The clinical signs vary with age and depend on the exact nature of the hip pathology. In unilateral dislocations, asymmetry is an important feature. Asymmetry may be identified as a discrepancy in length (Galeazzi test) and an external rotation deformity but limitation of abduction in flexion is regarded as the most reliable sign of DDH. Asymmetrical thigh creases will be found in the dislocated hip but the sign has low specificity and many children with normal hips demonstrate the same feature.

In the neonate the dislocated head may be palpable in the buttock but in the older child with hip dysplasia the uncovered femoral head can be felt as a lump in the groin.

All of these signs rely on asymmetry that makes it more difficult to identify the child with bilateral hip dislocations. The Klisic test is helpful in these circumstances; a line from the greater trochanter to the ASIS should point to the umbilicus, but in a dislocated hip, in which the trochanter lies more proximally, this line will point halfway between the umbilicus and pubis.

The Ortolani test reduces the dislocated hip. Having identified that the hip has limited abduction in flexion, the examiner holds the...
thigh between the index finger and thumb, and uses the middle finger to lift the greater trochanter ‘up’. When positive, the femoral head is felt to reduce into the acetabulum with a ‘clunk’.

The Barlow manoeuvre attempts to sublux or dislocate an enlocated hip, by applying a gentle posteriorly-directed axial force to the adducted and flexed hip. In a positive test, the examiner will feel the femoral head sliding out of the acetabulum posteriorly.

By the age of 3–6 months, the anatomic changes associated with DDH, particularly the soft tissue contractures mean that these tests will no longer be useful.

### Screening

Von Rosen introduced routine clinical screening in Sweden in 1957 and now most countries have some form of neonatal screening programme for DDH. Universal clinical examination forms the bedrock of all these programmes: good quality screening performed by experienced practitioners reduces the rates of late-presenting DDH but may not abolish it (Box 13.17.3).

#### Box 13.17.3 Questions to ask on clinical examination of the newborn

- Is the hip dislocated?
  - If, so is it reducible?
- If the hip is not dislocated—is it dislocatable?
- If the hip is neither of these—is it clinically normal?
  - If so, does it have the risk factors that mandate an ultrasound scan?

In order to improve detection, ultrasound imaging of the hip has been adopted widely albeit with significant differences in protocols for its use. In North America and most of the United Kingdom, selective ultrasound screening is used to investigate those hips that are clinically suspicious and/or the at-risk groups (e.g. family history, breech). In Austria, Germany, and a single district in England, universal ultrasound screening takes place in the neonatal period.

In the United Kingdom, the SMAC guidelines advocate additional clinical assessment of the hips at 6–8 weeks and 8 months of age.

Recently, some have questioned the validity of DDH screening. Proponents of screening argue that earlier detection makes a clear difference to management allowing the early use of effective non-operative treatment methods. The strongest argument against screening is the lack of knowledge regarding the natural history of DDH and the over-treatment that screening may encourage. A proportion of unstable hips will stabilize spontaneously requiring no treatment but as they are unidentifiable, it is likely that some hips are treated unnecessarily.

Ultrasound imaging complicates things further as it detects anatomically abnormal hips that may not be unstable. Universal screening as practised in Coventry (United Kingdom) has eliminated late-presenting DDH and proven to be cost-effective. Other reports have highlighted an increase in treatment rates with universal ultrasound. Prospective longitudinal studies that chart the outcomes of minor sonographic abnormalities may allow us to refine treatment criteria. Selective ultrasound screening intuitively sounds an attractive compromise but the evidence suggests that it does not reduce the incidence of late-presenting DDH more than competent clinical screening alone.

Another controversy is whether some late-presenting cases may in fact be a separate entity: they could develop after birth and so would be undetected by neonatal screening.

### Ultrasound examination

Graf introduced neonatal hip ultrasound over 30 years ago to assess hip joint morphology by evaluating two specific anatomic features (Figure 13.17.2):

- **Alpha angle**: measures inclination of the superior aspect of the bony acetabulum
- **Beta angle**: evaluates the cartilaginous component of the acetabulum
With increasing dysplasia and subluxation, the alpha angle decreases and the beta angle increases. Graf has created a classification system based on these parameters (Table 13.17.1). Put simply, class I hips are normal and class III/IV hips require treatment. Class II is a grey area for which the optimal management is unclear.

The methods of both Terjesen and Morin measure femoral head coverage by the bony acetabular roof but in different anatomical planes. Morin failed to find abnormalities in any hips that had more than 58% femoral head coverage. The normal values for Terjesen’s method are 55% and 57% in girls and boys, respectively.

Harcke described the use of real-time dynamic screening that allows direct visualization of femoral head instability and displacement from the acetabulum during the Barlow manoeuvre: minor subluxation can be detected. This dynamic assessment of hip stability is often considered to be of greater value in the management decision-making process than static images of morphology.

**Imaging**

Radiographs are of limited use as they demonstrate only the ossified portion of the pelvis and proximal femur; an imperfect indicator of the mainly cartilaginous hip joint. A femoral head uncovered on a radiograph may be well covered by the cartilaginous acetabular anlage. However, even if this is the case, failure of the cartilage to ossify results in dysplasia and possibly subluxation.

There are three primary lines that are of use in evaluating the hip on an anteroposterior radiograph (Figure 13.17.3A). The medial beak of the femoral metaphysis, or once present, the osific nucleus, should lie in the inferomedial quadrant of the four quadrants produced by Perkin’s and Hilgenreiner’s lines. The femur of a dislocated hip joint will lie lateral to Perkin’s line.
the femoral neck and continuing along the inferior border of the superior pubic ramus. This should produce a smooth curved line on any view of the hip, and if disrupted, a subluxation or dislocation should be suspected (see also Figure 13.17.1). The femoral head should lie in the inner medial quadrant defined by the H and P lines. The left hip is in joint, the right hip is dislocated. B) The AI is the angle formed between Hilgenreiner’s line and a line following the acetabular roof. The AI is significantly increased on the right side where the hip is dislocated. In the older child once the tri-radiate cartilages have fused, Sharp’s angle is measured using a horizontal between the inferior edges of the teardrops instead of Hilgenreiner’s line. C) The CEA of Wiberg is the angle subtended between a line through the centre of the femoral head, parallel to Perkin’s line, and a line from the centre of the femoral head to the lateral edge of the acetabulum. The right hip has a normal angle of 23 degrees. The left hip has a dysplastic acetabulum.

The acetabular index (AI) estimates acetabular dysplasia (Figure 13.17.3B). The normal limit for the AI is 30 degrees at birth: decreasing to less than 20 degrees by the age of 2 years. The acetabular angle of Sharp is a useful alternative once the triradiate cartilages have closed.

Normally, the U-shaped acetabular teardrop appears between 6–24 months of age. The teardrop is absent or its appearance delayed with a dislocated hip. A V-shaped teardrop is associated with dysplasia and a poor outcome. Following joint reduction, the acetabulum remodels and the teardrop narrows. The gap between the acetabular floor and femoral head should not exceed 5mm on a standardized radiograph. DDH can be classified according to the radiological appearance (Table 13.17.2).

The femoral head ossific nucleus should appear between 3–6 months of age, characteristically its appearance is delayed in the dislocated hip. The CEA becomes a useful measure of acetabular coverage of the femoral head after 5 years (Figure 13.17.3C). In childhood this angle should measure at least 15 degrees, reaching 25 degrees by maturity.

**Treatment**

In all patients, the primary aim of treatment is to obtain and maintain reduction of the hip providing an optimal environment for future development. The method by which this can be achieved depends on the chronicity of the dislocation, and thus on the age of the patient. A simple algorithm is shown in Figure 13.17.4.

**Non-operative**

A clinically unstable hip (either Barlow or Ortolani-positive) that persists at the age of 2–3 weeks should be treated with full-time splintage in flexion and abduction, maintaining it in a reduced position. As discussed previously, the management of clinically normal hips with sonographic evidence of dysplasia remains unclear as some spontaneous improvement in acetabular morphology is likely. The more severely dysplastic hips (Graf III and IV) are less likely to demonstrate spontaneous improvement particularly if associated with instability on ultrasound or clinical assessment: our personal protocol is to treat these with splintage from 2–3 weeks of age. As the Graf II hip is most likely to normalize spontaneously, our management is initially expectant. If a repeat ultrasound before the age of 6 weeks shows persistent dysplasia, treatment should be considered particularly in the presence of instability.

The Pavlik harness is the most commonly used DDH splint. It prevents dislocation by limiting hip extension and adduction whilst allowing some movement to encourage joint development (Figure 13.17.5). Other splints such as the Van Rosen splint also have high success rates with few complications.
The Pavlik harness must be applied properly both to achieve reduction and prevent complications. The chest strap should be at nipple level, the shoulder straps in the anterior axillary line and the posterior ‘abduction’ strap at the level of the scapulae. All splints must be applied appropriately. In the Pavlik harness, the hips should be flexed no more than 100 degrees, and the posterior strap adjusted to allow comfortable abduction within the safe zone (the arc of abduction/adduction that is between redislocation and unforced abduction). If the hip cannot be placed in this position, treatment with the harness is less likely to be successful. However, even hips that are irreducible at the start of treatment can be successfully managed with a harness. Our protocol is to review the infant at fortnightly intervals. Hip development is assessed both clinically and ultrasonographically. It is also important to review the harness to ensure that it remains appropriately fitted. Strap adjustments may be necessary to accommodate growth of the child, as otherwise the hips will gradually become over-flexed.

If the dislocated hip remains irreducible after 2 weeks of treatment, the harness is unlikely to be successful and should be discontinued. Persisting with treatment risks damage to both the femoral head and the posterior acetabular wall. The minimum treatment advised is 6 weeks from the time the hip reduced. If at this time, the hip is found to be both stable and anatomically normal on ultrasound, the harness can be discontinued. The child should be reviewed at 4–6 months of age with a pelvic radiograph and again at 1 year of age with further follow-up as required.

The success rate of Pavlik harness treatment has been reported as 95% for the Ortolani-positive hip and 80% for dislocated hips that are not initially reducible. The failure rate increases in children older than 7 weeks of age at the start of treatment reaching 50% after the age of 6 months: primarily because of the difficulty in keeping the larger child compliant with harness wear. Bilateral hip dislocations are associated with higher failure rates (Box 13.17.4).

**Box 13.17.4 Pavlik harness**

Less suitable for patients with:

- Significant muscle imbalance (myelodysplasia)
- Joint stiffness (arthrogryposis)
- Excessive ligamentous laxity (Ehlers-Danlos syndrome).

A number of different splint complications have been reported, most associated with improper application or use. The most serious complication is avascular necrosis (AVN) of the femoral head due to excessive pressure from incomplete reduction or excessive abduction, with an incidence of 2.4% in one series. Femoral nerve palsy also occurs and quadriceps function should be checked during treatment. Prolonged excessive hip flexion may lead to inferior dislocation of the femoral head. Other problems include skin rashes, foot deformities, brachial plexus palsy, and knee subluxation.

**Closed reduction**

Closed reduction of the hip is indicated in those who either fail conservative treatment or for whom it would be inappropriate due to age or associated disorders.

**Arthrography**

A closed reduction should always be performed under general anaesthesia and include a hip arthrogram. The arthrogram provides a dynamic examination of hip morphology, identifying obstacles to reduction and defining the position of ‘best fit’. Only a small
amount of contrast medium is required otherwise anatomical detail is obscured.

The arthrogram demonstrates the extent of the cartilaginous roof and the labrum. When the head is appropriately covered by the labrum, a ‘rose-thorn’ is seen, representing a recess lateral to the labrum. This thorn will not be seen with a subluxed femoral head because the labrum is deformed (Figure 13.17.6).

Fig. 13.17.6
A) Arthrogram of the left hip showing a dislocated femoral head. The femoral head outline is overlapping the acetabulum and the infolded labrum can be seen. B) Bilateral hip arthrograms. The patient’s right hip is essentially normal. The rose thorn of the normal labrum has been accentuated by added lines. On the left side, the femoral head has been reduced underneath the labrum which is still deformed (as outlined by the heavy line). The labral shape improves with time once the head is reduced.

If the head is concentric within the acetabulum, then a narrow rim of contrast will outline the femoral head in all positions. With femoral head subluxation, dye pools medially. If there is associated acetabular insufficiency, this pool will move superiorly as the femoral head reduces with abduction and flexion.

The hip is reduced by the Ortolani test and then screened clinically and radiographically to determine the range over which the hip remains reduced. The ‘safe zone’ as described by Ramsay is the arc of abduction/adduction that is between redislocation and unforced abduction: a relatively wide zone implies a stable reduction, whereas a narrow zone in which wide abduction is required, is considered unstable.

If an adduction contracture is limiting abduction, an adductor tenotomy should be performed concomitantly with the closed reduction. This increases the range of hip movement and the safe zone, thereby helping to obtain and maintain joint reduction. The adductor tenotomy also reduces pressure on the reduced femoral head. An iliopsoas tenotomy can be performed through the same incision for the same reasons.

If despite soft tissue releases, the closed reduction is difficult to maintain, it should not be forced, for fear of avascular necrosis.

Our policy is to use a short leg (above-knee) spica cast after closed reduction, as rotation is not usually required to hold the reduction. The hip spica plaster should be applied with the hips flexed to at least 90 degrees and in safe abduction. The cast is completely responsible for holding the reduction so it must be well moulded, especially dorsal to the greater trochanters.

Plain radiographs of the pelvis can be used to confirm satisfactory reduction but limited multiplanar CT scans and MRI are perhaps more helpful.

Treatment times vary: our protocol involves a total treatment time of 4.5 months with 3 months in a cast and 6 weeks full-time in an abduction brace. If indicated, hip stability and morphology can be checked with a repeat arthrogram to ensure that satisfactory progress is occurring.

Open reduction

Open reduction is indicated in cases in which closed reduction has failed or not been possible. It is often the treatment of choice for teratologic dislocations. Irrespective of the approach, the surgeon must address all soft tissue obstacles to reduction (Box 13.17.5).

Box 13.17.5 Soft tissue blocks to reduction

♦ Adductor muscles
♦ Iliopsoas tendon
♦ Capsular constriction
Deformed/infolded labrum
Hypertrophied ligamentum teres
Pulvinar
Thickened transverse acetabular ligament.

Medial approach

The medial approach is considered most appropriate for the child under or around walking age. The approach can be either in the plane between adductor brevis and adductor magnus (after Ferguson) or in the interval between iliopsoas and the pectineus (after Ludloff, and modified by Weinstein and Ponseti). The medial approaches are associated with higher rates of AVN than the anterior approach partly because of injury to the medial circumflex artery. Advantages include preservation of the iliac apophysis and reduced blood loss. Bilateral dislocations can be addressed at the same operation. The medial approach does not allow any other concomitant surgical procedures such as capsulorrhaphy to be performed although the ligamentum teres can be shortened and anchored to the inferior acetabular margin to aid hip stability.

Anterior approach

The anterior approach uses the interval between tensor fascia lata and sartorius. Traditionally performed through the longitudinal Smith–Petersen approach, most surgeons now use a bikini-line incision below the inguinal ligament. The capsule is opened with a T-shaped incision: the long arm passing along the femoral neck to allow a capsular reefing at the end of the procedure, with or without excision of redundant capsule superiorly. Bilateral open reductions should be staged.

The medial approach allows the adductor and iliopsoas tendons to be divided through the same incision whilst with the anterior approach, an intramuscular lengthening of the psoas tendon is performed at the pelvic brim. A separate medial incision is required for an adductor tenotomy.

Following an anterior approach, the ligamentum teres is divided at its femoral head attachment. The ligament is followed to its inferior attachment to identify the true acetabulum and then excised. The transverse acetabular ligament is divided. The pulvinar, if excessive, can be removed. The limbus must be preserved as excising it endangers the lateral acetabular epiphysis with adverse affects on later acetabular development.

In longstanding dislocation, the superior capsule must be freed from its adhesions to the iliac wing above the true acetabulum and the inferior capsule released fully to allow the femoral head to reduce. Every effort is made to preserve the posterior capsule but in some instances, such as revision surgery, this is not possible. In these cases, the capsule must be released carefully at the acetabular margin to minimize vascular injury.

The acetabular floor is often thickened in DDH, and may limit deep seating of the otherwise reduced femoral head. Maintaining the head within the acetabulum will encourage further acetabular development and ‘thinning’ of its floor.

With the anterior approach and a capsulorrhaphy, our protocol is to apply a ‘one-and-a-half’ spica cast for 8–10 weeks. As a capsulorrhaphy cannot be performed with the medial approach, the cast is usually maintained for 12 weeks.

The role of osteotomies

As detailed previously, subluxation that has progressed to an established dislocation results in a shallow and anteverted acetabulum, often associated with an anteverted and valgus femoral neck. Following hip reduction, these abnormalities can remodel but the potential for this depends on the age of the patient. Several schools of thought exist regarding the indications for additional osteotomies (Box 13.17.6).

Box 13.17.6 Questions regarding the role of osteotomy in the initial management of DDH

- Are they needed?
  - Or will the hip remodel with time?
- Above the joint or below?
  - Femoral – varus ± derotation ± shortening
  - Pelvic – redirectional or reshaping
- At the time of open reduction or as a staged procedure?

Some surgeons believe that children older than 18 months have poor potential for acetabular development and must undergo a pelvic osteotomy with their open reduction. Others believe that in children younger than 3 years, the acetabulum has significant development potential for 5 years following reduction. In most cases, the acetabulum is not actually deficient but its cartilage has
failed to ossify. Thus, if the reduction is stable, normal acetabular development can be expected and observed radiographically. With time the acetabular cartilage ossifies thereby correcting the dysplasia. The majority of this occurs during the first 12–18 months.

Radiographic indicators of adequate development include a decreasing AI and an improvement in teardrop morphology. The development of the superolateral acetabular margin, (the ‘sourcil’ or eyebrow) is also regarded as a reliable indicator of acetabular development. If significant acetabular dysplasia persists beyond the age of 5 years, a pelvic osteotomy is required.

Another area of controversy is whether the osteotomy should be performed on the femur or the pelvis. As the primary abnormality lies within the acetabulum, some surgeons will always direct their attention to the pelvis, in the knowledge that femoral neck anteversion will often correct spontaneously. Others will perform a varus derotation osteotomy on the dysplastic proximal femur to redirect the femoral head towards the centre of the acetabulum and stimulate normal acetabular development. In this situation, the femoral osteotomy should be performed before the age of 4 years.

Pelvic osteotomies

In broad terms, there are three groups of pelvic osteotomy, differentiated by indication and by the manner in which they improve femoral head coverage (Table 13.17.3).

Redirectional procedures

The prerequisite for considering a redirectional acetabular osteotomy is that the subluxed hip can be placed in a position where the joint is congruent throughout a useful range of motion. This "best-fit" position must then be recreated by the osteotomy. In such cases, the acetabulum is essentially an appropriate size and shape but it is facing the wrong way. Acetabular orientation is changed by the osteotomy, which improves anterosuperior cover in the weight bearing position.

The Salter innominate osteotomy is the classic example of a redirectional pelvic osteotomy. A transverse osteotomy is performed through the ilium, between the anterior inferior iliac spine and the greater sciatic notch. The distal fragment is rotated anterolaterally: the osteotomy must remain closed posteriorly and the resultant anterior gap is filled with a triangular bone graft from the iliac crest. Threaded wires are used to stabilize the osteotomy. It provides anterior cover at the expense of posterior cover and if a derotation femoral osteotomy is performed concurrently there is a risk that the femoral head will sublux posteriorly. Redirection is achieved by rotation of the acetabulum around the symphysis pubis. With skeletal maturity such rotation is impossible and thus osteotomies of the pubic ramus and the ischium are required (Sutherland double and Steel triple osteotomies). Perhaps the best correction is achieved with the technically more complex periacetabular osteotomy.

Reshaping procedures

This group of acetabuloplasties, including those described by Pemberton and Dega, reshape the acetabulum. Their ‘volume-reducing’ effect makes them most useful when the dysplastic acetabulum appears too capacious for the femoral head and hence these hips do not show a congruent ‘best-fit’ position on arthrogram. An open triradiate cartilage is a prerequisite for this procedure as it acts as the fulcrum upon which to hinge the acetabular correction. Injury to the triradiate cartilage is a serious but uncommon complication that could result in premature physeal fusion.

Pemberton’s pericapsular osteotomy is an incomplete curvilinear iliac osteotomy that follows the contour of the acetabular roof inferomedially to the triradiate cartilage. The acetabular roof is then levered downwards to improve anterolateral cover, and a graft placed into the gap that is created. The Dega osteotomy is similar in principle: it is perhaps used most frequently for hip dysplasia secondary to neuromuscular disorders where the primary acetabular deficiency is more commonly posterior.

Salvage procedures

These procedures augment acetabular cover and hence support of the femoral head by placing bone over the hip capsule and inducing fibrocartilaginous metaplasia within the capsule. These procedures are used in circumstances in which there is irreducible subluxation or if the other osteotomies cannot be performed due to previous surgical interventions.

The Shelf procedures improve femoral head coverage in cases with mild to moderate acetabular insufficiency. Various techniques have been reported, but common features are the use of a slab or strips of cortical graft taken from the ilium and placed on top of the hip capsule (the ‘shelf’), which is then buttressed from above by a bone graft that is supported proximally against the ilium. Over time and in response to loading from the femoral head, the shelf hypertrophies and remodels.

If acetabular insufficiency is associated with pronounced lateralization of the femoral head, the joint should be medialized. The Chiari osteotomy is performed through the ilium, allowing medial displacement of the acetabular fragment with its attached hip
The interpositional arthroplasty described by Colonna, is suitable in cases of severe femoroacetabular incongruity but when the femoral head is still spherical. The capsule is divided circumferentially at its acetabular insertion, and oversewn over the femoral head. The acetabulum is then enlarged using serial reamers until it can provide a stable articulation for the capsule-enveloped femoral head.

Treatment in later childhood

Occasionally, children present later in life with established DDH. The surgeon must note that the untreated child is unlikely to develop pain before adolescence, whilst the unsuccessfully treated child will do. The remodelling potential of those over 3 years is limited, so as well as a femoral shortening ostetomy, a concomitant corrective acetabular and femoral procedure must be considered. Unilateral dislocations are more likely to affect gait and function and so treatment is recommended up to the age of 10 years. Surgical reduction is not recommended for bilateral dislocations after the age of 6-8 years as the complication rate is higher and the surgical outcomes inferior to the natural history of the condition.

Late complications

The two most common late complications are residual dysplasia and AVN of the proximal femur. Thus regular follow-up until skeletal maturity is advised for all children who undergo operative treatment for DDH.

Residual dysplasia

Deficiency of the anterior acetabular wall is one of the primary anatomic abnormalities in early childhood but by adolescence the deficiency is often more global. Late-onset femoral dysplasia is usually secondary to AVN. Treatment of the dysplastic young adult hip is a subspecialty in its own right.

In cases of unilateral DDH, the opposite hip may show subtle signs of acetabular dysplasia that are exacerbated by a leg length discrepancy. Follow-up should include assessment of both hips.

Avascular necrosis of the proximal femur

AVN is potentially disabling and difficult to manage successfully. It is not a feature of the natural history of DDH and is therefore regarded as a consequence of treatment. Some controversy exists over the term 'AVN': there is little histological evidence that this is the underlying pathology and 'proximal femoral growth disturbance' may be a better term.

Several factors have been implicated in the development of AVN, including forced reduction, and the use of extreme positions of abduction and/or internal rotation. The femoral head has a rich blood supply, predominantly endarteries arising from the medial and lateral circumflex branches of the profunda femoris. Extremes in hip positioning can result in compression of the medial femoral circumflex artery. In order to reduce the incidence of AVN, certain management strategies have been adopted but their role remains controversial.

The protective role of the ossific nucleus

Until the ossific nucleus appears, the femoral head has a cartilaginous structure that can be deformed when it is forcibly reduced or held in an extreme position. This, together with its poor vascular anastomoses, makes the cartilaginous femoral head particularly vulnerable to infarction. A recent meta-analysis found that the presence of the ossific nucleus reduced the probability of AVN by 60% after closed reduction but its presence had no significant protective effect following open reduction. The results also suggested that the ossific nucleus protects against the higher grades of AVN. The possible protective effects of the ossific nucleus have to be weighed against the pathological changes that develop the longer the hip is left dislocated and that may reduce the likelihood of a successful closed reduction.

Traction versus femoral shortening

In the older child with a longstanding high dislocation and soft tissue contractures, reduction of the hip can be considerably more difficult with concerns about the effects of excessive forces acting on the newly-reduced femoral head. Several studies have demonstrated that preoperative traction does not reduce the rate of avascular necrosis. Femoral shortening prevents excessive compression of the proximal epiphysis and has been shown to reduce the rates of AVN more significantly than pre-operative traction.

A diagnosis of AVN is made when the femoral head is not seen to ossify or grow within a year of reduction. The variable extent of the subsequent growth disturbance forms the basis of the Bucholz–Ogden classification system (Table 13.17.4). Type II is most common and may not be manifest until after the age of 12 years, making long-term follow-up of all patients essential. In type III, the entire metaphysis is affected, resulting in a very short femoral neck. The greater trochanter remains unaffected in AVN and develops normally leading to relative overgrowth compared to the stunted femoral head and neck in types III–IV (Figure 13.17.7).

AP pelvic radiograph demonstrating severe AVN of the left femoral head with a short femoral neck. In contrast, trochanteric growth is unaffected and the greater trochanter is 'high-riding'.

Surgical treatment for AVN is aimed at correcting the resultant anatomical abnormalities including any leg length discrepancy. Epiphysiodesis of the opposite distal femoral physis may be considered to equalize leg lengths and trochanteric epiphysiodesis could prevent trochanteric overgrowth. In late cases, trochanteric advancement can restore normal abductor function and improve the Trendelenburg gait. Valgus and varus deformities of the femoral neck can be addressed by corrective osteotomies but femoral neck length must also be considered when planning these procedures.

Outcomes

Few papers look at the long-term outcomes and most have significant methodological differences, making objective comparisons impossible. Most studies use the Severin classification for radiographic outcome of treated DDH (Table 13.17.5) despite its low levels of inter- and intraobserver reliability and there is little uniformity in the literature with respect to the use of functional measures. Excellent functional outcomes in the short to medium term are reported with poorer radiological outcomes although the latter are more accurate predictors of long-term outcome.

A recent series looking at the natural history after treatment with a Pavlik harness found a late dysplasia rate of 3.5% and AVN rate of 1%. Importantly, they found no significant differences in development between normal hips and those treated successfully with the harness. Another study investigating long-term outcomes after similar treatment found good or excellent radiological outcomes in 90%, but an AVN rate of 12.3%. Contrary to contemporary practice, the mean time spent in the harness was 6 months.

The published results for closed reduction have varied with a recent long-term study of closed reduction finding excellent or good radiological outcomes in only 46% of cases. There was some evidence of AVN in 60%, degenerative joint disease in 43%, and residual subluxation in 36%. Contemporary belief is that current results are better than this.

Medium term outcome studies of open reduction via the medial approaches have reported AVN rates that vary from 16–43% with residual dysplasia requiring surgical intervention in almost a third. A skeletal maturity review of 95 hips treated by anterior open reduction and concomitant pelvic or femoral osteotomy as indicated by the ‘test of stability’ showed 86% of hips were Severin VII. AVN was associated with a poorer outcome and treatment under the age of 2 with a better result.

Most recently, the Toronto group have presented the outcomes after open reduction, capsulorrhaphy and inominate osteotomy at a mean follow-up of 45 years: 35% had good function, 13.5% had definite osteoarthritis, and 46% of patients had undergone arthroplasty.

In summary, various treatment methods result in good functional outcomes for the first two decades of life. The radiological outcomes are not of a similar high standard and consequently a substantial proportion develops premature osteoarthritis. There is some evidence that treatment at an earlier age and by closed methods leads to a better outcome.

Edgar Somerville wrote that ‘in the treatment of congenital dislocation of the hip it is our successors who will judge our results rather than ourselves’. Good quality, objective, long-term studies are required to evaluate those results, in order to improve the outcomes for tomorrow’s patient.

Further reading

Summary points

- Avascular necrosis of the femoral head initiated by unknown factors is followed by gradual restoration of blood supply and regeneration
- Current treatment methods aim to prevent development of an aspherical and incongruent femoral head and acetabulum
- Treatment should be offered to the child with a poor prognosis so that the natural history of the condition can be improved: identification of such cases is difficult
- Early and late management strategies differ significantly.

Introduction

The radiological changes of Legg–Calve–Perthes disease were identified soon after the development of x-ray machines for clinical use. In 1909, Waldenström was the first to publish a description of the radiological changes seen in the condition but his name is not credited to the disease because he considered the appearances to be a form of tuberculosis of the hip.

In 1910, Legg, Calve, and Perthes secured their place in history when each published observations distinguishing the condition from tuberculosis, reflecting a more benign clinical course and dissimilar radiological progression. Perthes original description (1913) is still valid today:

*a self-limiting, non-inflammatory condition, affecting the capital femoral epiphysis with stages of degeneration and regeneration, leading to a restoration of the bone nucleus*

Currently it is accepted that the series of changes described by Perthes are initiated by events that lead to avascular necrosis (AVN) of the osseous nucleus followed by gradual restoration of the blood supply and subsequent regeneration. The underlying aetiology of these events remains elusive and so the condition cannot be prevented. Management is focused on trying to limit progressive femoral head deformity after the AVN has occurred.

Epidemiology

Perthes disease occurs worldwide. The incidence is relatively low in black populations (0.45/100 000), intermediate in Asians (3.8/100 000), and high in Caucasians (15.4/100 000). Within populations, the incidence varies from region to region and reports from the United Kingdom and South India suggest an association with deprivation. Most clinicians will be aware of patients with a family history of the disease but the evidence for a genetic predisposition is unclear. Some studies show little support for a genetic aetiology whilst others suggest a multifactorial inheritance pattern.

The condition is four to five times more common in boys than girls. Eighty per cent of children present between 4–9 years of age. Patients may share some typical characteristics and the notion of the ‘susceptible child’ has emerged (Box 13.18.1).

Box 13.18.1 The susceptible child

- Male
- Aged 4–9 years
- Delayed bone age
- Family of low socioeconomic status
- Disproportionate short stature: distal limb segments predominantly.

Pathology

The blood supply of the child’s femoral epiphysis is vulnerable. No blood reaches the epiphysis from the metaphysis because the physeal plate presents a complete barrier and the blood supply from the ligamentum teres is negligible. The primary supply to the femoral epiphysis is derived from the medial femoral circumflex artery which pierces the capsule of the hip joint in the posterior trochanteric fossa and becomes the lateral ascending cervical artery (Figure 13.18.1).
Effectively, a single trunk vessel supplies the epiphysis which makes it vulnerable to ischaemic necrosis. The anteromedial part of the femoral epiphysis is furthest from the main trunk and this may explain why it is the first area to show evidence of AVN in Perthes disease and why the posterolateral portion, closer to the trunk vessel, is sometimes preserved.

The nature and cause of the disturbance in the blood supply in Perthes disease is uncertain. A single infarct of the femoral epiphysis does not necessarily lead to the radiological changes seen in the disease. Most reports to date support the notion that recurrent infarcts are necessary to cause the typical radiological features. Once AVN is established, progressive changes may occur. The current working hypothesis suggests that a fracture develops in the weakened avascular bone which is unable to unite until it is revascularized. As revascularization ensues, the repair process results in the characteristic radiological changes, as dead bone trabeculae are slowly removed and replaced. This process can take years to complete and during this time the cartilaginous femoral head, devoid of its internal supporting structure, can become deformed.

Why an infarct should occur is still unknown. Reports have implicated disturbances on both the arterial and the venous side of the femoral head circulation. Trauma has been postulated as a potential explanation as has transient synovitis: both may tamponade the circulation but although symptoms of synovitis are often the first presentation of the disease, most studies do not support a causal relationship between transient synovitis and Perthes disease. More recent reports implicated various abnormalities of the plasma proteins involved in the coagulation cascade. Some are associated with a predisposition to clot formation (thrombophilia) and others are associated with a limited potential to ‘lyse’ clots once formed (hypofibrinolysis). To date no single explanation for the aetiology has been identified and it may be that Perthes disease is simply the final common pathway of a variety of circumstances, environmental and/or genetic, that leads to AVN of the femoral epiphysis.

Radiological stages and pathological correlation

Perthes disease occurs in healthy children and therefore there are few accounts where the sequential radiological changes have been correlated with the histological morphology (Figure 13.18.2).
Early stage
In the early stages following infarction, there is a growth disturbance. The bony epiphysis, devoid of its blood supply, stops growing but the cartilage does not and this relative overgrowth, particularly on the medial and lateral aspects of the femoral head, results in a cartilaginous coxa magna. Thus, in the early stages of Perthes disease, radiographs sometimes reveal a smaller bony epiphysis on the affected side although the apparent joint space is wider (Figure 13.18.2A).

Sclerotic stage
It is postulated that recurrent infarction within the epiphysis eventually weakens the bony epiphysis and trabecular fractures and collapse occur. Radiographically, this leads to loss of bony epiphyseal height and increased density (Figure 13.18.2B). Catterall has shown that the density noted on fine-detail radiography during the stage of sclerosis is, in part, due to mechanical compression of the fractured necrotic trabeculae but, in the main, is due to calcification of the necrotic marrow within the epiphysis. During this stage, the growth plate becomes abnormal with distortion of the cell columns and an increase in the quantity of calcified cartilage in the primary spongiosa.

Fragmentation stage
Once infarction has occurred, a process of repair becomes established to revascularize the avascular area. A process of creeping substitution slowly removes the necrotic bone and replaces it with fibrocartilage (Figure 13.18.2C). This repair process produces the radiological appearance of fragmentation. Islands of new bone formation in the thickened anterior and lateral articular cartilage gradually enlarge and coalesce. These islands appear radiologically as areas of calcification lateral to the epiphysis and reveal the extent to which the cartilaginous femoral epiphysis has been extruded outside the confines of the acetabulum. In the growth plate, areas of unossified cartilage extend down into the metaphyseal region producing the radiological appearance of a metaphyseal cyst. If these are large, the normal architecture of the growth plate is lost. It has been postulated that such an area might act as a tether to further growth in the anterolateral part of the neck, leading to tilting of the femoral head on the long axis of the neck. In the long term, this process might explain the radiological transcervical line described as the sagging rope sign. This radiological appearance is the result of superimposition of the anterolateral part of the femoral head overhanging the femoral neck, like the head of a mushroom overhanging its stalk (see Figure 13.18.14).

Healing and late stage
In the healing phase of the disease the necrotic trabeculae have been removed and replaced by fibrocartilage which is progressively reossified. The last portion to reform is the anterosuperior portion of the epiphysis and this is seen as a residual central lucency on the anteroposterior (AP) radiograph (Figure 13.18.2D). As the structural function of the epiphysis to maintain the femoral head shape is lost during the stages of sclerosis and fragmentation, the cartilaginous femoral head becomes flatter and broader under load, and when the healing process is complete the femoral head is ovoid rather than spherical. Clearly the extent to which the shape changes, depends on how much or how little of the epiphyseal support is affected by the disease.

Clinical presentation, differential diagnosis, and investigation
Early Perthes disease typically presents with groin, thigh, or referred knee pain and an antalgic limp. This is the clinical picture of an irritable hip. On examination the most sensitive sign of hip irritability is discomfort with internal rotation, but as irritability increases abduction becomes limited and eventually an external rotation, adduction, flexion posture develops. When a child presents with an irritable hip, ultrasound identification of a joint effusion is the key investigation to confirm the clinical suspicion that the hip joint is the source of the problem. Perthes disease is but one cause of hip irritability and other differential diagnoses must be considered depending on the age of the child at presentation (Box 13.18.2). The most common explanation for an irritable hip is
transient synovitis. Septic arthritis is an important differential diagnosis in any child and must always be considered. In older children a slipped upper femoral epiphysis is possible.

**Box 13.18.2 Irritable hip: differential diagnosis**

- Transient synovitis (commonest)
- Septic arthritis
- Perthes disease
- Slipped capital femoral epiphysis (>10 years)
- Juvenile idiopathic arthritis.

At initial presentation there may be no radiological evidence of Perthes disease and the condition is difficult to differentiate from transient synovitis. If a patient’s symptoms do not resolve within a week or two of presentation then a diagnosis of transient synovitis should be questioned.

A radionuclide bone scan is a useful investigation because it will show a ‘cold’ area of decreased uptake in Perthes disease which distinguishes the condition from most other differential diagnoses (Figure 13.18.3).

![Click to view larger](Fig. 13.18.3)

**Fig. 13.18.3**
Radionuclide bone scan: Scan shows a ‘cold’ area of decreased uptake in the ischaemic area of epiphyseal bone in Perthes disease.

Magnetic resonance imaging (MRI) scanning may help identify altered signal from the epiphyseal marrow in Perthes disease but, in the author’s opinion, offers little advantage over bone scanning (Figure 13.18.4).

![Click to view larger](Fig. 13.18.4)

**Fig. 13.18.4**
MRI scan: scan shows altered signal from the epiphyseal marrow in a case of Perthes disease.

Eventually radiological changes will be apparent. While Perthes disease is the most common explanation for the radiological appearance of epiphyseal AVN of the hip in children, other known causes of AVN will give a similar appearance. Conditions including systemic corticosteroid therapy, sickle cell disease, other haemoglobinopathies, and storage diseases (Gaucher’s) should be considered. Bilateral Perthes disease is unusual but when present it is asymmetrical with each affected hip at a different stage. Bilateral symmetrical disease should raise suspicion of bony dysplasias such as multiple epiphyseal dysplasia.

**Classification and prognosis**
Classification

The Stulberg classification

Premature degeneration of the hip joint due to joint deformity is the potential consequence of Perthes disease. Eighty-six per cent of patients will develop osteoarthritis by the age of 65, but in the majority symptoms will not become a problem until the fifth or sixth decade (Figure 13.18.5).

Fig. 13.18.5

Stulberg et al. (1981) classified hips according to the final shape of the femoral head and acetabulum. Hips were considered spherical if the femoral head could be fitted onto the circumference of the same circle on anteroposterior and lateral radiographs. There are three functional outcomes. 1) A head that is spherical with a congruent acetabulum. There may be some coxa magna or femoral neck shortening but spherical and congruent hips show no propensity to premature degeneration. 2) A head that is aspherical, often ovoid in shape, with a congruent acetabulum that has grown to match the femoral head. Again there may be some coxa magna or neck shortening or acetabular dysplasia. Such hips do degenerate prematurely but usually after middle adult life. 3) A head that is aspherical and flattened but the acetabulum remains round and thus the joint is incongruent. Such hips degenerate prematurely often before middle adult life.

It is important to understand why some hips have a better long-term prognosis than others and Stulberg’s work gives some insight into the explanation (Box 13.18.3). If the femoral head remains spherical and the acetabulum matches, the hip is termed spherical and congruent. Although this outcome is relatively uncommon such hips show no propensity to long-term degeneration. If the femoral head becomes ovoid and the acetabulum grows to match then the hip is aspherical and congruent. Such hips develop mild to moderate arthritis in late adult life. Finally, if the femoral head becomes ovoid or flattened and the acetabulum does not grow to match then the hip is aspherical and incongruent. Such hips develop severe arthritis before the age of 50. Current treatment methods focus on preventing the development of an aspherical and incongruent hip.

Box 13.18.3 The Stulberg concept—does the femoral head match the acetabulum?

♦ The spherical and congruent hip
♦ The aspherical but congruent hip
♦ The aspherical and incongruent hip.

The Catterall classification

An early report on Perthes disease described a favourable outcome when only the anterior half of the epiphysis was involved and Catterall later published a milestone paper introducing a classification of Perthes disease which separated patient groups based on how much of the epiphysis was involved by the condition (Figure 13.18.6). The findings of this study reflect the findings of the majority of published works both past and present. Children with limited involvement of the epiphysis (group I) were shown to have a favourable prognosis irrespective of treatment. Children with onset below the age of 4 years also had a favourable prognosis irrespective of treatment and girls had a worse prognosis than boys. The recognition that a subset of patients might have a favourable outcome without treatment spared many children from the blanket application of the treatment regimens such as prolonged recumbency, weight relief, and bracing that were popular at the time.
Catterall further described five head at risk signs that might give an early indication of a potentially unfavourable outcome (Figure 13.18.7).

**Fig. 13.18.7**

‘Head at risk’ signs. Catterall introduced the concept of a ‘head at risk’. Clinical signs constituted progressive loss of movement and radiological signs included fine calcification lateral to the epiphysis, and widening of the inferomedial joint space suggesting early flattening of the cartilaginous head. Other radiological features included extensive metaphyseal involvement, Gage’s sign (a lucent area of the lateral epiphysis and the adjacent metaphysis) and a relatively horizontal growth plate reflecting a clinical flexion/adduction posture of the hip.

The Herring lateral pillar classification

The lateral pillar classification recognizes the importance of the integrity of the lateral part of the femoral epiphysis (Figure 13.18.8). If the lateral portion is intact it functions like a strut, column, or pillar, bearing the load transmitted to the femoral head from the acetabular roof. The remaining medial and central parts of the epiphysis are thus protected from load bearing and epiphyseal collapse is prevented. Increasing fragmentation and collapse of the lateral pillar is associated with a worsening prognosis. This concept was first observed by Ferguson but recognition that changes in the lateral epiphysis are a bad prognostic sign was also embodied in some of Catterall’s head at risk signs.
Diagrams and radiographs illustrating the lateral pillar classification of Perthes disease into groups. Dark shading illustrates the remaining height of the lateral pillar or column of the epiphysis. See text for explanation.

Herring’s classification divides the femoral epiphysis into a lateral third, a central third and a medial third. Changes seen in the lateral pillar at the end of the fragmentation stage determine the group (Table 13.18.1). The Herring classification is reported to have lower intra- and interobserver variability compared to the Catterall classification.

The Salter and Thompson classification

Classification of the extent of femoral epiphyseal involvement using either the Catterall or the Herring system can only be established at the end of the fragmentation stage. Consequently neither system is able to predict how much collapse will develop until the collapse has actually occurred. This limits the usefulness of the two systems for determining who might do badly and therefore who might benefit from early treatment aimed at prevention or limitation of femoral head deformation. Salter and Thompson observed a subchondral crescentic radiolucent line early in the disease process. They believed that the line represented a pathological fracture and that the fracture was responsible for the onset of pain and clinical symptoms. It was observed that only the portion of the epiphysis underlying the subchondral fracture was affected by the avascular process. A simple classification that would predict the extent of the collapse was proposed. In Group A the fracture extended for less than half of the head and the prognosis was relatively good and in Group B (Figure 13.18.9) it extended over more than half of the head and the prognosis was relatively poor. Unfortunately the subchondral fracture was apparent in less than 33% of the patients studied.

Determinants of prognosis

Historically, patients have been enrolled into a variety of treatment programmes as soon as Perthes disease was recognized and it has therefore been difficult to unravel the natural history of the condition from the effect of treatment. Nevertheless most studies suggest that age, extent of epiphyseal involvement, and gender each influence the prognosis.

Age

The prognosis is better for the younger child. The remaining growth potential is at least part of the explanation for this phenomenon. Even if a young patient’s femoral head becomes deformed and aspherical there is still time for the immature acetabulum to grow to match the femoral head and the long-term result is an aspherical congruent joint with a fair prognosis. In an older patient the more mature acetabulum has already grown to match a spherical femoral head: if the femoral head then deforms, the mature acetabulum is unable to remodel because remaining growth is limited and the result is an aspherical and incongruent joint with a relatively poor prognosis. Nevertheless, being young at disease onset does not guarantee a good outcome and up to 20% of cases in young children can ultimately reach a poor outcome, even with adequate treatment. Nonetheless most children who develop long-term poor results have disease starting over the age of 8 years.

Extent of epiphyseal involvement and stage at diagnosis
The extent of epiphyseal involvement is defined by the Catterall, Salter and Thompson, and Herring classification systems. The prognosis for an individual case is proportional to the degree of the radiological involvement. It is also accepted that early treatment, before significant deformity has occurred, is likely to deliver a better outcome.

**Gender**

Most series reveal that girls have a worse outcome than boys. The reason for this is not entirely clear but some reports show that, although the condition is much less frequent in girls, a greater proportion of girls present with more extensive epiphyseal involvement than boys.

**Defining early and late disease**

If there is extensive epiphyseal involvement during the early stages of Perthes disease, the cartilaginous femoral head loses its internal bony support and its spherical shape may not be maintained because living cartilage is a plastic material. During this period of plasticity, the ultimate shape of the femoral will be influenced by the external mechanical forces applied to it. Later in the disease process when the femoral head is healing or healed, a new bony epiphysis is in place and the cartilaginous femoral head is again supported by an internal bony structure, albeit often a different shape from the original. At this stage, the femoral head is no longer plastic and the shape is fixed. Thus, once radiological healing is established there will be no further deterioration in femoral head shape and its shape cannot be influenced by the external mechanical environment. The management approach to these two periods is thus quite different. The approach to the early plastic stage requires strategies that attempt to keep the cartilaginous femoral head as spherical as possible by altering its external mechanical environment; in contrast, the approach to the late non-plastic stage must accommodate the new shape by orientating it into a congruent position, relative to the acetabulum, whilst maintaining a functional arc of movement.

## Management

### Early (plastic phase) Perthes disease

#### Review of current management approaches

The femoral head remains plastic over a prolonged period (1–2 years) until there is radiological evidence of healing. Consequently, unless the physiological processes at the root of fragmentation can be stopped or reversed, any treatment directed at changing the external mechanical environment of the cartilaginous femoral head, in order to influence shape, must be equally prolonged.

**Non-weight bearing**

When Perthes disease was discovered, the initial management approach was similar to that used for tuberculosis of the hip joint. Programmes of prolonged non-weight bearing, including hospitalization and enforced recumbency or via the use of crutches or weight-relieving calipers were adopted. From the outset the efficacy of such treatment methods was questioned and gradually the approach was superseded by the development of newer strategies. Currently, it is accepted that non-weight bearing alone is ineffective: it does not succeed in unloading the femoral head. Indeed biomechanical studies suggest that an ischial bearing caliper might actually increase hip joint loading because of compressive muscle forces acting across the joint.

**Containment**

When the hip is in the anatomical position, the lateral part of the epiphysis is directly below, or just outside, the lateral rim of the bony acetabulum. In the absence of hip movement, compression forces will tend to flatten the superior part of a plastic femoral head while the uncovered anterolateral part is pushed outwards. Hip abduction brings the lateral epiphysis under the cover of the bony acetabulum redirecting the forces applied to the femoral head. The 'containment' hypothesis suggests that the femoral head should then become the same shape as the surrounding acetabulum, like jelly poured into a mould. This hypothesis has been adopted widely and is the principle behind most current treatment approaches.

Containment can be achieved by a number of means. The hip can be abducted, the epiphysis can be realigned surgically to face into the acetabulum by means of a femoral osteotomy, or the acetabulum can be redirected or extended over the femoral epiphysis by various pelvic osteotomies. At presentation, many patients have significant limitation of abduction usually as a consequence of synovitis and muscle spasm but occasionally due to a true mechanical limitation of abduction because of established femoral head deformity. It is self-evident that abduction must be restored before any containment approach can be applied. Methods for restoration of abduction include bed rest, traction, serial abduction casting, or even tenotomy, but if abduction cannot be restored then the epiphysis cannot be contained and treatment following the containment concept is futile.

**Abduction bracing**

Initially, good results were reported using bilateral above knee cylinder casts with broomsticks applied to hold each leg abducted to 45 degrees and internally rotated to 5–10 degrees for around 18 months. The Petrie cast, like many subsequent braces, is a restrictive device not conducive to 'a normal life'. Such treatment methods have become unacceptable and a plethora of ambulatory braces such as the Atlanta Scottish Rite brace were developed to maintain abduction whilst preserving mobility. Although bracing is still used, its efficacy compared to the surgical alternatives is questioned.

**Femoral osteotomy**

A femoral osteotomy aims to redirect the lateral or sometimes the anterolateral epiphysis inside the confines of the lateral rim of
the bony acetabulum. An intertrochanteric osteotomy is performed and then fixed in varus angulation. On occasion, some internal rotation or extension of the proximal fragment is included and some advocate simultaneous trochanteric growth arrest to limit the high trochanter that commonly occurs in this condition. Before embarking on surgery, it must be documented that the affected hip will abduct sufficiently to contain the epiphysis and that the patient will be left with some residual abduction range after the osteotomy has been performed. These prerequisites are usually confirmed by examination under anaesthesia and arthrography. If they are not met a varus osteotomy will only serve to put the affected leg into an adducted posture and the epiphysis will not be contained. Children who are treated between the ages of 5–8 years, when the disease is in the early or fragmentation stages and before significant femoral head deformity has developed, have the best outcome. Femoral osteotomy is not without its side effects and reported problems include failure of the varus to remodel, especially in the older patient, limb shortening, increased abductor lurch, trochanteric overgrowth, and the need to remove the fixation device.

Salter osteotomy

While the femoral osteotomy moves the uncovered epiphysis under the acetabulum, the Salter innominate osteotomy does the reverse. The prerequisites for the procedure with regard to range of movement and epiphyseal containment are thus the same and again are often confirmed with an examination under anaesthesia and arthrography. Advantages of the Salter osteotomy include the absence of the iatrogenic varus and consequent limb shortening that is associated with femoral osteotomy. The Salter osteotomy typically leads to modest limb lengthening which may be advantageous given that Perthes disease usually leads to limb shortening. However, relative overlengthening tends to offset the containment effect by adducting the limb slightly when the patient bears weight. Nevertheless comparative studies show little difference between the outcome of Salter versus femoral varus osteotomy.

Shelf osteotomy

The Shelf osteotomy is a form of acetabular augmentation which extends the acetabular roof to cover the uncovered anterolateral femoral epiphysis. Once again the procedure has the advantage of avoiding iatrogenic varus and limb shortening from a femoral osteotomy. This can be important in the older patient who may not have the growth potential to remodel a varus alignment. This procedure is used less frequently than the femoral or Salter osteotomies but encouraging reports of its use, especially in the older patient, are growing.

Bisphosphonates

If the structural integrity of the femoral epiphysis could be maintained during the revascularization of the epiphysis then femoral head collapse and deformity might be prevented. It is on these grounds that some groups are attempting to treat Perthes disease with bisphosphonates.

Joint distraction

Some authors postulate that joint distraction in early Perthes disease may prevent collapse and enhance recovery by unloading the femoral epiphysis. A few studies report the use of external fixators to distract the joint in this way but again the efficacy of this approach remains uncertain.

Decision-making in early disease

The clinician faces the challenge of identifying the patient who is likely to benefit from intervention and then choosing the appropriate intervention. In 1971, Catterall wrote ‘the reported results of treatment are so variable that it is difficult to be sure that the (published) series are strictly comparable’. More than two decades later Herring wrote ‘it is difficult if not impossible to compare the results of these (published) studies’. To date, no adequate prospective randomized controlled trial has compared the outcome of untreated cases of Perthes disease against similar cases treated by various means.

Herring and associates studied prospectively the outcome of Perthes disease in children over 6 years of age who had been managed by various means. The outcome of physiotherapy and several containment methods (surgical and non-surgical) were compared. The study identified a group of patients who benefit from containment treatment and showed that surgical containment methods (both femoral varus osteotomy and Salter innominate osteotomy) led to a better outcome that non surgical containment by abduction bracing but only some patients benefited (Table 13.18.2).

When the lateral pillar was completely preserved (Herring A) all patients did well and treatment, by any means, made little difference. Therefore if a Group A patient could be identified accurately, treatment could be withheld safely. When the lateral pillar collapsed completely (Herring C) the outcome was poor and treatment by any means made little difference. This implies that it is futile to offer such patients any of the containment methods studied. Unfortunately the clinician managing a patient who presents with early disease is unable to foretell whether the presenting hip will remain a Herring A or become a Herring C and it is therefore difficult (or impossible) to decide to withhold treatment for a particular patient on radiological grounds alone. Moreover it is accepted that treatment before deformation occurs is preferable and it is therefore difficult to deliberately delay treatment, and risk compromising the outcome, while waiting for the hip to declare itself.

It is apparent that although the Catterall and Herring radiological classification systems are useful as research tools to ensure that studies can compare like patients at final review, they cannot be used to determine which patients should be treated in the early stages of the disease. With this backdrop how can the clinician make rational management choices?

Author’s approach

The concept of passive and active containment

How can current knowledge regarding Perthes disease be resolved into a useable clinical management approach? The clinician manages patients not radiographs and the author’s philosophy is a clinical rather than a radiological approach (Figure 13.18.10).

All patients who develop Perthes disease must contain the vulnerable epiphysis. Some patients achieve this containment for themselves by maintaining a full range of movement, especially abduction. The author refers to this circumstance as passive containment and the patient simply requires observation not intervention.

Clinical evaluation of abduction is therefore the most important decision making assessment. During the clinical examination it is important to abduct the unaffected hip maximally and flex the knee over the edge of the examination couch to lock the pelvis before measuring abduction on the affected side otherwise unconsciously rolling or tilting of the pelvis means that abduction of the affected hip can appear spuriously good.

Passive containment is most apparent in the young patient (under age 4). Clinical experience shows that many young patients maintain an excellent range of movement with modest symptoms. These favourable clinical findings do not always match the sometimes unfavourable extent of radiological epiphyseal involvement but may explain why the outlook is often good for younger patients. The bony nucleus of the young epiphysis only represents a small proportion of the whole cartilaginous head and its contribution to maintenance of femoral head shape is modest in the younger (and lighter) patient. In older patients extensive femoral epiphysseal involvement is typically matched by significant clinical symptoms and loss of movement, especially abduction.
If a patient begins to lose range of movement, particularly with abduction less than 20 degrees, then the lateral femoral epiphysis will not move in and out of the acetabulum during normal activity. Such patients are unable to contain their own epiphysis adequately. This loss of clinical abduction is the cue that the patient needs help in containing the epiphysis and the clinician must intervene. The author refers to this circumstance as active or interventional containment. This approach is inclusive to all patients, even for the rare case of a young patient who presents with such loss of abduction. It is possible that the small proportion of young patients who present in this way are likely to represent the young patients whose outcome is unexpectedly poor when managed passively. Given current evidence it seems reasonable to expect interventional containment in such children to improve the outcome, although there is no study to date to support this notion.

Based on current evidence, the author’s preferred interventional containment procedure for children under 8 years of age is a femoral varus osteotomy (Figure 13.18.11).

![Click to view larger](Fig. 13.18.11 Radiograph of 7-year-old boy with Perthes disease of the right hip, 9 months following a femoral varus osteotomy.]

Following the surgical procedure the patient is immobilized in a spica cast for 6–8 weeks to maintain abduction. Experience has shown that without the cast, movement is lost and the hip adducts.

Femoral varus osteotomy in the child over age 8 years has some distinct disadvantages. There may not be enough growth remaining for the iatrogenic varus deformity to remodel with time and if the deformity persists it leads to limb shortening and a Trendelenburg lurch. The author’s preferred method of interventional containment for the older patient is the shelf osteotomy (Figure 13.18.12).

![Click to view larger](Fig. 13.18.12 Radiograph of 9-year-old boy with Perthes disease of the left hip, 8 months following a shelf osteotomy.]

This procedure has none of the disadvantages of the varus osteotomy and increasingly, reports show its efficacy as a containment procedure. The author has found that postoperative immobilization with a spica cast is unnecessary. Partial weight bearing is allowed with increase of the load allowed over a period of 12 weeks.

**Arthrography**

Before embarking on an interventional containment approach the prerequisites of the chosen method must be met. Examination under anaesthetic and arthrography confirms that containment is possible and sufficient abduction is available. Early flattening of the cartilaginous femoral head is acceptable provided the lateral part of the epiphysis comes under the cover of the bony acetabulum (Figure 13.18.13A).
Fig. 13.18.13
Arthrogram images illustrating two hips in abduction. The femoral head in image A is flattened but is nevertheless containable. The lateral pillar of the epiphysis comes under the lateral edge of acetabular roof. The contrast pool reveals middle column flattening at the level of the upper arrow but the medial column still touches the floor of the acetabulum near the teardrop at the lower arrow. In contrast the femoral head in image B is too deformed to enter the acetabulum in abduction and demonstrates so called ‘hinge abduction’. The lateral column does not come under the roof of the acetabulum but impinges at its edge acting as the fulcrum for further abduction. Consequently the femoral head is levered from the acetabular floor. The middle column does not touch the floor and the medial column is pulled further away from the floor adjacent to the teardrop figure. Arrows illustrate the widening contrast pool.

According to the author, interventional containment is indicated because the patient has lost abduction in the outpatient setting. This loss of abduction is present only when the patient is conscious: it is usually the result of muscle spasm secondary to synovitis and pain. Once the patient is under general anaesthetic the spasm is overcome and most patients then have an adequate range of abduction and a containable epiphysis. If abduction is limited, even under anaesthetic, it may sometimes be restored by serial casting, or tenotomy, but if the restriction is mechanical because of hinge abduction (Figure 13.18.13B) then the epiphysis is not containable and interventional containment is contraindicated.

Follow-up
The author believes that patient follow-up following the management of Perthes disease should be continued until they reach skeletal maturity. Patients rarely develop symptoms that require attention in their childhood or early adult life but most do develop a modest shortening on the affected side of about 10–15mm. Although this rarely requires intervention, limb length monitoring is the primary reason for follow-up. If the discrepancy is greater than expected or if symptoms develop, then monitoring during growth will facilitate limb length equilibration using a well timed epiphysiodesis.

Late non-plastic Perthes disease
Many childhood hip disorders leave a deformed femoral head in their wake. If a patient develops an aspherical and incongruent joint then symptoms of discomfort can present as early as the late teens or early twenties. The typical anatomy of the deformed hip includes a short broad femoral neck with a high greater trochanter and a large broad aspherical (flattened) femoral head (Figure 13.18.14). The acetabulum may match the femoral head shape or not and the severely deformed femoral head develops a saddle-shaped depression under the region of the bony acetabular rim.

These anatomical deformities present clinically as a short limb and a Trendelenburg lurch with abductor fatigue and discomfort in the gluteal muscles after activity. Superior flattening and increasing width of the femoral head makes the head ovoid rather than spherical. While a spherical joint allows easy movement in all directions the ovoid head behaves more like a roller with its long axis in the coronal plane. There is usually good flexion but limited rotation and abduction. Although patients often have good flexion they cannot always achieve full flexion with the leg in the sagittal plane. As flexion proceeds the bulge of the deformed anterolateral part of the femoral head will not fit under the anterior lip of the acetabulum. To achieve further flexion the patient’s leg (and femur) must externally rotate to direct the bulge around the anterolateral rim of the acetabulum: the classical sign of a deformed femoral head.

In the worst cases the superior surface of the femoral head is flat or even concave and abduction is severely limited because the deformed femoral head will not fit under the lateral rim of the acetabulum when abducted. If the hip is forced into abduction, the lateral part of the head impinges on the lateral rim of the acetabulum. Further abduction causes the hip to be levered from the medial floor of the acetabulum with the fulcrum or ‘hinge’ of the lever at the point of impingement. This is so called ‘hinge abduction’. A patient whose hip hinges will not allow any abduction when conscious because it is too painful. Under anaesthetic the hip can be forced into abduction and the hinging demonstrated on an arthrogram (Figure 13.18.13B).

Once the femoral head has reached the healing stage its shape is fixed and cannot be further influenced by containment. The objective now is to accept the shape and align the femoral head with the acetabulum in a congruent position that also offers the patient a functional arc of movement. The management principle is the ‘position of best fit’ and can be applied to any deformed femoral head.

Dynamic arthrography is the key investigation for evaluation of the deformed hip. In the typical case, following Perthes disease the arthrogram often demonstrates a congruent fit when the hip is adducted. In these circumstances a proximal femoral valgus osteotomy will reproduce the congruent alignment when the patient is standing (Figure 13.18.15).
Fig. 13.18.15
An ovoid femoral head with a broad, short neck and a high trochanter is illustrated (A). The arthrogram illustrates hinge abduction (B), in this case primarily because of impingement of the high trochanter, although the impingement is usually secondary to an extruded lateral part of a flattened epiphysis in Perthes disease. When the hip is held in adduction the arthrogram reveals a reasonably congruent position of ‘best fit’ (C). A valgus osteotomy can reproduce the position of ‘best fit’ (D) restoring a functional range of abduction.

The valgus osteotomy will allow some clinical abduction before the point of impingement is reached. Furthermore the osteotomy can sometimes lengthen the short leg and the greater trochanter will be brought to a lower and more lateral position, lengthening the abductor lever arm and improving the Trendelenburg lurch and abductor fatigue. The procedure reduces symptoms and can extend the lifespan of the patient’s hip joint before interventions such as joint replacement become necessary.

Summary points

- Slipped capital femoral epiphysis occurs during rapid growth periods of adolescence
- Delay in diagnosis remains a major problem
- Acute, severe, and unstable slips are an orthopaedic emergency; the preferred treatment option remains controversial.

Introduction

Slipped capital femoral epiphysis (SCFE) is a condition that occurs during a period of rapid growth in adolescence, when shear forces, particularly in the obese individual, increase across the proximal femoral growth plate resulting in a posteromedial displacement of the epiphysis relative to the femoral metaphysis.

Delay in diagnosis remains the major problem because of the failure to associate knee and thigh pain in the adolescent with hip pathology. AP pelvic radiographs are easily misinterpreted in the early stages.

Most slips can be treated by cannulated single screw stabilization. There is continuing debate about the necessity for prophylactic contralateral fixation and the management of the acute unstable slip.

Incidence and aetiology

The reported incidence varies from 1–7 per 100 000. Males are affected three times more than females. Bilateral slips occur in approximately 20% of cases.

The typical phenotype of obesity and possible hypogonadism implicates an endocrine cause. There is a clear association with hypothyroidism and with growth hormone treatment and pathological values of follicle stimulating hormone, luteinizing hormone, and testosterone have been identified. Cases are also seen in association with metabolic bone disease such as renal rickets and in survivors of childhood malignancy who had received chemo- or radiotherapy. Perhaps more worringly, recent evidence has highlighted a close correlation between rising childhood obesity and increasing incidence of SCFE. There is also a link between SCFE and femoral retroversion.

Ultrastructural studies of SCFE growth plates have shown diminished cellularity and marked distortion of the architecture in both the proliferative and hypertrophic zones. The diminished cell number has been shown to be due to abnormal frequency and distribution of chondrocytes undergoing apoptosis. In this context the concept of 'preslip' has been confirmed by magnetic resonance imaging.

Classification (Box 13.19.1)

There are various classifications related to onset of symptoms (temporal), ability to weight bear (functional), and extent of epiphyseal displacement relative to the neck (morphological).

Temporal

An acute SCFE is one that occurs in a patient with prodromal symptoms of 3 weeks or less followed by an acute event often after minor trauma, considered to be too insignificant to cause a type I physeal fracture.

The chronic SCFE is the more common presentation. There is usually several months’ history of vague groin, thigh, and knee pain with increasing limp and out-toeing gait. Radiographs reveal signs of remodelling.

In the acute-on-chronic slip, there has been a history of prodromal symptoms for more than 3 weeks followed by a sudden exacerbation of pain.

Functional

The concept of stability popularized by Loder relates to the patient’s ability to weight bear after the acute event. Both acute and acute-on-chronic slips may be categorized further in this way. Patients with an unstable slip are in such severe pain that they are unable to weight bear.

Box 13.19.1 Classification systems for SCFE

- Temporal according to onset of symptoms: acute, acute-on-chronic, chronic
♦ Functional according to ability to bear weight: stable, unstable
♦ Morphological according to extent of epiphyseal displacement relative to the neck: mild, moderate, or severe.

Morphological

The degree of displacement is assessed on radiographs. Lines are drawn corresponding to the axis of the femoral shaft and the base of the capital epiphysis. It is not necessary to obtain a computed tomography scan. A grade I slip is 0–30°, grade II 30–60° and grade III 60–90°+.

Diagnosis and imaging

The symptoms and physical findings vary according to the type of slip. In a stable chronic SCFE the presenting complaint is usually of groin pain and/or vague anteromedial thigh and knee pain. This localization of the pain continues to cause diagnostic delay and confusion. The relationship between delay in diagnosis and increased slip severity has been confirmed and there have been calls for a more robust educational strategy, particularly for allied health professionals.

The early physical signs are perhaps subtle, with loss of internal rotation of the hip progressing to limb shortening and external rotation deformity. Acute unstable or acute-on-chronic slips will usually present with sudden pain and inability to bear weight.

The standard radiographs of an anteroposterior (AP) pelvis and lateral views of the hips are usually sufficient for diagnosis. The earliest sign is a widening of the physis (pre-slip). The diagnosis may be difficult to detect on the AP view. A line drawn parallel to the superior femoral neck (Klein’s line) will intersect the lateral portion of the epiphysis but not in an early slip (Trehnowan’s sign). Steel described the ‘metaphyseal blanch sign’ that corresponds to increased density caused by overlapping of the femoral head and displaced epiphysis (Figure 13.19.1 and Box 13.19.2). An ultrasound scan may demonstrate an effusion and confirm an early/mild slip.

Treatment

The primary aims of treatment are to stabilize the epiphysis and prevent further slip. Prevention of avascular necrosis (AVN) and chondrolysis are secondary aims. A treatment algorithm is presented in Figure 13.19.2 (and see Figure 13.19.1).
The chronic slip

The majority of slips are chronic and can be treated with single cannulated screw fixation. The screw thread should traverse the physis into the centre of the epiphysis. Recent biomechanical studies have indicated that there should be equal distribution of threads across the physis for optimum stability. Joint penetration should be avoided to reduce the risk of chondrolysis. It is not necessary to employ a reverse cutting thread to facilitate screw removal, since there is now a consensus that screws should not be removed because of the associated morbidity.

Box 13.19.2 Radiographic features of a SCFE

- Widened physis
- Klein’s line
- Trethowan’s sign
- Metaphyseal blanch sign.

Single screw fixation is reliable but in the more severely displaced slips, knowledge of the pathoanatomy is required for accurate anterior placement of the screw. Remodelling will occur and often the external rotation deformity will resolve but there is concern among some about long-term femoroacetabular impingement.

In younger patients with endocrine disease, smooth pins may be inserted and subsequently removed if it is anticipated that healing will occur with endocrine replacement therapy, for example in hypothyroidism.

The acute unstable slip

The primary treatment of the acute unstable slip remains controversial mainly because of the incidence of AVN as a consequence of the injury to the epiphyseal blood supply. Many support the proposition that the displaced epiphysis should be gently repositioned on the operating table and stabilized with single screw fixation (some authors believe two point fixation with two screws is preferable). One study performed such a manoeuvre in acute slips within the first 24h and no cases of AVN were encountered whilst another report documented a 7% incidence of AVN for reductions less than 24h from presentation, but 20% if treatment was delayed. This author advocates a period of traction for 3 weeks in those acute slips that present after 24h before any subsequent intervention followed by a femoral neck osteotomy or screw in situ if possible.

The acute-on-chronic slip

In acute-on-chronic slips no attempt should be made to reposition the epiphysis beyond its acute displacement and full correction should be avoided. In situ screw fixation is used.

The severely displaced slip

There are protagonists who believe that anatomical realignment of the capital epiphysis should be attempted in severe slips in order to improve function and to reduce the risk of later osteoarthritis. They therefore advocate osteotomy or open reduction in acute slips to correct the deformity with single or double screw stabilization.

Reference has already been made to the capacity for femoral neck remodelling but recent studies have drawn attention to femoroacetabular impingement as a cause of early structural abnormalities in the acetabular rim and late osteoarthritis.

Some surgeons advocate surgical dislocation of the hip and osteochondroplasty at the femoral neck junction, even for minor slips but conventionally, neck osteotomies at the level of the physis are performed. The cuneiform neck osteotomy of Fish results in complete excision of the physis from the metaphysis and epiphysis allowing bone on bone apposition and healing. The AVN rate is variable (4.5–35%). Chondrolysis has an incidence of 10–30%. The high complication rate leads many to advise primary screw stabilization and a subsequent osteotomy to correct deformity if necessary (vide infra).

The contralateral slip

It remains debatable whether the contralateral normal hip should undergo prophylactic screw fixation. The development of AVN or chondrolysis in such a hip is a devastating complication. A systematic review of the literature identified the probability of contralateral SCFE occurring as 19%. They concluded that the overall optimum decision path is observation. When the probability of contralateral slip exceeds 27%, for example in endocrinopathies, or when reliable follow-up is not feasible, screw stabilization is favoured.

Box 13.19.3 Complications of SCFE

- AVN:
• Open reduction
• Femoral neck osteotomy
• Manipulation of stable slips
• Late/forcible manipulation of unstable slips
• Down syndrome

♦ Chondrolysis:
• Hip spica treatment (rarely used)
• Pin penetration?

Delayed bone age does not appear to be a predictor for a contralateral slip.

Salvage

Residual deformity can be managed by subsequent intertrochanteric osteotomy. Southwick described a triplane osteotomy at the level of the lesser trochanter. It is technically difficult and corrects the deformity a long distance from the site of the deformity. The osteotomy described by Dunn (and that by Fish) is performed at the site of deformity but the complication rate is higher. Such osteotomies do increase hip range of movement but may not provide improvement in functional outcome. Furthermore the influence of such osteotomies on late onset osteoarthritis, and the ease with which subsequent arthroplasties can be performed, remains uncertain.

Complications (Box 13.19.3)

AVN is the most common complication but radiological changes may take 18 months to become evident. The acute unstable slip has a relatively high incidence (up to 35%). The risk factors for AVN include open reduction, femoral neck osteotomies, manipulation of stable slips, forcible manipulation (late) of unstable hips and Down syndrome. Many hips with AVN will require early arthroplasty.

Chondrolysis is defined as narrowing of greater than 50% of the joint space. Hip spica cast treatment increases the incidence. The aetiology is not exactly known but appears to be related to immune system activation. Historically, there may be an association with joint penetration of implants. Maximum joint space narrowing occurs in the first year and improvement in up to 50% of cases can occur for up to 3 years. Some hips will require joint replacement.

Common knee conditions

DOI: 10.1093/med/9780199550647.003.013020

Summary points

- All children who complain of knee symptoms must be assessed for ipsilateral hip and spine pathology.
- Congenital or persistent lateral dislocation of the patella and obligatory dislocation of the patella have two different clinical presentations: surgical treatment (if required) is often complex.
- The natural history of stable osteochondritis dissecans lesions is generally favourable in a child with open physes.

Introduction

The knee is one of the most common joints that paediatric orthopaedic surgeons are asked to evaluate. All children who complain of knee symptoms also need to be assessed for ipsilateral hip and lumbar spine disorders. This chapter will discuss common knee conditions seen in the paediatric population. Knee disorders specific to young athletes will be reviewed in the section on sports medicine (see Chapter 13.23). The adolescent patellofemoral joint has also been covered in Chapter 8.10.

Congenital and habitual dislocation of the patella

The patellofemoral articulation is a complex joint that relies on bony conformity as well as on static and dynamic soft tissue components for stability. Any disturbance of the normal anatomical relations due to dysplasia, malalignment, or trauma can affect this balance and lateral subluxation and dislocation are common.

The patella forms during the seventh week of embryonic life. The cells develop deep to the patellar tendon as an uncalcified cartilaginous anlage that grows over time, ossifying between 4–6 years. The soft tissues surrounding the patella contribute significantly to patellofemoral joint stability. More specifically, the medial patellofemoral ligament (MPFL) and the vastus medialis obliquus (VMO) provide the greatest restraints to excessive lateral patellar displacement. The MPFL crosses the anteromedial aspect of the knee from the adductor tubercle of the femoral epicondyle to the superomedial aspect of the patella (Figure 13.20.1). It has been estimated to provide 50–80% of the restraining force to lateral translation and isolated release of the MPFL increases lateral displacement of the patella by 50%. The VMO is important as the primary dynamic medial stabilizer and is intimately associated with the MPFL.

![Fig. 13.20.1](image)

Click to view larger

Fig. 13.20.1
A) AP and B) lateral simplified line diagrams of the knee demonstrating the position of the medial patellofemoral ligament (MPFL) with relation to the medial collateral ligament (MCL) and the pes anserinus.

With the knee in full extension, the patella naturally rests superolateral to the femoral sulcus. Engagement between the patella and trochlea does not occur until the knee flexes about 10–30 degrees. This can be affected by changes in patellar tendon length. Patients with patella alta, for instance, engage the trochlea at greater flexion angles, leading to less bony constraint at earlier degrees of flexion, theoretically increasing the risk for dislocation (Figure 13.20.2). Trochlear dysplasia has also been identified as a contributing factor to patellar instability. Broadly defined as flattening of the trochlear sulcus, dysplasia has been seen in 29–85% of patients with patellofemoral instability (Figure 13.20.3). Various torsional deformities of both the femur and tibia have also been implicated in this disorder. Historically, increased Q angles have been considered a risk factor for patellar instability: larger Q angles subject the patella to a larger overall lateral force vector (Box 13.20.1). Recent reports, however, question the significance of this finding. Generalized ligamentous laxity has been implicated in as many as two-thirds of patients with patellar instability but again the relevance of this has been queried recently.
Congenital dislocation of the patella is uncommon and two clinical syndromes have been described. One is referred to as a fixed lateral dislocation of the patella and the second described as habitual dislocation of the patella. Others have used the term obligatory dislocation of the patella to describe habitual, acquired, or atraumatic dislocation. Congenital or persistent lateral dislocation of the patella and obligatory dislocation of the patella have two different clinical presentations as shown in Table 13.20.1.

The child with congenital lateral dislocation of the patella presents with a knee flexion contracture and no patella palpable anterior to the femoral condyles. Palpation of the hypoplastic patella in its lateral position is difficult. A magnetic resonance imaging (MRI) scan may be necessary to ascertain the location of the cartilaginous patella. This child may present with a delay in the ability to walk independently or with an abnormal gait related to a knee flexion contracture and the associated external tibial torsion. Affected patients may have a musculoskeletal syndrome of which the patella dislocation is one feature. Congenital dislocation of the patella may occur bilaterally but more commonly it is unilateral (Box 13.20.2).

Box 13.20.2 Syndromes associated with congenital dislocation of the patella

- Arthrogryposis
- Larsen’s
- Rubinstein–Taybi
- Downs (trisomy 21)
- Nail–patella
- Ellis–van Creveld
- Dyschondrosteosis.

The pathoanatomy of congenital patellar dislocation always includes a joint contracture, with contracted posterior capsule and hamstring tendons, and may include congenital absence of the cruciate ligaments. In addition, there are varying degrees of contracture of the lateral retinaculum, iliotibial band, vastus lateralis, rectus femoris, vastus intermedius, and also the lateral patellofemoral, patellotibial, and patellomeniscal ligaments. In cases of fixed lateral dislocation of the patella, the extensor mechanism becomes a flexor and external rotator of the knee, leading to progressive genu valgum.

Acute atraumatic, habitual, or obligatory dislocation of the patella characteristically presents after the child begins to walk. Patella alta, trochlear dysplasia, and hyperelasticity contribute to the pathoanatomy. These patients do not have a flexion contracture but they do complain of knee instability which may be surprisingly well tolerated. Knee extension may be weak. In childhood, dysfunction and deformity, rather than pain, are the presenting complaints (Figure 13.20.4).

Relocation of the patella can encourage the development of an adequate trochlea and patellofemoral congruence and thus surgical intervention is recommended when the child presents at an early age. For the adolescent, reduction and reconstruction is recommended only if symptoms warrant.

Whether the patella dislocation is fixed or obligatory, the surgical management can be quite complex. Understanding that the pathoanatomy includes significant soft tissue contractures is critical. An extensive release of all abnormally tight lateral structures is necessary: this includes the lateral retinaculum, the lateral capsule with the imbedded patellofemoral ligaments, and the lateral
patellomeniscal ligaments found within the fat pad of the knee. The retinaculum is repaired in a lengthened position after the patella has been realigned. The vastus lateralis is also invariably involved and either shortened or abnormally adherent to the iliotibial band or lateral intermuscular septum. To avoid overcorrection, lengthening of the vastus lateralis after release from surrounding adhesions is preferred to release alone.

After an extensive lateral release, the patella should lie well-centered within the trochlea. However, in most cases, there is still a contracture of the central portion of the quadriiceps mechanism which must be lengthened if the patella stability is to be maintained as the knee flexes. In the presence of an arthrogrypotic like flexion contracture of the knee, a formal posterior approach may be required for a hamstring lengthening and release of the posterior capsule.

The medial retinaculum with the inclusion of the MPFL is always severely attenuated with congenital patellar dislocations. In the fixed type, the retinaculum may be adherent to the underlying medial femoral condyle and requires a careful dissection to free it from the underlying joint surface. After appropriate lateral releases and lengthenings have allowed the patella to be reduced, the medial retinaculum is repaired and the MPFL is reconstructed. In older patients, additional augmentation of the medial repair vector is required. Transferring the semitendinosus tendon into the patella accomplishes this.

In obligatory atraumatic dislocation, the contractures are generally not severe. Lengthening rather than release of the lateral retinaculum is performed to prevent overcorrection and to maintain the positive effect of the lateral retinaculum on patellar stability. MPFL reconstruction can be included if it is not associated with hyperelasticity and/or significant trochlear dysplasia.

### Adolescent acute traumatic patella dislocation

The mean annual incidence of acute traumatic lateral patellar dislocation is 5.8:100 000 increasing to 29:100 000 in the subgroup of 10–17-year-olds. Contrary to previous beliefs, the most commonly affected person is not an obese, sedentary female but rather a young athlete of either gender. Two common mechanisms of traumatic patellar dislocation are sports (61%) and dance (9%) injuries (Box 13.20.3). Dislocation may result from a non-contact injury with a mechanism similar to that responsible for anterior cruciate ligament injuries or it may be a result of blunt trauma producing either a valgus/external rotation moment about the knee or a laterally directed force on the patella that exceeds the tensile strength of the MPFL in patients predisposed to dislocation. Particular care should be taken to determine whether the patient has had a previous patellar dislocation on the index or contralateral knee. A history of contralateral patellar dislocation increases the risk of recurrence sixfold: as much as a previous dislocation event on the index knee. A family history of patellar dislocation can be elicited in 9–15% of patients (Box 13.20.3).

#### Box 13.20.3 Injury mechanisms for acute traumatic patella dislocations

- **Non contact**: valgus/abduction moment about the knee combined with internal rotation of the femur and/or external rotation of the tibia
- **Blunt trauma**: valgus/external rotation moment about the knee or a laterally directed blow to the patella.

A significant number of patients with acute traumatic patellar instability will experience chronic instability or chronic patellofemoral pain. Reported redislocation rates range from 15–44% but perhaps more troublesome is that at least 30–50% of patients can be expected to have anterior knee pain more than 2 years after injury.

Medial dislocations are uncommon and almost universally iatrogenic: secondary to overzealous release of the lateral patellar retinaculum in the treatment of lateral instability. Intra-articular dislocations are exceedingly rare.

Physical examination for patellar instability should include assessment of resting position of the patella standing and in extension and tracking of the patella from flexion into extension looking for lateral translation (J sign) and from extension into flexion looking for capture into the trochlea. More than 50% passive lateral translation of the patella is abnormal, more so if it is accompanied by apprehension. Knee hyperextension and signs of general laxity should be sought and the strength and tightness of hamstrings and quadriceps should be assessed. A rotational profile often reveals internal femoral torsion and external tibial torsion, ‘squinting knees’, which may predispose to lateral subluxation of the patella.

Traditionally, plain radiographs have been the standard form of initial radiographic assessment to document patellar location and identify osteochondral fractures (Box 13.20.4). MRI may delineate the pathology further: it is 85% sensitive and 70% accurate in the diagnosis of MPFL ligament injury. The sensitivity for chondral injuries is variable but improves with specific cartilage imaging sequences. In addition, ultrasound has recently been reported to detect MPFL injury reliably in addition to identifying bony avulsions.

#### Box 13.20.4 Radiographic knee series

- **4 views**: AP, lateral, notch and skyline/axial (Merchant).

For patients with acute traumatic patellar dislocation without osteochondral injury, the knee should be immobilized, following
reduction, with a compressive dressing and a knee immobilizer. Weight bearing as tolerated is allowed, with the assistance of crutches. At first review, a failure to improve, as evidenced by persistent pain, swelling, and limited motion, heralds more significant intra-articular pathology which should prompt further radiographic investigation and/or arthroscopy. Early operative intervention should be considered in patients with associated osteochondral injuries, defects of the MPFL–VMO complex, and in children with high-level athletic demands. Damage to critical weight-bearing articular surfaces may require repair, debridement, or one of the many types of cartilage restoration procedures. These can be performed open or arthroscopically, depending on the size and condition of the lesion.

In children with recurrent atraumatic dislocation or persistent patellar instability despite a well-controlled rehabilitation programme, operative management should be considered to prevent progressive articular damage. Invariably the underlying aetiology is due to fixed pathoanatomy, which may be bony (trochlear dysplasia, increased Q angle, increased tibial tuberosity:trochlear groove distance). Many different surgical techniques for the treatment of patellar instability have been described (Box 13.20.5).

---

**Box 13.20.5 Surgical treatment of patella instability**

- Soft tissue balancing procedures:
  - Proximal or distal (Roux–Goldthwait) realignment
  - Alone or in combination
- Bony procedures: Elmslie–Trillat (contraindicated with open physes).

These can be grouped broadly into soft tissue balancing and realignment or bony procedures. In children with open growth plates, procedures such as the Elmslie-Trillat technique are contraindicated because damage to the growth plate risks subsequent deformity. Proximal or distal soft tissue realignment procedures, with or without tibial tuberosity transfer have had limited success in patients with trochlear dysplasia. In these knees, ligamentous insufficiency is not a cause, but rather a consequence of recurrent dislocation. Different surgical techniques have been described in an attempt to correct trochlear dysplasia and femoral or tibial osteotomies may be necessary to correct the overall limb alignment.

---

**Osteochondritis dissecans**

This is an acquired condition affecting subchondral bone that manifests as a pathological spectrum ranging from softening of the overlying articular cartilage with an intact articular surface, through early articular cartilage separation, with or without partial detachment of an articular lesion, to osteochondral separation with loose body formation. The prevalence of osteochondritis dissecans (OCD) is 15–29:100 000 individuals with males affected in a ratio of 5:3. The increasing participation of young children in competitive sports has led to a decrease in the mean age of presentation and an increased prevalence amongst girls. The site of the lesion in the femoral condyles does not differ between age groups, and more than 70% of lesions are found in the ‘classic’ area of the posterolateral aspect of the medial femoral condyle (Box 13.20.6 and Figure 13.20.5). Patellar involvement is uncommon.

---

**Box 13.20.6 Site of OCD lesions**

- Femoral condyles:
  - MFC—posterolateral 70%
  - LFC—inferocentral 15–20%
  - Trochlear 1%
- Patella:
  - Inferomedial 5–10%.
Idiopathic OCD must be differentiated from similar lesions resulting from avascular necrosis associated with chemotherapy, haemoglobinopathy, and steroid use. Several causes of OCD have been postulated, including inflammation, genetic influences, ischaemia, and defects in ossification but there is insufficient evidence to support any single factor. Histologically, the typical OCD lesion of the medial femoral condyle resembles a subchondral stress fracture. Lesions are typically associated with osteoid production and giant cell resorption and generally appear avascular. Fairbanks in 1933 suggested that OCD was the result of violent inwards rotation of the tibia, driving the tibial spine against the inner aspect of the MFC. Repetitive trauma may also induce a stress fracture within the underlying subchondral bone and if repetitive loading persists and prevents the subchondral bone from healing (non-union), necrosis of the fragment may occur and lead to fragment dissection and separation. External tibial torsion is increased in patients with bilateral OCD and even more so in patients with persisting complaints which suggests that tibial torsion has a role in the development of OCD of the knee.

OCD is traditionally divided into juvenile (open physes) and adult (closed physes) based on skeletal maturity. This distinction is useful because higher rates of healing have been seen in juvenile OCD than in the adult form. Juvenile OCD is seen more frequently in athletic children. Symptoms are preceded by a history of trauma to the knee in 40–60% of cases. It typically presents as anterior knee pain: worse with activity and improved by rest. Patients with early, intact OCD lesions, present with vague symptoms of poorly localized knee pain, stiffness with or after activities, and occasional swelling after activity. Mechanical symptoms such as grinding, locking, and catching are more commonly associated with the late stages of OCD where loose or detached OCD lesions are present.

An initial physical finding is tenderness over the involved condyle with the knee flexed. Later, patients develop a joint effusion and a decreased range of motion. The child may limp and the involved leg may be externally rotated to prevent impingement of the tibial spine on the MFC. Pain may be elicited with internal rotation of the tibia (Wilson’s sign) but this sign lacks sensitivity. In stable lesions, there is usually no effusion, crepitus or pain through a range of normal motion. Quadriceps atrophy may be noted in long standing cases.

Mechanical symptoms are pronounced with unstable lesions. An antalgic gait is common and there is usually a knee effusion, possibly associated with crepitus with motion. Both knees should be examined since the condition is bilateral in 20–25% of cases. If bilateral disease is present, lesions are typically asymmetrical in terms of size and symptoms.

Initial investigations include standing AP and lateral radiographs. If OCD is suspected ‘notch’ or ‘tunnel’ views should be requested to localize and characterize the lesion, rule out additional bony pathology, and evaluate skeletal maturity. In children less than 7 years of age, irregularities of the distal femoral epiphyseal ossification centre may simulate OCD but these asymptomatic sites are anatomic variants of normal ossification. The location of the lesion can be described and an estimate of size obtained from the radiographs (Figure 13.20.5). Characteristic findings include a well-circumscribed area of subchondral bone separated by a crescent-shaped sclerotic radiolucent outline of the fragment.

OCD of the knee can be diagnosed using plain radiographs alone but they are poor at establishing the stability of the lesion or the state of the overlying cartilage. MRI is considered the gold standard for evaluation of OCD. MRI can give an accurate estimate of the size of the lesion and status of cartilage and subchondral bone (Figure 13.20.6). The extent of bony oedema, the appearance of a high signal zone beneath the fragment, and presence of loose bodies are additional important MRI findings (Table 13.20.2). The most useful diagnostic feature of MRI is its ability to distinguish between stage II and III lesions. The presence of synovial fluid or granulation tissue at the interface between the fragment and the parent bone, manifested as increased signal intensity on T2-weighted spin echo MRIs, generally indicates an unstable lesion. Conversely, the absence of a zone of high signal at this interface is a reliable sign of lesion stability. In stage II OCD lesions, the low signal in the interface indicates fibrous attachment stabilizing the lesion. In contrast, stage III lesions will show high signal intensity at the interface, indicating synovial fluid between the fragment and underlying parent bone.

As the natural history of stable OCD lesions is generally favourable in a child with open physes, there is widespread agreement that initial non-operative treatment is indicated.

Kocher advocates a three-phase non-operative management protocol (Box 13.20.7). At the end of phase 1, the child should be pain-free, and repeat radiographs should be obtained. In phase 2, weight bearing as tolerated is permitted without immobilization. A rehabilitation programme is initiated emphasizing knee range of motion and low-impact quadriceps and hamstring strengthening exercises. Sports and repetitive impact activities are restricted. If there are radiographic and clinical signs of healing at 3–4 months after the diagnosis, phase 3 can begin. This phase includes supervised initiation of running, jumping, and cutting sports readiness activities. A gradual return to sports with increasing intensity is allowed in the absence of knee symptoms. An MRI may be repeated in phase 3 to assess healing. If symptoms return or follow-up radiographs show recurrence, repeat non-operative treatment can be considered.

Box 13.20.7 Three-phase non-operative management protocol

1. Knee immobilization 4–6 weeks, partial weight bearing (PWB) with crutches
2. Weeks 6–12, weight bearing as tolerated without immobilization and commencement of a rehabilitation programme
3. Months 3–4, if healing, staged return to sporting activity.

Operative treatment should be considered in patients with detached or unstable lesions (stage III and IV) regardless of the age of the child and in those patients approaching physeal closure whose lesions have been unresponsive to non-operative management (Box 13.20.8). In general, unstable lesions require partial takedown with debridement to remove fibrous tissue and restore vascularity. These techniques are based on the premise that the lesion is essentially a fracture non-union and rely on the penetration of subchondral bone to promote vascular ingrowth into the non-union site. Guhl described the system for arthroscopic staging of the lesions (Table 13.20.3).

Box 13.20.8 Goals of operative treatment of OCD lesions

Arthroscopic drilling of juvenile OCD to create channels for potential revascularization and healing may be transepiphyseal or transarticular. Antegrade drilling through the epiphysis avoids damage to the articular surface but is associated with technical challenges of maintaining accurate drill placement and depth. On the other hand, retrograde transarticular drilling is relatively straightforward, although the channels it creates through the articular cartilage heal with fibrocartilage. If partially unstable lesions...
have subchondral bone loss, autogenous bone graft is packed into the crater before fragment reduction and fixation.

Mechanical stabilization of unstable OCD lesions increases the likelihood of maintaining joint congruity postoperatively, and allows for the potential of early joint motion. Stabilization can be performed using a variety of implants including Kirschner wires, low-profile compression screws, cannulated screws, bone pegs, bioabsorbable fixation, or fibrin glue. A variety of treatments have evolved over the past few years aimed at addressing irreparable chondral defects and OCD lesions. Interventions include perichondral/periesteo autografts, autologous chondrocyte implantation (ACI) and matrix-induced ACI techniques, abrasion chondroplasty, microfracture, osteochondral autograft transplantation (OAT—mosaicplasty), and osteochondral allografts. Most of these treatment options result in the formation of fibrocartilage covering the exposed defect rather than true hyaline cartilage. The long-term results from these procedures have yet to be clearly determined. A completely separated OCD fragment in a skeletally immature person may be treated by arthroscopic or open excision, or by reduction and fixation. Recent separation and a larger bony fragment favour an attempt at reduction and fixation into the debrided defect. Failure to of the fragment to heal, or a chronic separation, favour excision with debridement of the defect: this itself will result in substantial fibrocartilage healing.

**Discoid meniscus**

Discoid menisci invariably affect the lateral meniscus and the overall incidence is 3–5% with up to one-fifth of cases being bilateral. Although the condition is a congenital anomaly, or perhaps simply an anatomical variant, no explanation for its occurrence has been found. Discoid menisci are more likely to tear due to the increased stresses on their larger surface area. The meniscus is also often hypermobile. The Watanabe classification (Table 13.20.4) is used most frequently. Type III lesions often present at a young age with symptoms of a ‘snapping knee’ and unexplained falls due to giving way. Pain is not a feature. Physical examination may elicit a reproducible ‘clunk’ on the lateral side of the knee as the flexed and externally rotated knee is brought into extension and internal rotation. Type I and II lesions present in later childhood, following a meniscal tear, with symptoms and signs similar to other types of meniscal injury. A widened lateral joint space may be seen on plain radiography and the diagnosis is often made on MRI.

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
</table>
| I    | Meniscus covers the entire tibial plateau  
      | Intact peripheral attachments |
| II   | Meniscus covers 80% of the plateau |
| III  | Meniscus covers 75–80% of the plateau with a thick posterior horn and abnormal peripheral attachments |

The asymptomatic discoid meniscus requires no treatment. A torn meniscus may have a stable rim in which case the central portion is simply ‘saucerized’. If there is instability or peripheral detachment of the remaining meniscus, meniscal suturing should be performed (see Chapter 13.23).

**Meniscal cysts**

As in adults, torn menisci can lead to the formation of meniscal cysts (Figure 13.20.7). Treatment is directed at the meniscal tear and the cyst will usually drain and close spontaneously.
Anterior knee pain

Osgood–Schlatter disease and Sinding–Larsen–Johansson syndrome are typically overuse injuries causing apophysitis of the anterior tibial tubercle and inferior pole of the patella respectively. They are common in active adolescents and associated with local tenderness and palpable swelling. Symptoms are often bilateral but both symptoms and signs may be markedly asymmetrical. Often a history of increased use, rapid growth, or jumping/landing sports accompanies the onset of pain. Repetitive small injuries to the tendon insertion are believed to be important in the aetiology of this condition. Growing children are particularly vulnerable because growth leads to tight muscles especially those, such as rectus femoris, which cross two joints. A tight rectus femoris (positive Ely–Duncan test) can often be elicited among adolescents with Osgood–Schlatter disease or jumper’s knee. Radiographs confirm fragmentation of the apophysis and in such cases other differential diagnoses for unilateral bony pain and swelling in this age group such as a malignancy become much less likely.

Management is conservative with physiotherapy indicated to address tight hamstrings or quadriceps and general advice on the use of cushioned insoles and restriction of sporting activity but only if symptoms warrant this. Attention to jumping and landing technique, or play on soft surfaces, may be useful adjuncts. Most cases of Osgood–Schlatter disease have resolved by skeletal maturity when the apophysis fuses with the rest of the tibial tubercle. For the small minority of cases that continue with symptoms, surgical excision of a painful residual ossicle(s) with decompression of the patella tendon may give dramatic symptom relief.

Further reading

Summary points

- Aetiology of idiopathic congenital talipes equinovarus remains unknown
- Antenatal diagnosis is common with good differentiation of the idiopathic from the syndromic foot
- The Ponseti method is the treatment of choice: results are poorer in the atypical and syndromic feet
- Surgery is required in selected cases as the primary treatment and in others, as treatment for residual and/or recurrent deformity.

Introduction

The treatment of patients with clubfeet in the twenty-first century has gone through a revolution pioneered in the mid-twentieth century: the primary treatment was surgical but now serial manipulation and casting is the mainstay of management. Surgery still has a role in the management of older children with relapsed deformities and especially for recalcitrant and teratologic feet.

Aetiology

The incidence of talipes equinovarus (TEV) varies with ethnicity: 0.4 (Chinese)–1.2 (Caucasians)–6.8 (Polynesians) per 1000 births. The male to female ratio is 2.5:1. Fifty per cent of cases show bilateral involvement and in 24% there is a positive family history. These factors indicate a polygenic inheritance. See Box 13.21.1.

Although the aetiology of idiopathic clubfoot remains unknown, there are numerous theories regarding its development. Intrauterine moulding as a cause of clubfoot was first proposed by Hippocrates and whilst it may play a role in some cases, the evidence from antenatal ultrasound scans is that most TEV deformities are identifiable early in pregnancy in the presence of adequate amniotic fluid.

Histological studies have identified abnormalities both in the muscles and in the medial ligaments with an increase in connective tissue content and a greater number of myofibroblasts. A higher prevalence of type 1 muscle fibres in affected feet compared to unaffected feet has been noted. One study found a significant reduction in the number of anterior horn cells in the affected side of stillborn fetuses with unilateral clubfoot but as with much of this work it does not distinguish between cause and effect. Subtle abnormalities have been identified on neurophysiological testing.

Contrary to popular belief, there is no known association with hip dysplasia.

Investigations into the genetic influences on TEV have progressed rapidly and are based on Hox genes involved in limb bud development. Chromosomal deletions (2q31–33) and candidate genes such as CASP8 and 10, and CFLAR that encode protein regulators of apoptosis during growth and development have been associated with clubfoot.

TEV found in association with other conditions is referred to as teratologic or syndromic TEV rather than idiopathic (Box 13.21.2).

Box 13.21.1 Demographics of TEV deformity

- Incidence: 1:1000 live births
- Males > females: 2.5:1
- Bilateral: 50%
- Family history: 24%
- Sibling risk: 3–7%.

Box 13.21.2 Syndromes associated with TEV deformities

- Larsen's syndrome
- Diastrophic dwarfism
- Freeman–Sheldon syndrome
- Arthrogryposis multiplex congenital
- Spinal dysraphism.
Anatomy

The essential deformities are a displacement of the navicular, os calcis, and cuboid around the talus, characterized by hindfoot equinus, internal rotation with varus and adduction, and supination of the forefoot (Figure 13.21.1).

Fig. 13.21.1
Photograph of a child with bilateral CTEV deformities.

The key to understanding the TEV deformity is to consider that the talus is firmly held by the ankle mortise and to assess the remainder of the foot in relation to the talus. Thus, the essential deformity is that the os calcis is internally rotated beneath the talus. In order to achieve this position it must assume an equinus and varus posture. The remainder of the foot is attached to the os calcis through the cuboid and the navicular allows rotation of the forefoot around the talar head. With the os calcis internally rotated, the forefoot must be in an adducted and supinated position. The metatarsals are joined in the transverse plane but there is independence of the medial and lateral columns in the sagittal plane and the first metatarsal often adopts a plantar flexed posture which explains the cavus deformity of the medial foot.

In addition to the abnormal bony architecture, the soft tissues are frequently abnormal and vascular studies have identified abnormalities in the arterial supply in patients with TEV.

The limb below the knee is thinner than normal and both the foot and the lower leg are usually short. The degree of shortening reflects the severity of the initial deformity.

Classification

Classification systems are of value in providing a prognosis to parents and for comparing the results of treatment between centres. There have been numerous attempts to classify clubfeet but the most popular in use today are those described by Pirani and Dimeglio. The Pirani system is based on 6 criteria: 3 each from the hindfoot and forefoot. Each criteria is graded 0, 0.5 or 1, giving a maximum score of 6 for each foot. The Dimeglio system scores each foot out of 20 points and then assigns it a grade. Both systems can be used for sequential assessments to monitor treatment and to predict the need for tenotomy when using the Ponseti method of treatment.

Treatment

The earliest documented treatment for TEV, in 1000BC, was massage and Hippocrates (circa 400BC) recommended treating the foot as near to birth as possible using gentle serial manipulations and fixation, aiming for over-correction. Special shoes were worn afterwards to help prevent relapse and maintain correction.

Surgery became a part of treatment in the eighteenth century and became increasingly common and increasingly aggressive during the twentieth century due to disillusionment with the protracted nature of the contemporary casting techniques such as that advocated by Kite. In time, however, it became apparent that the results following an aggressive surgical approach were also disappointing and a resurgence of the conservative management of TEV has been seen.

Kite’s view was that the fulcrum for correction of the clubfoot was the calcaneocuboid joint but correction at this site results in a midfoot break through the metatarsal–tarsal articulation. Ponseti has shown clearly that the fulcrum for correction is the lateral head of the talus and hence he developed his method of correcting a clubfoot by serial stretching and casting according to the principles of Hippocrates. The description was first published in 1963 but it took over 30 years for the method to be adopted by other surgeons.

The Ponseti method (Box 13.21.3)

The method consists of weekly manipulations during which the foot is stretched gently according to a well-defined sequence. After stretching, the foot is placed in a plaster cast to maintain the position that has been achieved. The procedure is repeated until correction is achieved. This takes approximately 6 weeks but varies depending on the flexibility of the foot (Figure 13.21.2).
Fig. 13.21.2
Examples of sequential casts used to correct a CTEV deformity by the Ponseti method.

Firstly the cavus of the first ray is elevated and the foot assumes a supinated position. This ensures that the metatarsals are in the same plane. The foot is then progressively abducted in the plane of the metatarsals, the effect of which is to correct the adduction deformity of the forefoot and additionally the internal rotation of the os calcis. As the abduction progresses the forefoot drives the os calcis from its position of internal rotation beneath the talus to its reduced position thus correcting the varus and part of the equinus deformity.

It is important to overcorrect the forefoot to 70 degrees of abduction to ensure accurate reduction of the hindfoot. As the forefoot abducts it adopts a more pronated position because of the change in position of the os calcis relative to the talus. Forced pronation should never be used as it recreates the original cavus deformity by plantar flexing the first ray thus locking the foot and preventing hindfoot correction.

The final correction required is the residual ankle equinus. Approximately 25% of feet correct completely with further stretching but most will not. If ankle dorsiflexion of 10–15 degrees cannot be achieved, a tenotomy is required. This can be done simply in the clinic under local anaesthesia. In 5% of cases insufficient dorsiflexion is achieved and surgery is required to gain complete correction. This can usually be achieved by a posterior release of the ankle capsule but in a few feet more radical soft tissue surgery is required. Following complete correction, the foot is held in a final cast for 3 weeks and then the child is treated with boots on a bar to maintain the correction (Figure 13.21.3). For the first 3 months, the boots are worn for 23 hours a day and then at ‘night time and nap time’ until the age of 4 years.

Box 13.21.3 Sequential correction of deformities with the Ponseti method

- First ray elevation
- Forefoot abduction
- Ankle dorsiflexion.

Fig. 13.21.3
Child using ‘Boots and Bars’ to maintain correction of deformity. Feet are held shoulder width apart with the foot externally rotated.

Pirani’s elegant MRI study showed that the cartilaginous deformities of the clubfoot correct with progressive manipulation and casting.

Results using Ponseti’s method

Cooper and Dietz published a 30-year follow up on 29 of Ponseti’s original group of 45 patients. The functional results did deteriorate over time but at 30 years, 78% of feet were rated as excellent/good with a supple, plantigrade foot. Relapse occurred in
50% overall but was treatable by repeated casting, with or without a further Achilles tenotomy and with a transfer of the anterior tibialis tendon in those feet with a supination deformity. Long-term results are better in those with a sedentary occupation and who are not overweight.

The true success of a procedure is whether the results can be repeated by others: initial reports failed to produce satisfactory results, invariably due to inaccurate casting techniques; however, with strict adherence to the Ponseti method, good results have been published from many centres. Relapse rates are significantly higher with poor brace compliance and although they may be treated by reapplication of the Ponseti method, compliance may still be a problem and open surgery is often necessary. A complete correction of the deformities is essential to ensure accurate brace fitting which is important to optimize brace compliance. In a series of 62 patients with 3-year follow-up from Southampton the author reports an initial failure rate of 5% and a subsequent relapse rate of 21% successfully treated with repeat casting, Achilles tenotomy or tibialis anterior transfer. All of the relapses occurred in patients with an initial hindfoot Pirani score of 2.5 or 3.0.

The Ponseti method has also been shown to be an effective means of treating clubfeet when performed by non-medical personnel such as physiotherapists and clinical officers in the developing world where facilities for surgery are less established. However, the involvement of a paediatric orthopaedic surgeon is essential to ensure continuity of care and to manage the early failures and recurrences.

The atypical or complex idiopathic clubfoot

Ponseti and others have identified certain atypical feet that behave differently to the standard idiopathic clubfoot. Clinically, they are defined as having rigid equinus, severe plantar flexion of all metatarsals, a deep crease above the heel, a transverse crease in the sole of the foot, and a short and hyperextended first toe. The Achilles tendon is exceptionally tight and fibrotic up to midcalf. In such patients, correction can be achieved by modifying the Ponseti technique and performing an Achilles tenotomy earlier than usual, prior to full correction of the forefoot. This has the effect of releasing the os calcis from under the talus. Casting may then proceed as usual but a further tenotomy may be required as little as 3 weeks later if the equinus cannot be corrected.

The syndromic foot

With teratologic or syndromic foot deformities, the Ponseti method is less likely to succeed, but it should be attempted and it may reduce the extent of the subsequent surgical release.

Box 13.21.4 The role of surgery in TEV

♦ Achilles tenotomy
♦ Posterior release
♦ Posteromedial release
♦ Lateral column shortening
♦ Circular frame correction
♦ Extra articular osteotomies.

Surgery also has a role in the treatment of relapses. As discussed previously the initial approach to a relapse is to repeat the Ponseti method. If the forefoot is supinating then a transfer of the anterior tibialis muscle is required. On occasion these steps are insufficient and more extensive surgery may be required. If the child is less than 5 years old, a posteromedial release can be performed to restore the orientation of the os calcis beneath the talus. Shortening of the lateral column can be very effective in correcting the adductus deformity that occurs. Several methods are described and include resecting part of the anterior os calcis or cuboid, or fusing the calcaneocuboid joint.

Relapse following surgical release is common: a 9–16-year follow-up study found that almost 80% of Dimeglio grade 4 feet had relapsed. With increasing age and increasingly rigid deformities, the prospect of further open surgery becomes less attractive due to the inevitable increased stiffness and scarring associated with it. For those feet that do require surgical intervention to obtain a plantigrade foot, the use of gradual correction using the principles of Ilizarov avoids the need to perform extensive soft tissue dissection. By using circular frames the complex deformities can be corrected gradually with distraction and fixed or virtual hinges. The Taylor Spatial Frame (TSF) is a circular frame device where the correction is calculated using a web-based software program. Using the principles of the Ponseti method, an olive wire inserted into the head of the talus can be used as a fulcrum to correct the deformity in the same way as the thumb is used in a standard manipulation.
Summary

TEV is relatively common affecting approximately 1 in 1000 live births. The optimal contemporary management is the Ponseti method of sequential manipulation and casting followed by maintenance of the correction by boots and bar for approximately 4 years. Ideally, treatment starts as soon after birth as possible but it can still be used for delayed presentations. The same approach is used for relapses that occur in approximately 20–30% of cases and a transfer of the anterior tibialis muscle may be required to treat supination of the forefoot. Soft tissue surgery may still be necessary for initial failures, for relapses and teratologic feet. Gradual correction using circular frames is one method of treating difficult deformities without the need for open surgery and the risk of associated fibrosis.

Further reading

Summary points
♦ Congenital foot anomalies are common; most are minor and do not affect function
♦ Postural problems must be differentiated from structural anomalies
♦ An underlying neuromuscular aetiology should be considered
♦ A pain-free, functional foot is the goal of treatment.

Foot development

The limb buds appear 4 weeks after fertilization and form rapidly over the next few weeks. By 10 weeks, joint cavitation has occurred and ligaments and capsule have developed with forefoot ossification. Ossification proceeds progressively to the hindfoot and at birth, ossification centres are seen throughout the forefoot, the calcaneum, cuboid, and talus. The navicular ossifies last between 2–5 years. An additional ossification centre develops in the posterior aspect of the calcaneum at approximately 6 years and numerous other accessory ossification centres may be noted with growth (Box 13.22.1).

Box 13.22.1 Foot size and shape
♦ At 12 months (girls)–18 months (boys) the foot is half its adult size
♦ Longitudinal arch appears by 2 years: best observed in the moving foot
♦ At 14 years (girls)–16 years (boys) the foot is mature adult size.

Genetic abnormalities

Genetic disorders can be inherited in either dominant or recessive modes and the associated anomalies may affect the foot alone or be part of a more generalized condition. Polydactyly and syndactyly are common examples of inherited conditions (Figure 13.22.2). Minor genetic variations, such as the number of phalanges in the fifth toe, often have little clinical significance.
common major chromosomal malformations are associated with foot abnormalities (Box 13.22).

![Fig. 13.22.2 AP radiographs demonstrating bilateral polydactyly. Both hands were also affected and the condition was familial.](image)

**Clinical evaluation**

Many conditions seen during the neonatal period are inherited and appropriate genetic counselling helps with management. In the older child, the history of onset of symptoms and deformity becomes more important. Clinical photographs and standard radiographs may help in documenting progression of deformity.

Pain becomes a more common complaint with increasing age. Severe unremitting night pain suggests a serious pathology. Pain occurring in a specific area during a specific activity suggests a mechanical cause whilst a burning pain in association with swelling may indicate an inflammatory condition. In children, the report of pain is often second hand and the parents’ and the child’s interpretation of the pain may be different. A child who truly has severe pain, even intermittently, is unlikely to behave normally at other times of the day.

**Box 13.22.2 Chromosomal malformations**

- **Trisomy 13 or 15:**
  - Polydactyly
  - Syndactyly
  - Midtarsal subluxations

- **Trisomy 8:**
  - Great toe clawing
  - Talipes equinovarus.

At all ages, it may be difficult to conduct an adequate foot examination but the standing posture, gait, and function should be observed with a particular focus on lower limb alignment and asymmetry. A generalized neuromuscular examination should be performed in addition to a survey of all lower limb joints and the spine.

The simplest active movements of the foot and ankle are dorsiflexion and plantar flexion but this movement is not confined to one standard axis. In the hindfoot joints, all movement is around an oblique axis such that dorsiflexion includes elements of both...
external rotation (motion around a vertical axis) and pronation (motion around a longitudinal axis). Plantar flexion includes an element of internal rotation and supination. Inversion as an active movement not only has supination but also plantar flexion and internal rotation; eversion includes mainly pronation, dorsiflexion, and external rotation (Figure 13.22.3). All hindfoot joints contribute to these movements and loss of movement at one joint is often disguised by increased movement at another neighbouring joint. Assessment of the passive joint ranges at differing levels helps identify this.

![Click to view larger](Fig. 13.22.3 Motion is complex occurring in all three planes: A: vertical axis; B: transverse axis; C: longitudinal axis. See text for details.)

The neonatal foot may be relatively easy to examine but careful observation is necessary to assess muscle activity and power. The neonate and young infant are best examined in an informal manner with the child supported on the parent's knee and distracted by suitable activity. In the older child, a more formal structured examination becomes feasible.

### Investigation

Children over the age of 4 years can generally stand for AP and lateral weight-bearing radiographs that allow the foot to be seen in its fully loaded position. The site of deformity can be identified and measurements made with reference to the weight-bearing surface to document progressive deformity. Under this age, non-weight-bearing films are accepted. An oblique view may demonstrate abnormalities of the midtarsal and tarsometatarsal regions identifying accessory ossicles or coalitions.

In the child, bone scans can be helpful in isolating inflammatory and infective aetiologies, while computed tomography (CT) and magnetic resonance (MR) scans are useful in the diagnosis and assessment of anatomic abnormalities such as coalitions (Figure 13.22.4) and soft tissue disorders. Three-dimensional CT imaging has a potential role in planning surgical intervention (Figure 13.22.5).

![Click to view larger](Fig. 13.22.4 Coronal CT scan showing a talocalcaneal coalition involving the sustentaculum tali and the medial portion of the posterior facet.)
Postural foot deformities

These deformities arise in late pregnancy, in an otherwise normal limb, and are generally due to fetal crowding and consequent moulding secondary to oligohydramnios or a twin pregnancy. They are characterized by the lack of significant structural changes and the ease with which they correct, usually spontaneously, soon after birth. Their greatest significance lies in the increased joint laxity with which they may be associated.

Talipes calcaneovalgus (Box 13.22.3)

This condition, the most common postural foot deformity, is associated with other postural deformities such as torticollis, plagiocephaly, infantile skeletal skew, developmental hip dysplasia, and hyperextension deformity of the knee. It is more common in girls. The foot is dorsiflexed with a variable degree of eversion. Most feet are passively correctible and improve promptly but if the soft tissues over the dorsum of the ankle are tight, stretching exercises are advocated.

Metatarsus adductus

Metatarsus adductus is a common benign postural deformity. It is often bilateral and associated with DDH as part of fetal moulding. The child often presents with an in-toeing gait with the abnormality confined to the forefoot. The metatarsals are adducted at the level of the tarsometatarsal joint and the severity of the deformity is assessed by the cunature of the medial border and whether the deformity is correctible or not (Table 13.22.1) (Figure 13.22.6). The forefoot may be supinated as well as adducted. A stiff foot with a deep medial sulcus represents a severe deformity.

Fig. 13.22.6
Clinical photograph demonstrating metatarsus adductus. The hindfoot is normal.

Plain radiographs of the foot are rarely needed but demonstrate the abnormal alignment of the forefoot compared to the hindfoot. The vast majority of cases resolve by the age of 3 years. Although widely advocated, stretching exercises probably make little difference to the long-term outcome. Straight or reverse-last shoes have been recommended in children with flexible deformities and serial casting may be helpful in rigid deformities.

Significant persistent deformity beyond the age of 4 years may warrant surgical treatment. Up to the age of 6 years, soft tissue procedures (abductor hallucis recession, medial release, and tarsometatarsal release) may suffice. In older children with more rigid deformities, osteotomy of either the metatarsals or preferably the midfoot (lateral closing, medial opening wedge osteotomies) should be considered.

**Box 13.22.3 Talipes calcaneovalgus deformity**

- Exclude associated conditions such as developmental dysplasia of the hip
- Differentiate this postural deformity from structural vertical talus with equinovalgus position.

**Structural foot deformities**

Isolated forefoot anomalies may occur but they are often associated with more proximal problems and the foot must be examined carefully to identify them. The most frequent hindfoot and midfoot abnormalities lead to a position that is planus (flatfooted) and valgus, or cavus (high arched) and varus.

**The planovalgus foot**

**The flexible flat foot**

Flexible flat feet are found in up to 30% of the adult population so it is important to differentiate between the healthy ‘normal’ flatfoot and the ‘pathological’ flat foot that becomes mechanically inefficient and therefore symptomatic.

**Pathological anatomy**

The characteristic feature of the flatfoot is loss of the medial longitudinal arch. In the hindfoot there is plantar flexion and medial rotation of the talus that almost certainly becomes pathological at the point when the calcaneonavicular (spring) ligament fails, perhaps due to increasing laxity. This change in alignment has secondary effects: the calcaneum moves into valgus altering the line of pull of the Achilles tendon. This then becomes tight in its laterally displaced position limiting the ability of the heel to return to a neutral or varus position. In the normal foot the calcaneocuboid joint (CCJ) movement is approximately half that of the talonavicular joint, primarily because of its more complex anatomical shape. With hindfoot deformity, the CCJ becomes subluxed, effectively fixing the position of the forefoot; further deformity of forefoot abduction and supination can occur and if secondary contractures develop the deformity becomes fixed.

It is useful to consider whether the foot is primarily rigid or flexible. The ‘surgical sieve’ can be considered for each category. Asymmetry can indicate unilateral pathology as in the unusual event of a laceration of the tibialis posterior tendon or involvement of the subtalar joint with an inflammatory arthritis. The flexible foot may be normal or associated with excessive and generalized joint laxity commonly seen in conditions such as Ehlers–Danlos, Marfan, trisomy 21, and osteogenesis imperfecta. Other causes of acquired flatfoot are muscle imbalance, contractures, and arthritic conditions.

**Clinical evaluation**

Flat feet may present with problems due to ill-fitting shoes or with concerns about abnormal shoewear. As the child progresses into puberty, particularly if he or she is obese, there may be aching discomfort. These minor problems settle at maturity. The flexibility of the foot is determined by watching the behaviour of the longitudinal arch in walking and during tip-toe standing. The latter should improve the longitudinal arch whilst the calcaneum swings into varus. Passive dorsiflexion of the first toe as the child stands (Jack’s test) should produce the same appearance.

**Investigation**

Standing anteroposterior and lateral films identify the site of joint subluxation. Primary and secondary deformity can occur at any joint along the medial column but the talonavicular joint is the most common level. The navicular becomes abducted and dorsiflexed relative to the talus. Although the overall appearance is one of a pronated foot, differential dorsiflexion of the first ray and plantar flexion of the fifth ray may produce relative supination of the forefoot with respect to the hindfoot. The overall alignment of bones and joints can be measured and compared both with normal values and on serial films. Although these angles may illustrate the severity of the deformity, their main purpose is in monitoring its progression.
Treatment

Several factors should be considered before treatment is advocated.

Non-operative

Treatment of the asymptomatic mobile flat foot is unnecessary. These children have a normal exercise tolerance. If abnormal shoewear is causing problems, insoles may improve matters.

Box 13.22.4 Should flat feet be treated?

Consider:

- Age
- Severity and rate of progression of the deformity
- Shoewear
- Symptoms—the most important factor.

Some flat feet, despite having mobile joints, are functionally rigid because of the severity of their joint laxity or because the muscles have undergone secondary contracture. Exercises that stretch the gastrocsoleus complex and strengthen the tibialis posterior muscle may be important: once the foot regains its flexibility, orthotic supports can be used to maintain the neutral foot position. This may prevent symptoms and the tendency for contractures to occur which place an increasing pressure on the foot to deform as it grows. Evidence suggests that a variety of customized devices can control foot position and some studies have shown additional benefits including pain relief and improvement in gait pattern. Other studies suggest that such benefits are only seen in the more severely deformed feet. It is probable that if this form of symptomatic treatment is to be successful, it must continue throughout the adolescent growth spurt.

Operative

It is inappropriate to consider surgery in the vast majority of children with a flexible flat foot. The small group of children who have a functionally rigid foot associated with increased joint laxity may be suitable for surgical treatment if their deformity becomes progressive and there is a functional deficit with symptoms. Pain is often felt medially due to strain of the tibialis posterior and the medial capsular structures or laterally secondary to impingement in the sinus tarsi or between the lateral malleolus and the calcaneum. Operative treatment should only be considered if all conservative methods have failed to relieve symptoms or prevent progressive deformity. Surgery may involve soft tissue procedures, osteotomies or fusion of selected joints.

In planning surgical management, several factors must be considered. Soft tissue procedures include those that aim to reef or tighten the medial ligamentous structures and those which seek to redirect the pull of various tendons in the foot, but they are rarely performed in isolation. Osteotomies correct the valgus position of the calcaneum or lengthen the functionally short lateral border of the foot. Arthrodesis of one or more of the hindfoot joints is a last resort.

Box 13.22.5 Surgery for the flexible flat foot

- Options:
  - Soft tissue release/rebalancing
  - Osteotomy
  - Arthrodesis: hindfoot or midfoot or triple

- Factors to be considered:
  - Heel position
  - TA contracture
  - Severity of joint involvement:
    - Subluxation of midfoot
    - Presence/rigidity of forefoot supination
    - Degenerative change.

The rigid flat foot

Congenital tarsal coalition (Box 13.22.6)

The overall incidence of this condition is less than 1%. Occasionally they are associated with carpal coalitions. There is evidence
Coalitions are classified according to the site of involvement and whether they are part of a complex malformation or not. Coalitions may be complete or incomplete, or may be bony (synostosis), cartilaginous (synchondrosis) or fibrous (syndesmosis).

Clinical evaluation

Although present from birth, they are rarely recognized before the adolescent growth spurt when the coalition becomes partially or completely ossified. This leads to a reduction in hindfoot movement that may be associated with pain, especially if the coalition is fibrous. Patients may also present with deformity. A planovalgus foot may be associated with peroneal muscle spasm (peroneal spastic flatfoot) whilst a heel with mild varus and reduced subtalar movement may present with symptoms of ankle instability.

As a simple screening test, the lack of a longitudinal arch when the flat-footed child stands on tip-toe is highly suggestive of a coalition. In the presence of a coalition, inversion/eversion may appear to be preserved but in reality the movement is often occurring at ankle level.

Investigation

Initial anteroposterior, lateral, and oblique views may show talonavicular and calcaneocuboid coalitions (Figure 13.22.7). Talocalcaneal bars are the most difficult to diagnose radiologically; they may be seen on an axial view of the calcaneum and by the 'C' sign on a lateral view of the hindfoot (Figure 13.22.8). Imaging techniques such as CT and MRI scanning (Figure 13.22.4) are more helpful and will also reveal incomplete and fibrous coalitions.

Treatment

Initially, activity restriction or a period of cast immobilization may help but if symptoms persist then surgical treatment is warranted (Box 13.22.7). The nature of the surgery will depend on the age of presentation and the type, site and extent of the coalition. The options lie between bar excision and fusion. Arthrodesis should only be considered for non-resectable bars, for joints with extensive involvement or in the older patient where there is evidence of joint degeneration. Bar excision results in good relief of pain but surgery does not usually lead to a significant improvement in joint motion.

Box 13.22.6 Tarsal coalition

- Common:
  - Talocalcaneal
• Calcaneonavicular

♦ Rare:
  ♦ all others
  ♦ 50% are bilateral
  ♦ More than one coalition may be present per foot
  ♦ Complete or incomplete
  ♦ Bony, cartilaginous, or fibrous.

Box 13.22.7 Surgery for tarsal coalition

If conservative treatment fails:

♦ Excision:
  ♦ Relieves pain
  ♦ Does not restore movement

♦ Arthrodesis:
  ♦ For extensive talocalcaneal bars
  ♦ Greater than 50% of the posterior facet of the subtalar joint on CT
  ♦ If degenerative change present.

Congenital vertical talus (Box 13.22.8)

This rare disorder has an equal sex distribution and the majority of cases occur bilaterally. It may occur as an isolated deformity or in combination with other congenital malformations.

The primary deformity is a dorsal dislocation of the navicular onto the talar neck effectively locking the talus in the vertical position. The secondary deformities of hindfoot equinus and forefoot dorsiflexion and eversion arise from this producing the typical rocker-bottom foot (Figure 13.22.9).

Clinical evaluation

The sole of the foot is convex with the talar head prominent on its medial aspect. The forefoot is abducted and dorsiflexed while the hindfoot is in equinovarus. The muscles of the anterior and lateral compartments are tight. The deformity is rigid such that there is no restoration of the longitudinal arch with any foot position. Passive correction of the deformity is not possible.

Investigation

On plain lateral radiographs the talus lies vertically with its axis parallel to that of the tibia. The calcaneus is in equinus and the forefoot is dorsiflexed. In infancy, the cartilaginous navicular is not visible but later, when ossified, it can be seen lying on the dorsum of the neck of the talus (Figure 13.22.10).
Fig. 13.22.10
Weight-bearing lateral radiograph demonstrating a vertical talus. The navicular is displaced dorsally and is 'articulating' with the talar neck.

Treatment

The aim of treatment is to reduce the talonavicular joint dislocation and restore normal alignment of the forefoot on the hindfoot and the hindfoot on the tibia.

Non-operative treatment is with passive stretching, which should be started as soon as possible after birth. The principles of the Ponseti management of the talipes equinovarus deformity have been 'reversed' and used with some success for this equinovarus deformity. Once the talonavicular joint has been reduced, it is stabilized with a K-wire. A tenotomy of the Achilles tendon is then performed to achieve ankle dorsiflexion. Foot abduction orthoses (‘boots and bars’) are used and supplemented with AFOs once the child is able to weight-bear.

If these measures fail to reduce the dislocation, operative management will be necessary. A full peritalar release is often required. Many surgeons transfer the tibialis anterior tendon to the talar neck in addition to reefing the tibialis posterior tendon and the stretched capsular tissues on the inferior aspect of dislocated joint. In syndromic cases, talectomy may need to be performed as a primary procedure although usually it has been reserved for management of the relapsed foot with significant recurrent deformity.

In older children, soft tissue procedures alone are unlikely to be successful, and excision of the navicular has been advocated. After the age of 6, open reduction is associated with a significant risk of avascular necrosis of the talus, and in children presenting at this late stage, it is better to delay surgery until a triple fusion is appropriate.

  - Myelomeningocele
  - Arthrogryposis
  - Trisomy 18.

The cavovarus foot

A variety of foot deformities present with a high longitudinal arch. This may be due to abnormalities in the hindfoot, the forefoot, or both and a significant number of children will have an underlying neurological abnormality.

Pes cavus

Pes cavus is a high arched foot where the longitudinal arch fails to flatten with weight-bearing. A high arched foot has an angle of 150 degrees or less between the long axes of the first metatarsal and calcaneum on a standing lateral radiograph.

Pathological anatomy

The calcaneum is dorsiflexed and often in varus. The forefoot deformity varies but frequently involves a degree of plantar flexion of the metatarsals. Claw toes are commonly seen in the cavus foot along with tightness of the plantar fascia. At the metatarsophalangeal joints (MTPJs), there is a range of deformity from fully mobile claw toes to toes that are dorsally dislocated.

The hindfoot varus may be due primarily to a stiff subtalar joint or, more commonly, it may be secondary to plantarflexion of the medial metatarsals relative to the lateral rays. This differential plantarflexion pronates the forefoot which can only be accommodated if the hindfoot goes into varus.
Feet with a cavus deformity can be classified according to the level of the aetiological insult within the neuromuscular system (Table 13.22.2). In children, dysraphism, cerebral palsy, undercorrected clubfoot, and arthrogryposis are the most common causes of cavus feet.

Clinical evaluation

In children, the family history is crucial. The age of onset of the deformity may indicate the likely cause and predict the rate of progression. Evidence of progression must always be documented carefully. Each component of the foot (hindfoot, midfoot, forefoot) must be examined in turn to define the deformity and ascertain whether it is flexible or fixed. The Coleman block test is particularly important when assessing hindfoot varus. It tests the flexibility of the hindfoot in the presence of fixed forefoot deformity.

The neurological examination must include assessment of the spine especially when there is asymmetrical foot involvement.

Investigation (Box 13.22.9)

Standard weight-bearing radiographs are important in assessing the degree of deformity, monitoring its progression and planning treatment. If the calcaneal pitch, (the angle between the plantar surface of the calcaneum and the weight-bearing surface) is greater than 30 degrees, the calcaneum is excessively dorsiflexed. Spinal radiographs supplemented with MRI are often required to identify treatable causes of a progressive neurological lesion.

Other investigations may be necessary to identify the neurological cause.

Management

Non-operative

Stretching exercises for the Achilles tendon, other long tendons, and plantar structures should be performed regularly. A flexible deformity can be held with an AFO or balanced with outside wedges on the shoes or by posting the outer border of an insole. Appropriate, customized shoewear can be used to accommodate a fixed deformity. The aim of treatment is to reduce pain and prevent progression of deformity.

Box 13.22.9 Pes cavus—investigations

- Plain radiographs and MRI spine
- Biopsy of nerve and/or muscle
- Nerve conduction studies
- Gait analysis.

Operative (Box 13.22.10)

In childhood the deformity is usually mobile. Release of the soft tissues of the longitudinal arch in combination with tendon transfers may help to correct deformities and rebalance muscle pulls which should reduce recurrence.

Correction of claw toes can be achieved by soft tissue surgery in children. In the younger child with significant growth potential, the
great toe can be corrected by a modified Jones procedure where the long extensor is used both to elevate the first metatarsal by transfer to the neck of the metatarsal and to tenodese the interphalangeal joint (IPJ). Alternatively, the long extensor can be transferred to peroneus tertius. The older child may undergo a more traditional Jones procedure where the IPJ is fused. The lesser toes can be treated by a variety of methods including tendon transfer although IPJ fusions are often required eventually.

Box 13.22.10 Tendon transfers for the cavovarus foot

- Correct fixed deformity first
- Peroneus longus to brevis
- Tibialis posterior to PB or to the lateral border
- Transfer toe extensors to peroneus tertius or the metatarsal necks.

If the deformity is fixed, bony surgery is usually necessary. In general, arthrodesis should not be performed in a growing foot. Midfoot and hindfoot osteotomies can be performed. Metatarsal or midfoot osteotomies may correct fixed plantar flexion. A calcaneal osteotomy will correct a varus heel. In adolescence, a triple arthrodesis can be considered in order to stabilize the foot in a plantigrade position.

The skew foot

This uncommon deformity is characterized by hindfoot valgus and forefoot adduction and supination. Historically, many such feet were a result of aggressive surgery for a congenital talipes equinovarus deformity. The primary deformity is felt to be medial subluxation of the tarsometatarsal joints leading to fixed forefoot adduction. The talonavicular joint is subluxed dorsolaterally.

In infancy, this condition must be differentiated from congenital talipes equinovarus and metatarsus adductus which both have an adducted forefoot with a medial skin crease. The distinguishing features are in the midfoot and hindfoot. In talipes equinovarus, the hindfoot is fixed in equinus and varus but in the skew foot the hindfoot is in valgus although this may be difficult to appreciate in the newborn. The midfoot changes differentiate skew foot from metatarsus adductus: the medial border of the foot is concave in metatarsus adductus but in the skew foot, there is a medial convexity at the level of the talonavicular joint proximal to the forefoot concavity (Figure 13.22.11).

Investigation

Weight-bearing anteroposterior and lateral views reveal the hindfoot valgus and the forefoot adductus. The midfoot is shifted laterally with respect to the hindfoot. The lateral view may show a degree of midfoot cavus.

Management

The natural history of the skew foot is unclear. While some may correct either spontaneously or with simple measures such as serial casting, others persist to cause long-term disability. Casting may correct the forefoot adductus, but will have limited effect on the hindfoot valgus. If the Achilles tendon shortens, the hindfoot valgus is accentuated.

Symptomatic skew feet generally require operative treatment. Stretching the Achilles tendon may benefit those with plantar heel pain. All components of the deformity must be addressed. A calcaneal lengthening osteotomy to correct hindfoot valgus has good long-term results but should be combined with a forefoot correction, which might entail a medially based opening wedge osteotomy of the medial cuneiform and a closing wedge of the cuboid. The Achilles tendon may need lengthening to allow full correction of the hindfoot deformity.

Forefoot abnormalities

Congenital hallux varus
The hallux is in varus. It is important to establish whether this is an isolated abnormality or part of a more generalized condition. There is medial deviation of the proximal phalanx of the hallux.

**Pathological anatomy**

Three types of hallux varus can be recognized. The first is an isolated or local type where the primary abnormality is a tight band of tissue extending along the medial side of the foot. The effect of this band is to pull the great toe further into varus with growth. A second group relates to patients who have a set of congenital deformities including a marked varus of the first metatarsal, which is also short and broad. There may be an adjacent medial accessory bone. This type may be due to a longitudinal epiphyseal bracket. Finally, it can occur in more generalized conditions such as diastrophic dysplasia. Plain radiographs will distinguish the different types of the condition.

**Management**

Non-operative treatment has little or no effect. Surgical correction involves lengthening the tight medial structures and stabilizing the first MTPJ. Temporary K-wire fixation of the joint is needed. If there is varus deviation of the first metatarsal, a metatarsal osteotomy is indicated. In the second type, the growth disturbance of the first metatarsal may contribute to recurrence after surgery. In these cases, it may be necessary to syndactylize the first and second toes in order to prevent progressive deformity.

**Adolescent hallux valgus**

This is a relatively uncommon condition. The familial incidence is higher in adolescent hallux valgus compared to the adult onset type of hallux valgus. It is significantly more common in girls and its development may be influenced by footwear. Shoes with a narrow toe box force the hallux into a valgus position whilst high heels transfer weight from the lesser metatarsals medially and may also contribute to the deformity. There may be an associated primary varus angulation of the first metatarsal.

**Clinical evaluation**

The foot should be examined weight-bearing to determine the true degree of valgus and pronation. As with all childhood foot deformities, a neurological cause must be excluded.

**Investigation (Box 13.22.11)**

Weight-bearing anteroposterior radiographs are essential and various angular measurements should be made.

**Management**

Initial management should be non-operative with shoe wear modification. If the deformity is progressive or symptoms are severe, surgery may be warranted. Soft-tissue procedures alone are frequently unsuccessful. If the intermetatarsal angle between the first and second metatarsals is 15–20 degrees (metatarsus primus varus), a distal metatarsal osteotomy may suffice. Larger intermetatarsal angles require a more proximal osteotomy such as the Scarf combined with distal soft tissue realignment. Recurrence rates are higher than in mature feet.

**Congenital hallux valgus interphalangeus**

This is a congenital, often bilateral, condition where there is marked lateral deviation at the IPJ of the hallux. In young children, the condition is generally asymptomatic. Local irritation over the IPJ may cause problems in adolescence in which case a medial closing-wedge osteotomy of the proximal phalanx will correct the deformity.

**Congenital cleft foot**

This rare congenital anomaly is characterized by absence of two or three of the central rays of the foot and inherited as an autosomal dominant trait with incomplete penetrance. It is bilateral and often associated with cleft hand and other anomalies. Unilateral cases are sporadic in nature. The incidence is reported to be 1: 90 000 live births (see Figure 13.22.1).

**Clinical evaluation**

The hindfoot is normal but the central rays of the forefoot are absent to a variable degree. The classification system (Table 13.22.3) is based on degree of metatarsal deficiency. Types IV and V are the most common forms.

</tbody>
</table>

Management

The foot usually functions well and no surgery is necessary in the milder forms. Surgery is usually indicated for cosmetic reasons and to improve shoe wear. The foot is narrowed by basal metatarsal osteotomies and/or reduction of subluxed tarsometatarsal joints with closure of the cleft and soft tissue reconstruction. It is important to ensure that the resultant foot is supple and plantigrade. Surgery is usually performed between 1–2 years of age.

Box 13.22.11 Radiographic assessment of hallux valgus

- Intermetatarsal angle (<12 degrees)

Lesser ray problems

Curly toes

This common congenital condition affects one or more toes. It is usually bilateral, symmetrical and often familial. The affected toes (usually third and/or fourth) curl medially and tend to lie under the neighbouring toe. A tenotomy of all flexor tendons to the affected toe is often recommended for cosmetic reasons. An osteotomy performed later may be more effective in producing a lasting result.

Congenital overriding little (fifth) toe (Box 13.22.12)

This common familial abnormality is often bilateral. The toe is dorsiflexed and adducted, overlying the fourth toe. The MPTJ is subluxed due to capsular contracture. Symptoms develop in about 50% of cases. Non-operative treatment methods (stretching, strapping) are rarely successful. Surgical treatment is warranted for symptom relief or for cosmesis and is usually successful. Recurrence may occur but bony surgery such as proximal phalangeotomy is rarely indicated and never in a child.

Macroductyly

This is a rare deformity that may be secondary to neurofibromatosis (NF), haemangiomatosis, or congenital hyperplasia of the lymphatic and adipose tissue. The diagnosis of NF must be excluded by careful clinical examination. In true gigantism, there is an increase in size of all the elements of the toe. The degree of hypertrophy is variable: sometimes the deformity is static in that the increase in size is proportionate to growth but in others there is progressive disproportionate growth. If the appearance is unacceptable, surgery is indicated. Several procedures have been described, none of which is very successful. Simple debulking and epiphysiodesis is frequently followed by recurrence. Ray amputation may be indicated in severe cases of recurrence but may be complicated by the development of hallux valgus.

Box 13.22.12 The overriding fifth toe—surgical management

- Soft tissue release: V–Y plasty
- Extensor tendon lengthening
- Circumferential MTP joint capsulotomy.

Polyductyly
Polydactyly is a common deformity occurring in 2:1000 live births (see Figure 13.22). It is often inherited in an autosomal dominant fashion but sporadic cases do occur. There may be associated polydactyly of the hand or other major congenital malformations such as tibial aplasia. It is also seen in syndromes such as Ellis–van Creveld syndrome and chondroectodermal dysplasia.

The extra toe may be preaxial (15%), postaxial (80%), or central. The child must be assessed thoroughly to look for associated malformations. The extra digit may be either fully formed or rudimentary. Plain radiographs will show the level and extent of bony duplication.

The extra toe should be excised both for cosmetic reasons and for shoe fitting although some cultures are opposed to this. The operation is best performed when the child is around 9–12 months old. Generally the most peripheral toe is excised, although radiographic appearances must be considered.

Miscellaneous conditions

Osteochondroses

Osteochondroses affect active growth areas and involve a defect in ossification in either an epiphysis or an apophysis. They generally occur soon after the ossific nucleus has appeared when the epiphysis is growing rapidly. Most are more common in boys.

Kohler’s disease

Osteochondritis of the navicular occurs predominantly in children aged 3–6 years. Boys are more commonly affected and up to 33% are bilateral. The navicular is the last bone of the foot to ossify and may be subjected to significant pressures while still cartilaginous as it is the keystone to the longitudinal arch. Histologically, avascular necrosis is seen.

Clinically, there is pain, swelling, and tenderness around the navicular and the child limps. There may be surrounding warmth and erythema but the normal movement at the mid-tarsal and subtalar joints distinguishes this from inflammatory arthritides.

Radiographs show a small, sclerotic ossific nucleus and diagnosis rests on the combination of radiographic appearances and the clinical picture (Figure 13.22.12).

Fig. 13.22.12
Kohler’s disease of the navicular. The radiograph shows a sclerotic ossific nucleus.

The condition is self-limiting and the prognosis good. Symptomatic improvement usually occurs within a few months. If symptoms are severe, a period of immobilization in a cast may be warranted.

Sever’s disease

Osteochondritis of the calcaneal apophysis affects boys predominantly between the ages of 8, when the apophysis first appears, and 12 years, when it fuses with the parent bone. It is a common cause of heel pain in the immature athlete, probably related to overuse. The diagnosis rests on clinical symptoms and signs. There is pain and tenderness around the insertion of the Achilles tendon to the calcaneum. Radiographs show sclerosis and fragmentation of the calcaneal apophysis, features which are consistent with normal apophyseal development.

Like the other osteochondritis, this is a self-limiting condition and symptoms abate once the apophysis has fused. Stretching the gastrocnemius and soleus with strengthening of the anterior muscles helps to reduce symptoms and activity should be reduced. A period of rest in plaster may be necessary to control symptoms.

Freiberg’s disease

Infraction of the metatarsal head occurs in adolescents, mainly girls, and may be bilateral. Although any metatarsal can be affected, it is most frequently the second, perhaps because it is the longest and subject to overloading of the MTP joint. Clinically, there is pain under the metatarsal head with swelling, tenderness and restriction of MTPJ movement particularly dorsiflexion.

Radiographs shows flattening and irregularity of the metatarsal head with sclerosis and metatarsal shaft hypertrophy.

Initial treatment is conservative. Often all that is required is modification of shoewear and activity levels. A metatarsal bar may offload the joint. If symptoms persist, curettage and bone grafting of the defect is indicated. At skeletal maturity, if there are
ongoing severe symptoms, a dorsiflexion osteotomy may be necessary. Debridement of the metatarsal head or resection of the base of the proximal phalanx is a salvage procedure.

**Congenital constriction bands**

Congenital constriction band syndrome (Streeter’s dysplasia) is believed to be due to constriction of the limb by amniotic bands. The bands may be either partial or complete. The clinical picture is variable but includes congenital amputations, syndactyly and equinovarus foot deformities (Figure 13.22.13). The bands can cause obstruction to venous and lymphatic drainage and Z-plasties may be required urgently in the neonatal period. The clubfoot deformity may be resistant to conservative treatment.

**Accessory ossific centres**

Almost a quarter of children have one or more accessory bones visible on radiographs. Many are unimportant but some may cause problems in childhood.

**Accessory navicular (Box 13.22.13)**

The accessory navicular represents a separate ossification centre for the navicular tuberosity. Three types have been described (see Table 13.22.4). Generally, the accessory centre fuses with the main ossific nucleus but in about 2% of people it remains as a separate ossicle. The tendon of tibialis posterior is therefore attached to the medial aspect rather than the inferior aspect of the navicular, weakening the support for the longitudinal arch, and the foot becomes planovalgus. Midfoot pain may develop after activity, together with tenosynovitis of the tibialis posterior tendon. Pressure from shoe wear may lead to local pain, swelling and tenderness.

<table>

<td>II</td>
<td>An ossicle connected to the navicular via a synchondrosis</td>
</tr>
<tr>
<td>III</td>
<td>A comunate navicular after a synostosis between the accessory and main ossific nucleus</td>
</tr>
</tbody>
</table>

Anteroposterior and external oblique radiographs reveal the accessory navicular located on the proximal medial aspect of the navicular. Its smooth outline distinguishes it from a fracture (Figure 13.22.14). The bipartite navicular appears on the dorsal surface of the navicular as a separate comma-shaped segment and is a separate entity from the accessory navicular.
Non-operative treatment is indicated initially. An orthosis may be useful if there is a flexible hindfoot valgus. A short period in a plaster cast with or without a local anaesthetic injection of the synchondrosis may settle acute symptoms. Persistent symptoms may warrant surgery. The Kidner procedure involves excision of the accessory navicular and advancement of the tibialis posterior tendon onto the plantar surface of the navicular but simple excision of the accessory navicular with trimming of any residual prominence is a simpler and equally reliable alternative.

**Os trigonum**

An os trigonum is seen in nearly 10% of the population. It represents failure of fusion of the posterolateral tubercle of the talus with the main ossific centre. Repetitive minor trauma may be an aetiological factor.

The main clinical features are pain around the posterior aspect of the ankle and limitation of plantar flexion and it is frequently seen in ballet dancers and gymnasts. It must be distinguished from flexor hallucis longus tendinitis, although the two conditions coexist. Radiographs reveal an ossicle at the posterior aspect of the talus. Non-operative treatment consists of limiting ankle plantar flexion. Local steroid injections may help control symptoms and open excision may be warranted for persistent symptoms.

Sports injuries and syndromes

Summary points

- Paediatric sports medicine is an evolving multidisciplinary specialty with increasing rates of injury in paediatric athletes:
  - Injury prevention programmes are important
  - Training regimes must be adapted to the age group and the sport

- Sports injuries to the immature skeleton require different treatment approaches to those in adults even when injury patterns appear similar
  - The knee is the most commonly injured region—anterior cruciate ligament ruptures in children and adolescents are higher than previously appreciated
  - Upper limb paediatric sports injuries are more commonly secondary to overuse than acute injury—physiotherapy and activity modification are the mainstays of treatment.

Introduction

As a truly multidisciplinary specialty, sports medicine crosses traditional medical boundaries. The focus of this chapter is on sports-related injuries, rather than injuries from accidents but the epidemiological data for such injuries are sparse for some disciplines and studies use varying definitions and methodology. Nonetheless, it is clear that the majority of children and adolescents aged 5–17 years participate in organized sport in both the United Kingdom and United States of America that accounts for a significant proportion of injuries in this age group. For most sports, the knee is the most common site of injury. Increased participation in competitive sport is reflected in a 15% increase in reported knee injuries in the under 17-year age group between 1996 and 2001 despite increased injury prevention programmes.

Injuries in children secondary to sports trauma are modulated by the unique properties of the growing musculoskeletal system with vulnerable epiphyseal and apophyseal cartilage plates but with greater capacity for healing and remodelling than in adults.

Lower limb injuries

Knee injuries

Meniscal injury

If discoid menisci and other congenital malformations are excluded, meniscal injuries in the immature athlete are uncommon, particularly under the age of 10 years. Their incidence is on the increase, however, with greater and more vigorous sports participation. The menisci are similar in structure and function to those in the adult but differ critically in their increased vascularity and thus improved potential for healing. Magnetic resonance imaging (MRI) is less accurate in the diagnosis of meniscal tears in children compared to adults so reliance on clinical evaluation and a lower threshold for repair over excision are the key differences in management of childhood meniscal injury.

The anxious child or apparently indifferent adolescent may not recall a twisting injury or varus/valgus strain and decreasing age and increasing time from the relevant injury further diminish the value of direct questioning. Key features in the clinical examination are the presence of focal joint line tenderness and the presence of an effusion. In the acute setting, this indicates a likely haemarthrosis (Box 13.23.1).

Box 13.23.1 Differential diagnosis of a haemarthrosis

- Meniscal tear:
  - 47% of preadolescents (aged 7–12 years)
  - 45% of adolescents (aged 13–18 years)
- ACL rupture:
  - 47% of preadolescents
  - 65% of adolescents
- Osteochondral fracture: 7% overall
- Extensor mechanism rupture: rare.
There is a high rate of concomitant meniscal and anterior cruciate ligament (ACL) injury in children with haemarthrosis, especially adolescents. With chronic tears, intermittent locking, clicking, or ‘popping’ and the presence of an effusion and quadriceps wasting are common findings.

Despite reports of improved specificity and sensitivity in the diagnosis of meniscal tears using contemporary MRI sequences, this modality is less accurate in children, especially those aged less than 12 years, in part because of differing patterns of vascularity. The presence of joint line tenderness and a modified McMurray’s test in the clinic is at least as accurate for diagnosis as MRI, with arthroscopic evaluation the gold standard for assessment of tear morphology. The majority are vertical longitudinal (‘bucket-handle’) type; oblique, radial, and degenerative tear patterns are seen less commonly than in adults. Standard plain orthogonal radiographs form part of the diagnostic work-up to exclude occult pathology such as infection or bone tumour as a cause for symptoms. Additional skyline patella and tunnel or notch views are helpful to search for osteochondral defects or patellofemoral incongruity.

Short (<10mm) longitudinal tears that are stable when probed can be left to heal. A hinged knee brace permitting 0–60 degrees of flexion restricts activity for 4–6 weeks. All other unstable and arthroscopically reducible tears should undergo repair, particularly if anterior cruciate ligament reconstruction is also required. A combined repair is associated with improved healing rates, most likely reflecting an enhanced vascular response. Similarly, in chronic tears, local preparation of the tear site with an arthroscopic shaver or rasp is advisable to promote vascular ingress. Early meniscal resection causes increased joint contact stresses which are associated with osteoarthritis. Adult guidelines for repair versus excision, based on tear location in relation to centrally decreasing zones of vascularity, are less relevant in children with greater healing capacity, except perhaps for very central tears which can be debrided back to a stable rim.

Arthroscopic techniques for meniscal repair include placement of ‘inside-out’ or ‘outside-in’ sutures, employing polaromedial or posterolateral incisions to protect the saphenous and peroneal nerves for posterior horn tears. The latest generation of ‘all-inside’ suture passing kits with an appropriate tissue-guard and straight and curved needle tips are increasingly favoured over the ‘inside-out’ technique for most tears. Exceptions include anterior horn tears which are difficult to access and are an indication for ‘outside-in’ suture placement. Similarly, concerns about the ‘all-inside’ needle damaging structures behind the capsule in a small knee mean the ‘inside-out’ technique is preferred with posterior horn tears in younger children. A hinged knee brace restricted to 60 degrees of flexion should be worn for 6 weeks after meniscal repair, followed by a gradual return to sport once a full range of knee motion has been restored. Larger and more chronic tears may benefit from a period of partial weight bearing postoperatively but clear guidance regarding rehabilitation is lacking.

Anterior cruciate ligament injuries

ACL injuries in the skeletally immature knee are currently a focus for debate. It is increasingly clear that ACL deficiency in this age group is associated with high rates of symptomatic instability and secondary osteochondral and meniscal damage. Techniques for anatomical placement of a tunnelled, intra-articular graft reconstruction have been refined in the last 20 years for adult injuries. In children and adolescents, the open physes around the knee account for two-thirds of lower limb growth. Damaging either risks limb length discrepancy or angular deformity that may be difficult to manage. With an increasing incidence of immature ACL injury, especially in female adolescents, interest has focused on whether, when and by what means tunnels can be placed safely around the immature knee. Similarly, older techniques such as non-anatomical reconstruction and primary repair have been revisited.

Below the age of 12 years, ACL failure by tibial spine fracture is much more common than intrasubstance rupture: after this the relative likelihood of these injury patterns is reversed. Meniscal tear is the commonest associated injury but physeal fracture, patellar dislocation, and posterior cruciate ligament injury are also reported.

The hallmark clinical features in the history of a ‘pop’ at the time of injury (sustained during a sudden deceleration, pivoting movement or awkward landing) followed by an immediate haemarthrosis, inability to complete the game, and subsequent instability with a return to cutting sports are much harder to elicit in this younger age group. The Lachman and anterior drawer tests should be performed but the pivot shift test is the best predictor of symptomatic ACL insufficiency although it requires optimal relaxation in the conscious child. Signs of an effusion or meniscal injury should be sought. As mentioned previously, standard radiographs with additional tunnel/notch and skyline patella views may be required to exclude bony injury such as tibial spine avulsion and associated osteochondral lesions. MRI may delineate primary, high signal and/or ligament discontinuity, and secondary, bone bruising, signs of ACL injury. Overall, this modality is less accurate in children and is considered an adjunct to clinical diagnosis determining the presence of associated injuries.

ACL injury in the immature athlete does not require urgent operative intervention in the absence of an associated tibial spine fracture or incarcerated meniscus. A phased non-operative programme of rest followed by restoration of range of movement and strengthening exercises and finally sports rehabilitation is indicated. Recurrent instability with ongoing risk of cumulative damage to the knee should prompt consideration of surgical intervention (Box 13.23.2).

Box 13.23.2 Reconstructive options for ACL injury

- Direct repair
- Physeal sparing techniques:
  - Non-anatomical (non-isometric) with iliotibial band graft taken ‘over the top’ and under transverse inter-meniscal ligament
  - Anatomical using ‘all epiphyseal’ tunnels for graft placement and fixation
Partial trans-physeal—such as ‘over the top’ femoral attachment and transtibial tunnel
Transphyseal—adult-type surgery but with more centrally placed, vertically orientated tunnels.

The physeal-sparing iliotibial band technique is well described for preadolescent children (Tanner Stage 2 or less) with ACL rupture. The iliotibial band is detached proximally but left attached at Gerdy’s tubercle and brought into the knee through the ‘over the top’ position of the femur. It then passes out under the intermeniscal ligament and is secured in a groove in the anteromedial aspect of the proximal tibial epiphysis. Non-anatomical reconstructions such as this are unlikely to be isometric throughout the range of knee motion, predisposing to graft failure and suboptimal function. Furthermore, iatrogenic injury to the perichondrial ring of the distal femoral physis, which is in close proximity to the over-the-top position, predisposes to growth arrest with angular deformity.

Technically challenging, ‘all epiphyseal’ reconstructions involve the placement of short tunnels within the confines of the epiphysis. The undulating femoral physis provides resistance to shear but the projections into the epiphysis increase the risk of damage.

The literature in adult knee ACL reconstruction emphasizes the importance of anatomical tunnel placement to ensure isometric graft function. Animal studies indicate a low risk of growth arrest with violation of up to 7% of the total cross-sectional area of a physis. Six to nine-mm centrally placed tunnels, in the femur or tibia, damage less than 5% of the physis. They have not been associated with angular deformity or limb length discrepancy except when material other than a soft tissue graft is placed across the defect. Hence the consensus recommendation for ACL rupture in the skeletally immature is increasingly for adult-type surgery using soft tissue graft fixation techniques that avoid bone plugs or screws across the physis. Nonetheless this remains an area of controversy. Historically, direct repair has been associated with poor outcomes although there are obvious advantages to this procedure in the immature knee. Interest is now centred on attempts to produce a biological scaffold to augment the repair.

Any consideration of surgical reconstruction requires a careful assessment of skeletal age and development. Growth rate peaks during puberty between 13–15 years bone age in boys and 11–13 years in girls; after this lower limb growth is virtually complete with remaining growth occurring simply through the spine. Chronological age is generally a good guide to skeletal age, but this generalization cannot be applied to individual cases (Box 13.23.3).

**Box 13.23.3 Methods of assessment of skeletal maturity**

- Chronological age
- Gruelich–Pyle atlas comparative method using hand/wrist radiographs to derive bone age
- Sauvegrain method or simplified olecranon method using lateral elbow radiograph
- Tanner and Whitehouse classification of sexual maturity stage
- Patency of triradiate cartilage (closure occurs half way up the accelerating phase of the pubertal growth spurt).

The Gruelich–Pyle atlas method for determining skeletal maturity derives from old population data which may no longer be applicable and bone age determinations for the hand do not always coincide with growth remaining at the knee. Secondary sexual characteristics are staged in the Tanner classification and provide a guide to skeletal growth remaining but these milestones are not familiar to most orthopaedic surgeons and are rarely used. The Sauvegrain or simplified olecranon method of assessment is perhaps the most useful (Figure 13.23.1). At the beginning of puberty, there are two olecranon centres of ossification visible on a lateral elbow radiograph marking the start of the accelerating phase of pubertal growth. Two years later, the olecranon apophysis appears fused and growth decelerates. During the intervening period, morphology of the olecranon ossification centre(s) is a reliable staging guide to the accelerating phase of growth with closure of the triradiate cartilage occurring half way through this phase.

![Click to view larger](Fig. 13.23.1)

Therefore in adolescents approaching skeletal maturity with a fused olecranon and bone age greater than 15 in boys and greater than 13 in girls, adult-type ACL reconstructive surgery is to be preferred when indicated. The same recommendation can be applied.
to younger adolescents providing the physeal tunnels are no greater than 9mm in diameter and bridged by soft tissue graft only. Although tunnelled ACL reconstruction is reported in prepubertal children without secondary growth arrest, this remains controversial and non-anatomical reconstruction avoiding physeal graft placement should be considered even if only as a temporizing measure.

Avulsion fractures of the ACL

This injury pattern is seen mainly in 8–14-year-olds whose ACL is attached to the chondroepiphyses of the distal femur and proximal tibia. These attachments are relatively weak compared to the adult fibrocartilaginous insertions into bone and so, in this age group, ‘the bone ‘fails’ before the (midsubstance) ligament’. Femoral fractures are rare; most are an avulsion of the tibial spine (also known as the tibial eminence).

The mechanism of injury is commonly a valgus force to the knee with rotation or forced flexion. The patient presents with a tense haemarthrosis, reluctance to weight bear, and restricted motion. Anteroposterior and lateral radiographs are indicated (Figure 13.23.2A). Computed tomography (CT) scans are reserved for evaluation of fracture displacement either at presentation or after manipulation. The fractures are classified as a guide to treatment (Table 13.23.1).

![Fig. 13.23.2](image)

A) AP and lateral radiographs of the right knee in a 9-year-old patient demonstrating a type 3 avulsion fracture of the tibial spine. B) AP and lateral radiographs of the same patient following open reduction and screw fixation of the fracture.

</tbody>
</table>

Casting after closed reduction is recommended: the cast position of hyperextension, extension, or flexion 20 degrees does not affect outcome. Entrapment of meniscus or the intermeniscal ligament may block closed reduction. A range of open (mini-arthrotomy) and arthroscopic reduction and fixation methods are reported. There are case reports of anterior physeal arrest with screw fixation across the physis; hence cannulated all-epiphyseal screws are to be preferred (Figure 13.23.2B). Fixation techniques using smooth wires or heavy sutures, which can be passed across the physis via cannulae, are also described.

Slight reduction in motion, with loss of hyperextension and deep flexion, is common but rarely symptomatic: arthrofibrosis is rare. During the original injury, it is postulated that the ligament substance stretches prior to the bone failing and this may be the cause of subsequent knee laxity after the fracture has healed. A study comparing treated tibial spine fractures with ACL deficient and reconstructed knees indicated that reduction with fixation restored both adequate stability and proprioception to the knee after fracture.

Osteochondritis dissecans of the knee (see also Chapter 13.20)

This Latin name describes the tendency of articular cartilage to separate from subchondral bone. The aetiology is unknown but currently the theory of a primary, ischaemic defect of subchondral bone secondary to repetitive microtrauma is popular. The bone then offers inadequate support to the overlying cartilage which subsequently accrues damage.

Presentation is with activity related knee pain and ache postexercise. Local palpation may indicate the site of the lesion. An
Acute patellar dislocation is the most common acute knee disorder in children and adolescents with a peak age incidence of 15 years. The mechanism of injury for the first episode can be identical to that for an ACL rupture. In changing direction whilst running or pivoting the femur rotates internally relative to the tibia which is fixed by a planted foot. This in association with quadriceps contraction causes lateral patella dislocation. Thus, ACL injury and the less common diagnosis of a ruptured extensor mechanism (quadriceps insertion or patella tendon) are included in the differential diagnosis of an acute haemarthrosis with this history.

Relocation often occurs spontaneously on the sports field making the diagnosis less obvious in the Emergency Department. Examination demonstrates tenderness over the ruptured medial patellofemoral ligament (MPFL) or retinaculum and a haemarthrosis, confirmed on aspiration. There is often considerable apprehension to lateral displacement of the patella. There may also be tenderness palpable over the lateral femoral condyle or the medial patella facet which are the common sites for an associated osteochondral fracture. As an osteochondral fracture may be present in 25–50% cases, skyline patella and notch view radiographs in addition to standard films are essential. If an osteochondral fracture is suspected, an MRI is indicated to characterize the fragment: large fragments with sufficient subchondral bone to facilitate reattachment should be repaired, smaller fragments or those with only a sliver of bone should be removed arthroscopically. Arthroscopic reattachment is difficult in the patellofemoral joint and a mini-arthrotomy is usually required.

The rate of recurrent patellar instability after acute dislocation may be as high as 60% in children and adolescents and immediate repair of the ruptured medial restraints to dislocation has been advocated. However, in the acute setting, it can be difficult to delineate the MPFL clearly and to repair it in a durable fashion. A recent study showed that, compared to non-operative management, MPFL repair did not reduce the redislocation rate and therefore in the absence of a significant osteochondral fracture, conservative management with a period of immobilization followed by restoration of motion and quadriceps strength remains the treatment of choice. This rationale accepts a high rate of recurrent instability and the need for a secondary stabilizing procedure in some cases (see Chapter 13.20).

Osteochondral fracture

The relatively high incidence of this injury in adolescents reflects the transition period from the juvenile joint, in which the chondral surface is anchored to the underlying bone by interdiggitations of cartilage, and the adult joint in which the bond is formed orthogonally to this at the calcified cartilage layer (cement line or tidemark). During this period, the knee is at risk of osteochondral fractures. The commonest locations are the medial patella facet and the lateral femoral condyle, reflecting a strong association with acute patella dislocation. For these and other anatomical areas of involvement, the injury is often a direct blow or a twisting mechanism about a fixed foot.
Diagnostic work-up is similar to that for acute patella dislocation, with a low threshold for additional MRI studies. The false negative rate for osteochondral fracture may be over a third with plain radiographs alone. Large fragments should be reattached if possible, particularly when from a weight-bearing area of cartilage. The detached fragment may imbibe joint fluid and swell considerably, particularly if fixation is delayed, such that it must be trimmed to fit back into the defect. Smaller defects with a thin cortical fragment should be removed. Microfracture is indicated for the remaining defect if it is significant and involves a weight-bearing region (Box 13.23.5).

**Box 13.23.5 Radiographic ‘work-up’ of a knee injury**

- AP and lateral plain radiographs
- Tunnel/notch views
- Skyline views of the patella
- MRI to characterize cartilage injury.

Osgood–Schlatter disease and Sinding–Larsen–Johansson syndrome

Osgood–Schlatter disease and Sinding–Larsen Johansson syndrome are typical overuse injuries causing apophysitis of the anterior tibial tubercle and inferior pole of the patella respectively. They are common in active adolescents and associated with local tenderness and palpable swelling (see Chapter 13.20).

Hip injuries and syndromes

Avulsion fractures

Avulsion fractures around the pelvis are common injuries in football, gymnastics, and track and field. They are usually visible on a plain radiograph and are caused by the sudden contraction of powerful muscles against an apophysis. If presentation is delayed, radiographs may demonstrate a large ossified area and clinical examination may reveal an obvious ‘lump’. The possibility of a tumour must be considered but the classic history usually ensures that the avulsion fracture is correctly diagnosed (Figure 13.23.3 and Box 13.23.6).

![Click to view larger](Fig. 13.23.3)

AP radiograph of the pelvis showing an old avulsion fracture of the right ischial tuberosity.

**Box 13.23.6 Common sites for pelvic avulsion fractures**

- Anterior superior iliac spine: sartorius
- Anterior inferior iliac spine: rectus femoris (direct head)
- Ischial tuberosity: hamstrings and adductors.

The vast majority can be managed non-operatively with rest until symptoms subside. Repair may occasionally be indicated in high-demand athletes with symptomatic weakness or pain. Ruptures at the musculotendinous junction of the same muscle groups, particularly the quadriceps, are associated with weakness during kicking and visible bunching of the muscle belly on resisted motion. Repair may be attempted even after delayed presentation, with MRI or ultrasound useful to confirm the diagnosis and
location of the rupture.

'Snapping' hip

A 'popping' or 'snapping' hip, often reported by the patient or family as one which goes in and out of joint, should provoke consideration of an 'internal' snapping psoas tendon or 'external' snapping iliotibial band at the lesser and greater trochanters respectively. The Ganz test of snapped adduction in hip flexion can help differentiate these from a labral tear: injection of contrast into the joint for magnetic resonance arthrogram (MRA) is uncomfortable and best avoided. Physiotherapy is the mainstay of treatment, with injection of local anaesthetic and steroid for refractory cases. Surgical release should only be performed as a last resort: results are often disappointing.

Slipped epiphysis

Any child complaining of groin, thigh, or knee pain should undergo thorough clinical examination, in particular to assess range of hip rotation in flexion. There should be a low threshold for anteroposterior and cross table lateral views of the hip. Slipped capital femoral epiphysis can present with a sports injury and may be misdiagnosed as a 'groin strain': the consequences of missing this diagnosis or making a late diagnosis can be significant. See Chapter 13.19.

Ankle injuries and syndromes

Osteochondral lesions of the talus

Osteochondral lesions of the talus are uncommon but can be a cause of persistent ankle pain in children. In an adult study, lesions of the talar dome were slightly more common on the medial side with lateral lesions occurring more anteriorly and more commonly associated with trauma (see Chapter 14.11) (Figure 13.23.4). The staging system of Bernedt and Harty is a useful guide to prognosis and treatment (Table 13.23.2). Lesions up to Stage 3 can be managed non-operatively with a period of immobilization and a good result expected with open physis. Stage 4 lesions and symptomatic Stage 2/3 lesions that fail to respond to non-operative management can be considered for arthroscopic debridement, drilling, or microfracture. ACI and mosaicplasty is also described but is rarely indicated in the paediatric sports-injured population.

Ankle sprains and instability

Inversion injuries to the ankle are very common. In the paediatric population this can result in injuries to the lateral ligament complex, in particular the anterior talofibular ligament (ATFL), local bony avulsions, and fibular fractures including Salter–Harris injuries of the distal fibular physis. Diagnosis of a soft tissue sprain can be made by eliciting localized tenderness over the ATFL without bony or physeal tenderness. All are managed non-operatively and the vast majority have no persistent symptoms. Chronic pain may be related to instability or non-union of small fracture fragments. Examination may demonstrate a positive anterior drawer sign, indicative of ATFL incompetence, and varus stress radiographs may uncover talar tilt. Again, initial management should be with intensive physiotherapy to restore stability. Good results have been reported with a variety of procedures to repair, reconstruct or otherwise advance the capsular condensations which form the lateral ligament complex in children and adolescents with

persistent and symptomatic ankle instability.

**Upper limb injuries**

Most upper limb sports injuries are subacute and related to overuse. Their increased incidence reflects the earlier and more intensive sports training now seen in the paediatric population. The predominant mechanism is the repetitive overhead motion of the throwing action. This is best characterized for the sport of baseball; however, the biomechanical science is applicable to other disciplines such as tennis and swimming. Gymnastic sports have a particular range of injuries as the upper limbs are required to weight bear for many activities.

**The throwing action**

The throwing action can be divided into distinct phases; wind-up, early and late cocking, acceleration, deceleration, and follow-through. Most injuries are related to the late cocking and acceleration phases due to the extreme range of motion and forces generated in these actions. The late cocking phase places the shoulder in abduction and maximal external rotation generating large shear forces across the rotator cuff muscles and anterior structures. In the acceleration phase the forward force is generated by shoulder internal rotation and adduction combined with rapid elbow extension. This results in a varus force across the elbow with tension across the medial compartment and compression in the radiocapitellar joint. Forceful triceps contraction in elbow extension generates tensile stress at the triceps insertion.

**Shoulder injuries**

**'Little League' shoulder**

Repetitive microtrauma, secondary to rotational torque forces with overhead activity and throwing, can lead to epiphysiolysis of the proximal humeral physis. This is most common in the 11–13-year age group and is often associated with poor technique. The athlete presents with diffuse shoulder pain, exacerbated by the throwing action and often with characteristic radiographic features. MRI may demonstrate signal change in both the proximal humeral metaphysis and the epiphysis.

Treatment is with rest from throwing (which should be prolonged if radiographic changes exist—Box 13.23.7) followed by action modification and a gradual return to sport.

**Box 13.23.7 Radiographic features of epiphysiolysis (epiphyseal stress reaction)**

- Physseal irregularity and/or widening
- Metaphyseal demineralization and fragmentation or cystic changes
- Local periosteal reaction.

**Shoulder instability**

Anterior glenohumeral instability following acute traumatic dislocation is by far the commonest form of shoulder instability seen in the paediatric athlete. Reported recurrent instability approaches a rate of 100% in children with open physes, but in a 25-year prospective series it was only 50% in the 12–16-year age group. Initial management is typically non-operative. Surgery, in the form of an open or arthroscopic repair of the anteroinferior glenoid labrum (Bankart repair), is reserved for those with ongoing instability and the desire to continue with a sport that causes symptoms. There is good evidence of a reduced recurrence risk in young adults immobilized in external rotation for 3 weeks after the primary dislocation but, to date, there is little enthusiasm for this management. Otherwise there is no evidence to recommend immobilization beyond that limited by pain. A good randomized controlled trial of arthroscopic Bankart repair versus arthroscopic lavage alone performed in young adults (under age 30 years) after primary anterior dislocation, demonstrated a 76% reduction in risk of recurrent instability after immediate Bankart repair with better function, satisfaction and rate of return to competitive sports. Despite these results, the authors did not recommend primary operative stabilization for all first time dislocations in this age group because of the risk of over-treatment. However, the primary surgical management of choice would be an arthroscopic Bankart repair.

Multidirectional instability is typically seen in adolescents with underlying generalized hyperlaxity, compounded by an acute traumatic event or repetitive microtrauma. Physical examination of the glenohumeral joint will show increased translation in many planes; however, determining the direction of symptomatic subluxation is crucial as an athlete may display multidirectional laxity without instability. The diagnosis is clinical. Management is with intensive physiotherapy to address altered scapulothoracic biomechanics and dynamic glenohumeral stabilization. Occasionally, MRI or arthroscopy may be helpful to assess cuff or labral damage and to demonstrate redundant capsule.

The immature shoulder may undergo adaptive changes with repetitive overhead activity. Repeated maximal external rotation, particularly in late cocking, causes microtrauma to the anterior capsule and ligament complex creating anterior laxity. This is often associated with posterior capsular hypertrophy and contraction leading to a glenohumeral internal rotation deficit (GIRD). Secondary anterior instability and translation may follow together with internal impingement of the rotator cuff tendon at the posterosuperior rim on the glenoid. The presence of GIRD and anterior hyperlaxity is associated with a significantly increased risk of injury and with secondary adaptive bony changes such as a retroverted glenoid.
Impingement

Rotator cuff impingement in the subacromial space, generally a degenerative condition of early middle age, can occur in the young throwing athlete. Altered scapulothoracic biomechanics lead to a laterally placed, downwardly rotated, and protracted scapula secondary to repetitive overhead activity. The imbalanced scapulothoracic musculature fatigues easily and is often painful. This position of the scapula, particularly in association with GIRD, predisposes to rotator cuff impingement in the subacromial space. Management is with rest and anti-inflammatory medication followed by physiotherapy to address scapulothoracic biomechanics and modification of overhead throwing technique. Subacromial decompression is seldom if ever required in the paediatric athlete.

Elbow injuries

Little Leaguers’ elbow

Some 18–69% of players in the United States of America report some degree of elbow pain, most commonly in pitchers aged 8–16 years. The term ‘Little Leaguers’ elbow’ initially described an avulsion fracture of the medial epicondyle but now encompasses a combination of elbow complaints that occur due to repeated rapid extension in the acceleration phase of throwing leading to valgus strain across the elbow joint. This strain causes tension in the medial structures and compression in the lateral joint. Forceful extension in the acceleration phase and locked extension in the deceleration and follow-through place significant stress on the triceps insertion and olecranon apophysis (Box 13.23.8).

Box 13.23.8 Conditions associated with Little Leaguer’s elbow

- Medial epicondyle apophysitis
- Medial epicondyle epiphysiolysis
- Medial epicondyle fragmentation and avulsion
- OCD of capitellum, trochlear, and radial head
- Hypertrophy of the ulna
- Olecranon apophysitis

Initial symptoms of pain and reduced elbow function relate to inflammation of the common flexor mass or medial apophysitis, progressing to irregular ossification and enlargement of the medial apophysis which may separate and eventually fragment. Younger players tend to develop apophysitis whereas similar valgus stresses in an adolescent may result in complete or partial avulsion of the medial epicondyle. On the lateral side, repetitive compression leads to radial head hypertrophy or OCD of the capitellum. In the posterior compartment, repetitive extension may lead to the development of olecranon apophysitis, ulna hypertrophy, and traction spur formation. After treatment with rest, anti-inflammatory medication and physiotherapy a cautious return to sport may require specific limitation in the number of throws or pitches per session.

Osteochondritis dissecans of the elbow

Repetitive compression within the radiocapitellar joint causes articular cartilage to separate from subchondral bone secondary to ischaemic micro-trauma resulting in an OCD lesion (Table 13.23.3). This is distinct from the condition of Panner’s disease that has a presumed temporary avascular aetiology similar to that of Perthes disease of the hip. Panner’s disease has a defined clinical course: revascularization is to be expected with return of normal appearance and function to the radiocapitellar joint. (This differs from Perthes disease, presumably because the hip is a weight-bearing joint.) (Table 13.23.4).

OCD usually develops in adolescence with well-demarcated areas of cartilage damage that may progress to osteochondral fragmentation and loose body formation (Figure 13.23.5). Pain may be marked, particularly with ongoing sports participation, and mechanical locking may occur if loose bodies are present. As for the knee, treatment depends upon the size, stability, and articular continuity of the lesion and the state of the physis. Stable, continuous lesions may be managed non-operatively and loose bodies may be amenable to arthroscopic removal. Unstable, discontinuous lesions that restrict elbow motion, in the presence of a closed physis, may be suitable for subchondral drilling, open fragment fixation or osteochondral plug grafting. These procedures are technically difficult to perform arthroscopically and a mini-arthrotomy through a posterolateral approach with the elbow flexed is often useful.

### Hand and Wrist

**Gymnast's Wrist**

Wrist pain can affect up to 80% of elite gymnasts in whom wrist loads may regularly exceed twice body weight and peak to 16 times this level. Repetitive compressive forces at the distal radial physis cause a stress reaction (Box 13.23.7) (Figure 13.23.6) that can culminate in premature closure of the distal radial physis and positive ulna variance. Avascular necrosis of the lunate (Kienbock’s disease) has been noted in some athletes (Figure 13.23.7). Secondary overload of the ulna side of the carpus and wrist joint is a cause of degenerative changes and potentially long-term disability. The weight bearing upper limb position also places the elbow under valgus stress which can lead to a similar pattern of injury to that seen in the overhead athlete. Radiographic follow-up is required in children and adolescents with a pattern of physeal stress injury because of the risk of premature physeal closure.
Other injuries or syndromes

‘Shin splints’

This term has been applied to almost any type of lower leg pain that results from overuse in the teenage athlete, most commonly after running or hiking. The pain is usually felt on the posteromedial border of the tibia and may correspond with the medial origin of the soleus muscle. Pain may be exacerbated by resisted plantar flexion or toe raises. The differential diagnosis should include a stress fracture and an exercise-induced compartment syndrome whilst the possibility of infection or a benign or malignant bone tumour must also be considered.

An exercise-induced compartment syndrome should be confirmed with pressure studies both at rest and after exercise. The compartments most frequently affected are the deep posterior and the anterior compartments: numbness in the sole or on the dorsum of the foot may be part of the clinical picture. A careful surgical fasciotomy is the treatment of choice. The procedure can be performed through limited skin incisions to improve the cosmetic appearance.

Stress fractures

Stress fractures are increasingly common in those children and adolescents participating in sports involving running. True stress fractures (defined as abnormal stresses applied to normal bone) are rare in children who are active but not involved in training programmes. Training, particularly after a period of inactivity such as after an injury or a long vacation, leads to a stimulation of both osteoblastic activity and osteoclastic activity and perhaps an increased tendency to fracture. In adolescents, the combination of ligamentous laxity, muscle tightness, and relative muscle weakness are relative risk factors for a stress fracture and the risk may be increased if the athlete is tall and heavy and involved in a sport which requires bursts of explosive activity.

Fractures are often diagnosed on careful history taking and examination. Radiographic features may take some time to develop.
and imaging techniques such as MR and bone scans are often useful.

Treatment will depend on the age of the child, the site of injury and the severity of the symptoms but usually involves relative rest from the sporting activity and the use of a brace, orthotics, or a cast until symptoms resolve. Surgical treatment is sometimes required for fractures affecting the femoral neck and the medial malleolus (Box 13.23.9).

---

**Future developments**

Sports participation in children and adolescents is on the increase and is to be encouraged for the control of body weight, development of peak bone mass, and instilling the virtues of teamwork and discipline. Ongoing analysis of the environment and specific sports situations in which critical injuries occur will lead to better information for the development of injury prevention programmes for paediatric athletes. Greater recognition of particular injury patterns through ever-improving imaging techniques and better data collection with a denominator of hours and type of sports played will occur. The development of increasingly sophisticated techniques and instruments for arthroscopic management of osteochondral and meniscal injuries may improve outcomes and there is the potential for stem cell manipulation to aid reconstruction of damaged tissue.

**Further reading**

**Musculoskeletal injuries in children**

**Summary points**

- In children, bone is more flexible and heals faster than in adults but is at risk of growth disturbance. It is also capable of remodelling.
- The physis is weaker than the structures around it and therefore is liable to disruption in trauma.
- The possibility of injuries as a result of abuse must be considered in children and have a characteristic pattern.
- In poly trauma, children are more susceptible to hypothermia. Abdominal viscera and the cranium are more vulnerable. However, the central nervous system has more scope for recovery, and the cardiovascular system has an excellent capacity for coping with hypovolaemic shock.
- A reliable specific paediatric score should be used to plan treatment.
- The management of fractures is more likely to involve traction, plaster, and K-wires.

**Introduction (Box 14.1.1)**

Musculoskeletal injuries in children have some unique characteristics and differences from those in adults. Injury to the growing skeleton may cause growth disturbance. While the injured adult has to recover from the trauma itself, children also need to cope with any implications of trauma to their growth.

Bone healing is faster in children and complications affecting bone healing rarer than in adults because the bone is more biologically active with a thick vascular periosteum.

The biomechanical characteristics of the growing skeleton are also different. Bone is more elastic and incomplete fractures, that are rare in the adult, often occur. The periosteum is loosely attached to bone while tendons, ligaments, and muscles are firmly attached to the periosteum. As a result, children suffer fractures more often than sprains, ligament ruptures, and joint dislocations.

The biomechanical properties change with age and there are characteristic injury patterns for different age groups. Fractures involving the physis only occur in children.

The property of growing bone to remodel by asymmetric growth at the physes is also unique and age dependent. Overgrowth may complicate long-bone fractures in children.

Management of the multiply injured child follows adult principles but there are some differences that are essential for the treating physician to recognize. This also applies to the surgical treatment of children's fractures: while some general principles are similar to those in the adult, certain characteristics exist which may often be crucial for the optimal management of young patients.

Finally, child abuse is discussed—a clinical entity unique in children. Suspecting and diagnosing child abuse is essential for the safety and future development of infants and young children.

**Structure of the growing bone—physeal injuries (Box 14.1.2)**

Long bones begin to ossify in utero when the primary bone collar appears in the middle of the cartilage anlage. This region of primary endochondral ossification then expands and progresses towards the bone ends, establishing primary ossification fronts, the physes or growth plates, in both directions.

Vascular invasion of the hypertrophic cartilage inside this primary bone collar results in either direct cartilage resorption or a transient stage of endochondral bone formation followed by osteoclastosis. The medullary canal and an endosteal surface are thus established.

The entire anlage continues to grow in length by the proliferation and ossification of cartilage at the physis. Further growth and development of the diaphysis are achieved by direct bone apposition and resorption on the periosteal and endosteal surfaces, respectively. Therefore there are two different processes that contribute to the final structure of a typical long bone: appositional cortical bone formation, mainly in the diaphysis, and progressive endochondral ossification at the physes, leading to cancellous bone formation. Only after birth (with the exception of the distal femoral epiphysis) will secondary centres of ossification form at a time characteristic for each epiphysis.

**Box 14.1.1 Musculoskeletal injuries in children**

- May affect growth
- Incomplete fractures common
- Physeal fractures common.
These processes lead to the development of the final structure of the growing long bone: the tubular diaphysis in the middle is made of cortical bone, the conical metaphyses on either side of the diaphysis, and the epiphyses at both ends consist of cancellous bone; the cartilaginous physes separate the metaphyses from the epiphyses.

Injuries involving the physis occur as a result of the unique structure of bone during childhood. The physis is biomechanically the weakest structure of the growing bone, particularly when shear forces are applied, and is therefore the most vulnerable to injury. Physal injuries, their treatment, and their complications are discussed in Chapter 14.2.

**Biology and biomechanics of injury to the growing skeleton**

**Biology (Box 14.1.3)**

Bone in children is biologically more active than in adults. Apart from the activity at the growth plate, the modelling process, where bone is continuously absorbed and replaced by new bone, is more active in children. These processes of growth and modelling are genetically determined but are also influenced by complex factors including circulating hormones, nutritional intake, mechanical influences, and disease. At the age of skeletal maturity, bone growth is completed but the modelling process—frequently referred to as remodelling in adults—continues at a slower rate. Overall the biological activity of bone reduces after skeletal maturity.

The periosteum plays an important role in the biology of the growing bone. It shows greater osteogenic potential in younger children and has increased vascularity compared to adult periosteum. This contributes to the overall increased vascularity of the growing bone.

**Healing capacity**

As a result of the increased biological activity of the growing bone, fractures in children heal rapidly. This healing capacity is significantly dependent on age: fractures heal very rapidly in the newborn, less so in childhood, and reaches adult rates during adolescence. This generally accepted knowledge was confirmed in a clinical study in which the time required for union of fractures of the femoral diaphysis in children followed a log-normal distribution and the increment in mean time to union was 0.7 weeks for every year of age.

Bone healing and callus formation in children may follow a slightly different pattern compared to the adult. A study of the external periosteal callus using a scanning electron microscope, a transmission electron microscope, and a radiograph microdiffractometer, demonstrated that the rapid fracture healing in children is related mostly to brushite mineral deposition among the collagen fibres, while hydroxyapatite deposition is insufficient. In the adult, fracture repair relies on hydroxyapatite deposition among the collagen fibres. Deposition of brushite minerals in external periosteal callus in children may be compensating for the insufficient hydroxyapatite mineralization, thereby making fracture repair more rapid in children than in adults.

**Box 14.1.2 Physeal injuries**

- Physis is weakest part.

**Box 14.1.3 Biology**

- Healing is rapid
- Fewer complications until adolescence
- Open upper-limb fractures more commonly complicated.

When radiological fracture union criteria and staging are used, the pattern of healing in children is similar to that in the adult. Radiographic criteria can be used to date fractures. The length that each stage takes is age dependent but not sex dependent.

**Complications of bone healing**

Increased biological activity of the growing bone leads to a lower incidence of complications related to fracture healing. Delayed union, infection, and non-union have all been reported as a result of high-energy trauma and open injuries. Furthermore, displaced intra-articular fractures and/or soft tissue interposition within the fracture may lead to delayed or non-union.

The incidence of these complications in adolescents is similar to that in adults. Children under 12 years of age are at lower risk of developing any of these complications. The actively osteogenic periosteum and the overall increased vascularity of the growing bone account for this.

Current knowledge and understanding of fracture-healing complications in children is based on a number of clinical studies. In the absence of segmental bone loss or extensive soft tissue loss requiring major reconstruction, healing in children can be expected within 6 months after open lower-limb fracture, with younger children healing more quickly. Union times for open tibial fractures are
prolonged relative to closed injuries in similarly aged children, but bone grafting is seldom required. Delayed union is often a problem in children older than 11 years, while leg length discrepancy can complicate tibial fractures in children under the age of 11 years.

When a delayed or non-union occurs they are often associated with infection. The incidence of infection is also age related, being a rare complication in young children. Chronic osteomyelitis following acute wound infection after an open fracture in the lower limbs is also rare in children, and its incidence has been reported at 2–3%. The prevention of wound infection should follow the same principles as in adults: thorough immediate and, if necessary, repeated debridement and irrigation of the wound, stabilization of the fracture, and intravenous administration of antibiotics. Primary wound closure in the treatment of selected non-contaminated open fractures has been suggested, although the issue remains controversial.

Compartment syndrome following open injuries of the lower extremity is less frequent in children than in adults but it is important to recognize that it may occur in 2–4% of cases. Early fascial release is necessary to prevent the long-term consequences of unrecognized compartment syndrome.

Open fractures of the forearm and humerus in children are more frequently associated with healing-related complications. Delayed union, non-union, refracture, and malunion complicate about 25% of cases. Open type II and III fractures of the radius and ulna are at the highest risk. Excellent or good long-term results can be anticipated in 90% of all open fractures of the arm.

Biomechanics (Box 14.1.4)

There are several structural differences between growing and mature bone that account for their differences in biomechanical behaviour. Mature bone has a higher density, and growing bone more porosity due in part to increased vascularity. The increased porosity may be one of the reasons why fracture propagation is less likely to occur in growing bone and fracture comminution is more common in adults than in children.

Woven bone predominates in the neonate and is gradually replaced by lamellar bone as haversian systems develop and osteons assume a longitudinal orientation. The stiffness, strength, and resistance to stress of bone increases with increasing age.

In the metaphyseal area, the cortex is thinner and perforated with more vessels, while the haversian systems develop close to skeletal maturity. This area can fail under either tension or compression in children, while in adults it is much more resistant to compression forces.

The epiphysis becomes increasingly stiffer as secondary ossification centres develop and its response to stress and strain alters with age. The development of subchondral bone over the physis changes the biomechanical characteristics of the area even further. This explains why different patterns of epiphyseal fractures occur in different age groups.

The periosteum is thicker and stronger in children. It is loosely attached to the diaphysis and separates from it easily in the case of a fracture. For this reason, complete circumferential rupture of the periosteum is rare in children and usually a significant part of the periosteum remains intact. This remaining periosteal 'hinge' prevents severe displacement of the fracture and aids reduction. The periosteum is more firmly attached to the metaphysis where it blends into the perichondrial ring that surrounds the physis.

Muscles are attached to the periosteum, while tendons and ligaments blend into the fibrous regions of the metaphysis, perichondrial ring, and epiphysis. With few exceptions, no soft tissue structures are directly attached onto bone. The periosteum, together with all its soft tissue attachments, adds significantly to the overall stability of the bone. The loose attachment of periosteum to bone, the intrinsic mechanical weakness of the physis, and the firm attachment of ligaments, tendons, and muscles to periosteum, all contribute to the fact that sprains, ligament injuries, and joint dislocations are rare in children, while physeal injuries are common.

**Box 14.1.4 Biomechanics**

- Epiphysis becomes stiffer with age
- Periosteum thick and strong
- Periosteum rarely completely divided
- Bone has lower modulus of elasticity and bending strength
- Plastic deformation high before fracture.

There is experimental evidence that children's bone have a lower modulus of elasticity, a lower bending strength, and a lower mineral content. However, children's bone can deflect and absorb more energy before breaking by undergoing plastic rather than elastic deformation. The considerable plastic deformation occurring before the fracture starts may be due to multiple shear cracks opening up within the bone.

Furthermore, children's bone breaks at a lower load than adult bone and so the stress in the bone is less. The energy required for the fracture to be propagated through the bone comes mainly from the strain energy. Children's bone undergoes plastic deformation prior to fracturing, and therefore the bone in the region of the fracture will have yielded and have little strain energy.

Both of these factors—the small amount of strain energy available at the beginning of fracture and the difficulty a fracture has in propagating straight across the bone—tend to produce incomplete fractures in children.
Specific fractures (Box 14.1.5)

Greenstick fractures

Greenstick fractures are incomplete fractures produced by angulatory forces. The periosteum and cortex on the tension side are disrupted, while on the opposite side the cortex may be compressed or bent but remains in continuity. Greenstick fractures usually occur in the metaphyseal region of long bones but can occur in the diaphysis of long bones in neonates and young children (typically in the forearm).

Box 14.1.5 Specific fractures

Greenstick fractures
- Bending injuries
- Usually metaphyseal
- May require completion during manipulation

Torus fractures
- Axial compression
- Young children

Plastic deformation
- Paired bones
- May be difficult to correct

Stress fractures
- Adolescents
- Repetitive activity
- Heal rapidly.

Completion of the fracture with manipulation as well as simple manipulation to correct the angulation have keen supporters. This is a subject of debate since both methods have disadvantages. Completion of the fracture produces instability, makes immobilization more difficult, and increases the risk of late displacement. Simple manipulation of greenstick fractures of the diaphysis can lead to incomplete consolidation on the tension side of the injury, which may lead to refraction.

Buckle (torus) fracture

These are incomplete fractures of the metaphyseal region due to axial compression forces. The metaphyseal cortex, which is thin in childhood, gives way usually on one side. The fracture appears as a ‘kink’ in the cortex and minimal angulation may also occur. Typical sites include the distal forearm and the tibia. Buckle fractures occur in young children only. In older children similar injuries produce compression metaphyseal fractures. Treatment may be required to correct any significant angulation.

Plastic deformation

Angulatory or longitudinal forces applied to the immature bone may cause deformation beyond the limit of elasticity but below the fracture point. Plastic deformation then occurs without an apparent macroscopic fracture. Microfractures may occur on the tension side but are not apparent on radiographs. This type of injury occurs in young children and typically in paired bones. Usually one of the bones fractures and the other deforms. Plastic deformation may be missed but should be suspected when one of the paired bones is fractured and the other is apparently intact. Periosteal reaction does not usually follow plastic deformation.

Correction of the deformity with manipulation is difficult and may result in a complete fracture but is often necessary in order to reduce a fracture or dislocation of the paired bone.

Stress fracture

Stress fractures may occur in older children and adolescents. They are usually associated with increased and repetitive physical activity and typically occur in the tibia, fibula, and femur. They heal quickly, with modification of activities and immobilization, by extensive periosteal reaction and abundant callus formation. Careful history, physical examination, and radiographs can help diagnose most common stress fractures and differentiate them from infection or neoplasm that would need aggressive treatment.
Magnetic resonance imaging (MRI) scanning can also help establish the diagnosis and negate the need for histological diagnosis.

**Box 14.1.6 Epidemiology of fractures**

- 1 per cent per year
- Male predominance up to 5.5:1
- Adolescent fractures follow adult patterns
- Nondominant/upper limb more at risk
- Peak incidence in summer
- High-energy/multiple injuries from motor vehicle accidents.

**Epidemiology and age characteristics (Box 14.1.6)**

In developed countries, injury has become a leading cause of childhood morbidity and mortality. Musculoskeletal injury is one of the more important groups associated with high morbidity and mortality. The overall estimated annual incidence of limb fractures requiring hospital treatment in the age group up to 16 years is 0.5–1%. The age group of 4–11 years is at the highest risk. The sex distribution shows a male predominance in the range of 2–3:1 which increases with age and becomes 5.5:1 in adolescence.

Epidemiological studies on fracture incidence from different parts of the world show considerable variation because of cultural, socioeconomic, demographic, and other population characteristics. Despite this variation, there is overall agreement that the pattern, site, and frequency of childhood fractures all depend on age.

During birth, fractures of the clavicle, skull, and proximal humerus can occur. Fractures within the first 2 years of life are rare and should raise suspicion of metabolic disease or non-accidental injury. Greenstick and torus fractures occur in early childhood while fractures in adolescence follow a more adult pattern.

The secondary ossification centres appear at an age characteristic for each epiphysis, the increasing size changes the biomechanical characteristics of the epiphysis, making it stiffer. As a result, different epiphyseal fractures occur at different ages.

Upper-limb injuries in children are more common than lower-limb ones and the non-dominant side is at higher risk. Fractures of the forearm are the most common in all age groups with a peak between the years of 8–16. Clavicle fractures as well as hand and phalangeal fractures are frequent in all age groups. Supracondylar fractures of the humerus usually occur between the ages of 4–7 years. Tibial fractures occur in all age groups but the pattern of fracture is different: toddlers’ fracture between the ages of 2–5 years, and spiral or physeal fractures in the older age groups.

Multiple, high-energy, and open fractures are relatively rare in children compared to adults, and they usually result from road traffic collisions. Seasonal variations are also noted with summer usually being the peak period for childhood trauma. The relatively high prevalence of fractures resulting from bicycle or pedestrian injuries in adolescents has been highlighted recently.

**Joint and soft tissue injuries (Box 14.1.7)**

Ligament injuries and joint dislocations are rare in young children but reach adult frequency close to skeletal maturity.

In the growing skeleton, ligaments, tendons, and muscles are firmly attached to the periosteum. In the epiphyseal region and particularly around the physis periosteum is firmly attached on bone. Tensile forces to ligaments and tendons in this region lead to the failure of the weakest biomechanical structure, namely the physis. With this mechanism of injury, therefore, whereas an adult would suffer a ligament rupture or joint dislocation, a child sustains a physeal fracture.

**Box 14.1.7 Joint and soft-tissue injuries**

- Uncommon
- Dislocation is rare
- Fractures usually rather than ligament injuries
- Joint stiffness rare.

Dislocations can occur in children. The elbow or the radiocapitellar joint is the most frequently affected joint; other joints include the hip, knee and the proximal tibiofibular joint.

Ligament injuries around the ankle are rare, while physeal fractures are more common. The ligaments of the knee are also infrequently injured and tibial spine avulsion rather than anterior cruciate ligament rupture is a typical example. Also characteristic of the different behaviour of the growing skeleton is the low incidence of 4% of knee ligamentous instability associated with femoral fracture; in the adult this incidence is in the range of 40–70%.

Children tend to regain full range of movement quickly after removal of casts and splints and physiotherapy is rarely needed.
However, some particular types of intra-articular or physeal fractures in children may lead to permanent loss of full range joint motion despite treatment.

Articular cartilage in children does not differ from the adult. The superficial layers of the growing epiphyseal cartilage develop into adult-type hyaline cartilage and lose the ability to transform into bone or heal after injury. The recovery expected following damage to the articular cartilage should therefore be similar to that in adults.

There is no documented evidence that healing of soft tissues following penetrating or blunt trauma is faster in children than in adults or that complications after such injuries are rarer. Musculoskeletal injuries should always raise suspicion of neurovascular damage and this usually responds better to early intervention. Compartment syndrome is also associated with some paediatric fractures and decompression may be needed to avoid Volkmann’s ischaemic contracture.

Remodelling of the growing bone (Box 14.1.8)

Fractures may heal in a non-anatomical position. It is well recognized that the growing skeleton has, to a certain extent, the capacity to correct residual deformities after a fracture has healed and this process is usually referred to as remodelling. The remodelling potential differs according to the location of the fracture, the severity of its residual deformity after healing, and the skeletal age of the patient. Decisions upon the acceptability of a residual deformity have to be based on knowledge of the remodelling potential of the individual fracture so that unnecessary treatment or acceptance of a malunion should be avoided.

Box 14.1.8 Remodelling

- Asymmetric physeal growth mainly corrects angulation
- Periosteum is important
- Helical growth may correct torsion
- Little remodeling after age of 11 years
- Metaphyseal fractures close to joints remodel well
- Epiphyseal and intra-articular fractures have little ability to remodel
- Deformities in plane of movement of joint remodel well
- Remodeling is difficult to predict.

During fracture healing and remodelling in children, bone growth acceleration may occur. This overgrowth phenomenon has to be taken into account when treating fractures, particularly those in the lower limb.

Mechanisms of remodelling

Remodelling of adult fractures occurs at the site of the fracture and follows Wolf’s law: alteration in the mechanical environment, as a result of bone deformity, leads to new bone formation on the concave side (compression) and bone resorption in the convex side (tension). In adults this is a slow process and little correction of deformity can be expected.

The Heuter–Volkmann law suggests that, in children, the physis tends to align itself perpendicular to the resultant force acting across it by a mechanism of asymmetric growth. In the presence of an angulatory deformity, therefore, the physis would grow faster on the concave side of the fracture and would reorientate the joint and, eventually, the fracture.

The hypothesis of asymmetric physeal growth has been confirmed in animal experiments including radiological and histological studies. The overall alignment of the malunited bone corrects rapidly as a result of asymmetric growth at the epiphyseal plates. The joints at both bone ends regain their normal alignment with this mechanism. The angulation at the fracture site corrects slowly as a result of both asymmetric physeal growth and local remodelling at the fracture, following Wolf’s law. Local remodelling accounts for only 25% of the correction at the fracture site, the remaining 75% of correction being achieved by asymmetric physeal growth (Figure 14.1.1).
The exact mechanism of deformity correction by asymmetric physeal growth is not known. The role of the periosteum has been investigated but results were discouraging: experimental periosteal division to release tension has little effect on deformity correction. Mechanical factors may play a role but do not solely control the mechanism of correction: experimental studies demonstrated femoral overgrowth in animals with tibial fractures, suggesting a systemic factor contributing to the correction mechanism.

Rotational moments applied on the physeal plate may induce helical growth, which in turn may be responsible for the correction of torsional deformities following fractures. The same mechanism may be responsible for the development of late secondary torsional deformities following fractures healed with angulation.

Experimental findings on asymmetric physeal growth in malunited fractures are supported by clinical evidence. Measurements on radiographs of malunited forearm fractures showed most of the angular correction to occur at the growth plate. Furthermore, the plane of movement of the adjacent joint in relation to fracture angulation also influences remodelling. Deformities in the plane of movement of the adjacent joint remodel better than ones at an angle to this plane.

Expectations for remodelling

In clinical practice, knowledge of the remodelling potential of the specific fracture concerned is important. Precise guidelines are not available and, in clinical practice, a lot relies on the personal experience and training of the treating surgeon. This may lead to overtreatment of some fractures with good remodelling potential, or acceptance of deformities that are not going to remodel and may cause functional problems. Some attempts have been made to determine the factors that influence the remodelling potential in general and also to define guidelines for some specific fractures.

The age of the patient influences the potential for remodelling. In young children under the age of 2 years, angulations of up to 90 degrees in femoral fractures remodel well. This potential decreases with age to the degree that little remodelling should be expected after the age of 11 years. Since correction of deformity relies mainly on asymmetric physeal growth it is only logical that the younger and more active the physis, the greater the potential for remodelling.

The distance of the fracture from the physeal plate also influences remodelling potential. Metaphyseal fractures remodel better than diaphyseal ones. Radiographic studies of malunited forearm fractures have confirmed that midshaft radial fractures have less potential for correction than distal radial ones. Epiphyseal fractures, and particularly intra-articular ones, have little potential for deformity correction.

The severity of the residual deformity once fracture healing has been accomplished also plays an important role. The more severe the deformity, the less potential it has for complete remodelling. With the exception of some fractures that present late with deformity, the healed position is similar to the one accepted at the end of treatment. A 20-degree angulation of a femoral fracture is acceptable up to the age of 13 years, but this would not be the case for a tibial fracture.

The plane of movement of the adjacent joint in relation to fracture angulation also influences remodelling. Deformities in the plane of movement of the adjacent joint remodel better than ones at an angle to this plane.

Proximity of the fracture to the end of the bone with the most active physis appears to favour remodelling. For example, the radius relies a lot more on its distal than its proximal epiphysis for longitudinal growth, and therefore fractures of the distal radius remodel better than those of the proximal radius. Correction of rotational deformities varies in different parts of the skeleton. It is generally less optimal than angular remodelling, despite experimental evidence of helical growth of the epiphyseal plate under rotational moments. The proximity of the fracture to a joint with multiple movement may play a role. Proximal humeral fractures appear to remodel their rotational deformities well. The question, however, is whether the humerus shows true rotational improvement or the rotational realignment is compensated for at the glenohumeral joint.

Overgrowth (Box 14.1.9)

Acceleration of growth following long-bone fractures in children is a well-recognized phenomenon. There is experimental evidence that this overgrowth occurs at the epiphyseal plates but the exact mechanism of physeal stimulation is unknown. Femoral fracture in the rabbit also stimulates ipsilateral tibial overgrowth. At the end of this process the femur is overgrown by 2% of its length and the tibia by 1%

Radiographic measurements show that, in femoral fractures, growth acceleration reaches its maximum at about 3 months after the fracture. It is significantly higher than normal for about 2 years and then slows down but is still higher than normal until about 4–5 years after the fracture. The uninjured ipsilateral tibia follows the same time-pattern but overall its overgrowth is slower. A fractured tibia shows growth acceleration but does not influence the ipsilateral femur. Bone scintigraphy studies have demonstrated increased growth plate activity in the distal femoral and proximal tibial growth plates following femoral fracture. Recent evidence suggests that this may be due to increased mitotic activity at the growth plate, rather than increased vascularity as it was initially thought.

Growth acceleration is higher when there is overlap of the fracture ends. When there is little or no overlap between fragments the increase of the growth rate is minimal and results can be predictably good with leg-length discrepancy of 0.5cm or less at the end of growth. The average overgrowth following femoral fractures—with or without overlap of the fracture ends—is less than 1cm but can reach 2.5cm in some cases.

Overgrowth is also age dependent, with the 4- to 7-year-old age group being most likely to show significant growth acceleration. An
increased effect on boys has been reported but a much larger proportion of boys than girls in the 4- to 7-year-old age group were included in this study.

The multiply injured child (Box 14.1.10)

Injury is the leading cause of children’s morbidity and mortality in developed countries. Road traffic collisions and falls account for 80% of childhood trauma. Multiple injuries and multisystem involvement is frequent because of the small size of the young patients. The order and priorities in the assessment and management of the multiply injured child are the same as in the adult. However, there are unique characteristics in children that require particular attention and these are analysed in the following section.

Box 14.1.9 Overgrowth

- 1.25 cm for femur
- Maximal between 4 and 7 years of age
- Avoid distraction
- Overlaps should be less than 1 cm
- Upper-limb overgrowth in 20 per cent of fractures.

Box 14.1.10 Multiple injuries

- Head injury
- Fractures often absent in visceral injuries
- Large cardiac and pulmonary reserve
- Use Pediatric Trauma Score/Coma Scale
- Vital signs are age dependent
- Intraosseous infusion under the age of 6 years
- Early diagnosis/treatment reduces morbidity/mortality.

Priority should be given to the treatment of life-threatening injuries and limb-threatening injuries should follow. Errors in the management of ventilation and circulation, or failure to detect hidden injuries, are the most common causes of preventable death.

Special considerations in children

Size and shape

Because of the small body mass in children, there is a greater force per unit of body area during injury. Furthermore, because of the proximity of multiple organs, multiple system injury is frequent. This is often the case with the abdominal viscera which are not well protected by the poorly developed abdominal musculature. The head is large relative to the trunk; therefore it is injured in 80% of multiply injured children and is often the leading contact point.

Age- and size-appropriate equipment is also needed for the treatment of injured children. Drug doses and some equipment size determination are based on body weight.

Elasticity

The skeleton in children contains less mineral than in the adult and is therefore more elastic. In multiply injured children, soft tissue and visceral injuries may occur without concomitant bony injuries. For example, the thoracic cage is very elastic and rib fractures are rare. Lung injury with little external evidence may occur and mediastinal injury is not uncommon.

Surface area

Children have a higher ratio of body surface area to body volume. As a result, they are more prone to thermal energy loss, particularly in the presence of hypoxaemia.

Psychological status

The emotional instability of the injured child, together with difficulty in interacting with unfamiliar individuals makes communication difficult. Obtaining a history of the injury may be a challenge and cooperation of the young patient is not always available. Psychological and emotional support in the acute phase as well as during recovery are important in order to prevent long-term effects of psychological injury.
Beneficial features

Some of the beneficial features in children with multiple injuries include the low incidence of pre-existing disease, the high capacity for recovery from central nervous system injury, and the larger cardiac and pulmonary reserves. Their vascular system can maintain normal systolic pressure despite significant hypovolaemia by reflex tachycardia and vasoconstriction. However, with ongoing blood loss the body can no longer maintain normal blood pressure and haemodynamic deterioration in children is usually rapid.

Long-term effects

Injury may have long-term effects on growth and development. Unlike in the adult, the child’s temporary disability as a result of trauma may lead to long-term disability as a result of growth disturbance or abnormal development. Treatment should aim at helping the child not only to recover from the injury but also to continue the normal process of growth.

Management and outcome

Transport and triage in multiply injured children follows the same principles as in adults. Paediatric trauma scores have been developed to facilitate triage and offer a prediction of outcome (Table 14.1.1). The Revised Trauma Score, often used in adults, is not applicable in children, particularly young ones whose verbal communication is poor. The Paediatric Trauma Score is often used in trauma centres and is presented here.

<table>
<thead>
<tr>
<th>Table 14.1.1 Pediatric trauma score</th>

</tr>
<tr>
<td>Systolic blood pressure (mmHg)</td>
</tr>
<tr>
<td>Level of consciousness</td>
</tr>
<tr>
<td>Open wound fractures</td>
</tr>
<tr>
<td>Total score</td>
</tr>
</tbody>
</table>

Each variable is given one of three scores and the total score can vary between –6 and +12. Children with a score higher than 8 have better prognosis with usually preventable mortality, morbidity, and disability. Ideally, children with a score below 8 should be triaged to specialized centres with experience and facilities for paediatric trauma. The Paediatric Trauma Score has been evaluated and has been found to be predictive of outcome in multiply injured children.

Resuscitation of the multiply injured child

The same principles of resuscitation as in the adult apply in children and Advanced Trauma Life Support methodology is used in most major trauma centres.

Cervical spine control during this is important. The incidence of cervical injury in children is lower than that in the adult. However, children have a larger occiput, and lying on a spinal board may produce significant flexion of their cervical spine and/or obstruct their airway. Modified spinal boards with a recess for the occiput or a pad to raise the chest have been suggested. Orotracheal intubation in children is usually performed using an uncuffed tube. A guide for the size of the appropriate tube is the size of the little finger.

Managing circulation also follows the adult principles. It is useful to remember that the circulating blood volume of a child is 80mL/kg body weight. An estimate of the child’s weight is given by the following equation:

\[
\text{weight (kg)} = (\text{age} \times 2) + 8
\]

In children, hypotension occurs when blood volume loss is in excess of 45% and the patient can rapidly deteriorate and become comatose. It is important to remember that vital signs are age dependent: an infant can normally have a pulse rate of 160 beats per minute, a blood pressure of 80mmHg, and 40 respirations per minute, while for an older child these values would correspond to hypovolaemia and shock.

An alternative method for fluid resuscitation in children under the age of 6 years is intraosseous infusion. The proximal tibial or distal femoral metaphysis can be accessed but infusion in the proximity of fractures should be avoided. Infusion rate is similar to intravenous rate.

Urine output is age dependent and this should be remembered when assessing circulation in the injured child. Output is 1–2mL/kg/h in infants, 0.5–1mL/kg/h in children, and 0.5mL/kg/h in adolescents.
Part of the resuscitation protocol includes assessing the neurological status of the patient. A paediatric modification of the Glasgow Coma Scale is used for this purpose (Table 14.1.2). The 'best verbal response' part of the scoring is the only variable which has been modified.

Musculoskeletal injuries are common in the multiply injured child, with fractures of the long bones of the lower limb and the humerus being the most frequent. About 10% of the fractures in polytrauma are open. Central musculoskeletal injuries, involving the clavicle, scapula, spine, or pelvis, are more often associated with low trauma scores, long hospital admission, complications, and mortality. Early diagnosis helps in reducing the morbidity and mortality of these injuries.

Musculoskeletal injuries can be missed in the early stages of resuscitation and management. The priority of treating potentially life-threatening conditions is often the reason for overlooking skeletal trauma. Furthermore, imaging of the immature skeleton may often be more challenging.

### Treatment Options

Treatment options in children are largely similar to those in the adult. External immobilization or internal fixation are the two main forms of treatment and each has a variety of alternative methods available.

Traction, skin or skeletal, using different frames and devices has been the treatment of choice for many fractures. However, this requires prolonged hospital admission and close supervision, both clinical and radiographic. The impact of the prolonged hospital admission on the young patient’s psychology, the family implications, and other socioeconomic factors have now made traction a less favoured form of treatment.

Plaster cast immobilization, with or without previous manipulation and reduction of the fracture, is the treatment of choice for a large number of paediatric fractures. Immobilization of adjacent non-injured joints has very low morbidity in children who, almost without exception, recover full movement soon after removal of casts. Loss of fracture position ischaemia due to soft tissue swelling, and poor cast application are potential complications.

Functional bracing is an alternative external immobilization method for some fracture types. This allows joint movement while providing some stability to the fracture. Functional braces for the long bones of the upper as well as the lower extremity have been suggested.

A number of fractures in children are optimally treated with K-wire fixation following closed or open reduction. While this method is often insufficient for fixation of adult fractures, it works well in children where deforming forces are weaker and fractures heal faster. K-wire fixation is often supplemented by plaster casts. Wires are left prominent through the skin and do not usually require a second anaesthetic for removal. Potential complications include pin tract infection, ectopic ossification, and migration. Biodegradable pin fixation has been suggested as an alternative to avoid these complications. Polyglycolic acid pins are buried into bone and the risk of infection, ectopic ossification, or the need for further anaesthesia are much lower. They offer similar quality of fixation with ordinary K-wires but their insertion is technically more demanding.

Flexible intramedullary nails have become the treatment of choice for most long-bone fractures in children. The fracture site is not exposed, periosteal stripping is avoided, and stability is adequate for the low level of loading that is present in children. Overgrowth or malunion have not been observed and the only reported complication is skin ulceration at the ends of prominent nails, requiring early removal. Flexible nails offer optimal treatment for multiply injured children where fast and adequate early stabilization is essential. The use of external fixation devices is indicated mostly in open fractures with extensive soft tissue damage and/or bone loss. Open reduction and internal fixation with plate and screws is indicated in intra-articular and metaphyseal/epiphyseal injuries where anatomical reduction is essential.

### Indications for surgical treatment

Absolute and relative indications for surgical treatment of children’s fractures vary between centres. Specific experience with paediatric fractures is necessary for correct decision-making upon surgical treatment. Absolute and relative indications for surgical treatment are shown in Table 14.1.3 and discussed in the following sections.
### Table 14.1.3 Indications for surgical treatment in children’s fractures

#### Absolute indications

Open fractures require surgical exploration and debridement to prevent infection. All grades require attention and intervention. Grade I fractures with minimal skin laceration may be complicated by anaerobic infection or compartment syndrome and need prompt exploration. Stabilization of the fracture and soft tissue coverage where appropriate are also essential.

Multiply injured children with multiple long-bone fractures require surgical stabilization. This makes nursing and rehabilitation easier and facilitates treatment of other systemic injuries.

Neurovascular damage to the fractured limb, requiring repair, is an indication for surgical treatment to provide stability and facilitate repair. Vascular supply to the limb may be obstructed by the displaced fracture and limb oedema, without vascular injury. Fracture reduction facilitates blood flow through the vessel. At times, however, a vessel or nerve may be trapped into the fracture and attempts at closed reduction may cause further neurovascular injury.

#### Relative indications

Displaced intra-articular fractures do not remodel and require anatomical reduction and stabilization. Furthermore, the majority of these fractures in children are at the same time complex physeal fractures (type III or IV) which carry the potential of growth disturbance. This adds to the indication for anatomical reduction and stable fixation.

Older children who are close to skeletal maturity and have little remodelling potential should be treated as adults. When all the indications for surgery listed here are considered, the age of the child should be taken into account first as it represents the single most important factor influencing the final decision.

Children with conditions such as neuromuscular disorders which result in muscle spasticity, fracture immobilization, and maintenance of reduction may often be a challenge. Fixation of the fracture may offer an uneventful recovery and rehabilitation. Children with metabolic bone disease or skeletal dysplasias may also require particular attention and conservative treatment may be inadequate.

Late intervention may be required when early conservative treatment has failed. Failure of the fracture to produce early callus may be due to soft tissue interposition and may require surgical intervention.

There are fractures in specific locations in the skeleton that are prone to non-union. Furthermore, fractures at sites of muscle or tendon attachment may be inherently unstable and often require fixation.

Pathological fractures may need excision of the bone lesion and grafting, depending on the underlying pathology. Fixation may also be required in cases of instability or in high stress areas. Histological diagnosis is essential before proceeding with fracture fixation.

#### Non-accidental injury

Physicians involved in the care of children at any level should be aware of the possible diagnosis of non accidental injury and have a high index of suspicion when infants and young children are involved. In cases where the diagnosis of child abuse is missed and patients are discharged from hospital care, the risk of further non accidental injury is 20% with a 5% risk of lethal injury. The majority of deaths from injury under the age of 1 year are the result of child abuse.

In order to avoid missing the diagnosis or overdiagnosing child abuse, standard hospital, regional, and national protocols and
guidelines for suspected child abuse that involve senior medical personnel with experience in children from the early stages of the procedure are necessary. All health care professionals who interact with children should be aware of these protocols and report any suspected cases of non-accidental injury through the appropriate channels.

Risk factors and presentation

An unsettled family environment with immaturity or emotional instability of the parent(s), failure to cope with the crying baby, failure to establish bonding, drug and alcohol abuse, and social deprivation may increase the likelihood of non-accidental injury. However, it is not necessary for any of these factors to be present and incidents of child abuse may present in apparently settled and happy families. In an analysis of non-accidental injuries leading to death, no risk factors within the families could be identified. There was no recognizable pattern in the age and sex of the abusers, nor their ethnic origin and social and marital status.

Indications in the presentation and history of the injury may raise a suspicion of child abuse. The mechanism of injury as described by the parents/guardians may not fit with the degree and nature of the resulting injury. The history may differ between parents/guardians or discrepancies may exist when the history is repeated. A significant delay in seeking medical advice should raise suspicions. This is not necessarily true with subtle injuries, such as undisplaced greenstick fractures, but it is unusual for complete long-bone fractures not to be noticed.

Box 14.1.11 Child abuse—diagnosis

- Document
- Clinical photographs
- Exclude leukemia, osteogenesis, etc.

Repeated injuries in the same child, particularly when treated at different places, poor compliance with treatment, and non-attendance at follow-up appointments may be indicative of abuse.

Injury patterns

The typical ‘battered child syndrome’, as described by Caffey, includes a combination of multiple fractures at various stages of healing, subdural haematoma, failure to thrive, soft tissue swellings, and skin bruising. Some of the musculoskeletal injuries, although not unique, may be characteristic of the abused child and raise suspicions. Since the original recognition and description of child abuse, the patterns have changed with subdural haematomas and fractures being present in a smaller percentage of patients. In a recent epidemiological study, however, the most common non-orthopaedic injury was found to be the injury to the head, with or without skull fracture. The most common fractures were those of the femur and humerus.

Fractures

Fractures occur in a relatively small percentage of abused children, probably in the range of 10–15%.

Characteristic metaphyseal injuries include the chip fracture with periosteal avulsion and irregular/diffuse metaphyseal changes, while complete physeal separation is rare. Impaction and buckle fractures may occur, but these are also common in accidental injuries.

Metaphyseal injuries in children occur from indirect shear forces applied when the extremity is pulled, pushed or twisted, or when the infant is shaken. The fracture occurs proximally to the physis and a disk of bone is avulsed from the metaphysis. This disk has a peripheral margin that is thicker and denser than its central part, as a result of its protection by the subperiosteal bone collar at the chondro-osseous junction. The peripheral margin is therefore the most conspicuous component of the fracture which, when viewed tangentially, results in a corner-fracture (chip fracture) appearance and when viewed obliquely results in a bucket-handle appearance.

Diaphyseal fractures and spiral humeral fractures under 2 years are highly suspicious; the most common and transverse ones may be more common than spiral. Abundant callus formation, with or without gross deformity, is often seen due to the lack of fracture immobilization. Furthermore, several fractures at different stages of healing are characteristic.

Periosteal elevation is often seen in the metaphysis or diaphysis of long bones. However, normal infants may have symmetric long-bone periosteal elevation with double-cortex appearance persisting up to the age of 2 years.

Rib fractures, otherwise uncommon in children, may be seen in cases of abuse. Skull fractures and widened sutures are characteristic and spinal injuries may be observed.

Soft tissue injuries

The vast majority of abused children have soft tissue injuries. The age of the child is an important parameter when studying soft tissue injuries. Infants rarely present with soft tissue injuries after accidents. Abused infants have at least one major soft tissue injury at presentation, the head and face being the most common location. Abused children over the age of 3 years usually present with three or more soft tissue injuries. Head and face injuries, and particularly perioral trauma, are also common in this age group.

Burns should also raise suspicions, particularly the round, sharply demarcated burns from cigarettes or third-degree burns in areas
that are not usually exposed. Rope marks or linear ecchymoses are also characteristic. Visceral rupture without a history of major blunt trauma and trauma to the perineum and genitalia should also alarm the physician.

**Diagnosis (Box 14.1.11)**

History and clinical examination is the cornerstone of diagnosis of child abuse. If suspicion is raised, a senior physician with experience in children, usually a paediatrician, should be involved as part of a standard hospital procedure. All injuries should be recorded carefully and clinical photographs should be obtained for any external injuries. An impression of the family background and the rapport between child and parents/guardians should be established.

Further investigations may include radiographs and blood tests. Radiographic examination of clinically suspicious areas for new or old fractures is often sufficient. A complete skeletal survey is needed in cases of uncertainty and often in young infants. Isotope bone scans can create confusion because of the presence of the physes.

Determining the age of fractures and soft-tissue injuries is often important in order to establish the diagnosis of non-accidental injury. The radiographic appearance of a healing fracture depends on the age of the fracture and the age of the patient. Knowledge of the expected speed of healing and the corresponding radiographic appearance is important. Furthermore, the degree of soft tissue swelling at first presentation indicates how recent the injury is and may indicate delay in seeking medical advice.

A full blood count is necessary to exclude iron-deficient anaemia, leukaemia, and other haematological conditions that may cause bruising and petechiae. Coagulation tests to exclude haemophilia may also be needed. Copper level in serum can be ordered when multiple epiphyseal spurs are observed on radiographs. The differential diagnosis of child abuse is summarized in Table 14.1.4. Child abuse should be differentiated from conditions that cause multiple fractures or multiple soft tissue bruising.

Type IV osteogenesis imperfecta remains the most difficult type to differentiate because of its mild clinical presentation and the absence of blue sclerae. Collagen testing is available in specialized centres and can sometimes be helpful.

The diagnosis of one of the discussed conditions does not necessarily exclude child abuse, as these may coexist.

**Further reading**

Physeal injuries

DOI: 10.1093/med/978019550647.003.014002

Summary points

- Damage to the physis may lead to slowing or angulation of growth, especially if a bone bar forms
- Fractures involving the physis may be difficult to diagnose on x-ray
- The Salter–Harris classification is commonly used
- Fixation of fractures should not cross the physis if it can be avoided
- Partial growth arrest may be best treated with a complete epiphysiodesis followed by reconstruction.

Essentials

The primary role of the physis is coordinated, longitudinal growth. An injury to the physis may recover without adverse effect, or it may go on to cause a growth disturbance. This may take the form of a slow-down in the rate of growth or an angular deformity, although an increase in the rate of growth is also seen after some injuries. Physeal fracture is the most common, but not the only cause of a physeal injury; many authors use these terms interchangeably. Although progress has been made in understanding the nature and types of physeal injuries, much remains unknown.

Introduction

The anatomy of the physis and its relation to function is largely understood; however, less is known of the physiology of the physis and its response to injury. It is known to respond to the genetic, hormonal, and nutritional environment as well as to the local influences of blood supply, innervation, and mechanical stress. Thus the physis is not just an area of supportive tissue like the rest of the growing skeleton, but a responsive, specialized organ with a function (growth) that is subject to a range of pathological ‘injuries’ including endocrinopathy, ischaemia, autoimmune disease, and of course trauma. The various causes of physeal injury are listed in Table 14.2.1. Meningococcal disease is a particularly potent cause of multiple severe growth arrests in survivors. The physis is characteristically resistant to infiltration by malignant tumours, but some benign tumours are associated with disturbance of physeal function with deformity.

The rates of growth of the different physes vary (Figure 14.2.1), fast in some (the distal femur for example) and slow in others. Histologically, the physis is a layered structure. In humans this layered appearance is only easily seen in fast growing physes. Different authors variously subdivide them into three, four, or five zones. The main zones are the germinal layer (or resting zone) from which the cellular columns originate and which is critical to physeal function; the proliferative zone, the hypertrophic zone, and the zone of calcification (Figure 14.2.2) (see also Chapter 1.3).

Fig. 14.2.1

Fig. 14.2.2

The physis is surrounded by the perichondrial ring which is contiguous with the articular cartilage of the epiphysis and to which the metaphyseal periosteum is firmly attached. It encircles the physis just as periosteum encircles the bone. As well as contributing cells to the germinal layer for latitudinal growth (the zone of Ranvier), the perichondrial ring plays an important role in maintaining the structural integrity of the physis, in particular its resistance to shear and tensile forces. Logically a fracture line should take the path of least resistance and traverse the weakest of the layers, the hypertrophic zone, which is characterized by large voids occupied by apoptotic cells and relatively little supporting matrix. However, experimental studies suggest that in practice the fracture line propagates variably through the physis and can involve all layers.

Although the physis itself is devoid of vascular channels, it receives a blood supply via three separate sources (see Figure 14.2.2). Arteries descending from the epiphyseal vessels supply the dividing cells of the germinal layer of the physis, periosteal vessels nourish the perichondrial ring and the peripheral part of the physis, whilst the nutrient artery via its branches supplies the majority of the metaphyseal side of the physis. Damage to the epiphyseal vessels, which directly affects the nutrition of the germinal layer, is usually permanent and the consequences are severe. The damage prevents cell division in the region supplied by the vessel leading to differential physeal growth. Angular and/or longitudinal growth deformity may result. The central area of the physis appears more susceptible to vascular damage than the peripheral portion. By contrast, disruption of the metaphyseal circulation is
usually transient. It does not affect chondrogenesis in the germinal cell layer or its maturation, but it does temporarily hinder the subsequent transformation of cartilage to bone.

**Epidemiology**

Little data is available on the incidence of physeal injuries in general. As regards fracture, if the data from three large recent studies are amalgamated, physeal fractures account for 24.8% of childhood fractures.

The much quoted Olmsted County study, which used a meticulously documented database and a stable population, reported an incidence of 279.2 acute physeal fractures per 100,000 person-years as well as a 2:1 male to female ratio and a peak incidence that corresponded to pubescence (age 14 in boys, 11–12 in girls). The latter might have a hormonal basis which results in a relative weakness of the physis at this time, although the frequency of fracture-prone behaviour at these ages may also be a factor.

**Clinical features**

Bone fracture is usually followed by pain and loss of function and the same features are apparent with physeal fractures. In a young child it may be difficult to localize the site of the injury and therefore careful examination is essential. Swelling, tenderness, abnormal movement, and crepitus are the cardinal signs of an acute injury. Do not forget to consider non-accidental injury as a possible aetiological factor, particularly in the case of fractures involving the entire distal humeral physis.

The gradual development of limb length discrepancy with or without angular deformity may be the late presenting features of trauma that is occult or has been overlooked. Other causes of physeal injury aside from trauma also typically present in this way (see Table 14.2.1).

**Clinical investigation (Box 14.2.1)**

Plain radiographs are the basic means of investigation of physeal injuries and the accurate interpretation of radiographic features is required if acute physeal fractures are to be classified. However, the physis itself is radiolucent and assessment of the injury involves looking at the adjacent radiodense epiphysis and metaphysis. A single radiograph provides only a one-dimensional view of the complex three-dimensional structure that comprises the physis and even with two views at right angles to each other, only a limited appreciation of the injury is achieved. Radiographs should be taken at right angles to the physis (rather than the diaphysis). Supplementary oblique views are often necessary when assessing physeal fractures around the knee and ankle, and stress views can be useful in injuries around a uniplanar joint. For assessing late deformity following physeal injury, plain radiographs are crucial for determining the location, extent, and progression of the problem. Standing long leg films, with the patellae pointing forwards and the pelvis level (by placing the shorter leg on blocks if necessary), require a similar radiation dose to a computerized tomography (CT) scanogram and have the advantage of imaging the weight-bearing position. The advent of digital imaging and viewing has made these films far more manageable for measurement purposes.

**Box 14.2.1 Investigations**

- Plain radiographs
  - At least two views
  - Standing long leg (for assessing late deformity)
- CT
- Ultrasound
- Arthrography.

CT is useful to identify the degree of fragmentation and the orientation of the pieces, particularly in complex fracture patterns such as Tillaux or triplane injuries. Reconstructed images can be particularly helpful. In late cases, it can be used to image osseous bars. Although magnetic resonance imaging (MRI) has theoretical advantages with its ability to demonstrate cartilage and soft tissue, the severity of the bone and soft tissue oedema which accompanies the injury limits its use and its exact role has not yet been determined.

In very young children with small secondary ossification centres, ultrasound is occasionally used for diagnostic purposes; similarly arthrography can be useful for diagnosis and guiding treatment when the injury pattern is unclear.

**Classification**

Classification systems of acute physeal injuries are based on radiographic appearances. The Salter-Harris classification remains the most popular (Box 14.2.2). This defines five patterns of physeal injury. The authors felt that types I, II, and III were generally associated with a good prognosis provided the epiphyseal blood supply remained intact, because the germinal layer in theory remains largely undisturbed.
Box 14.2.2 Salter–Harris classification

- Type I: through the physis
- Type II: through the physis with metaphyseal fracture
- Type III: epiphyseal fracture
- Type IV: epiphyseal fracture extending across the physis to the metaphysis
- Type V: crush

The uncommon type V was thought to involve a longitudinal compression injury to the germinal cell layer which showed no visible discontinuity of bone (‘normal’ radiographs in two planes) but which had a high potential for subsequent growth disturbance. There has been considerable controversy over the nature and incidence of type V injury. Some authors feel that the true isolated type V injury may indeed be rare but that a crushing element may be associated with other fracture patterns and that this may account for the unexpectedly bad outcomes which are known to occur, on occasion, even with type II or III fractures.

Rang extended the Salter–Harris classification to include a sixth category where there was localized injury to the perichondrial ring (Figure 14.2.3). The injury was associated with a high risk of subsequent growth disturbance and angular deformity, though whether this was due to localized vascular insult or crushing of physeal cells is unclear. Although the original description was of a direct blow to the perichondrial ring, many authors have interpreted this to include avulsion injuries of the ring and open injuries where portions of the metaphysis, physis, and epiphysis are lost or damaged. Such patterns have been described classically in association with lawnmower injuries and those that occur as a result of burns, frostbite, or extravasation injuries.

Fig. 14.2.3
Rang’s modification of the Salter–Harris classification.

The relationship of this classification system to outcome is less predictable than was originally implied by Salter and Harris. Fracture line propagation is not as constant as was once thought and outcome is known to vary with many other factors including age, site, mechanism of injury, degree of displacement, and method of treatment as well as fracture type.

Other classification systems exist. With the shortcomings of the Salter–Harris classification in mind and based on the Olmsted County epidemiological study, Peterson has recently described a new classification system (Figure 14.2.4).

Fig. 14.2.4

The advantages of this system are that it has an anatomical basis and depicts physeal injury as a continuum from relatively minor damage (Type I), through complete transphyseal involvement (Type III), to disruption of the physis with loss of some of the physeal
cartilage (Type VI). It has an epidemiological basis as well, as the fracture types occur with decreasing frequency from Type II to Type VI. It includes two 'new' injury patterns not included in the Salter–Harris system; the Type I fracture (which is essentially a transverse metaphyseal fracture which extends to the physis), and the Type VI injury which occurs only in open injuries and involves loss of physeal cartilage and usually some epiphyseal and metaphyseal as well. There is also prognostic significance to this classification, in that from Type I to Type VI the need for immediate and late surgery goes up.

Some physeal fractures do not fit neatly into these classifications systems; examples are the Tilleaux and triplane fractures, which are multiplanar intra-articular fractures of the distal tibia occurring exclusively in patients close to skeletal maturity through a partially closed physis. For this reason they rarely cause significant growth arrest in practice, despite their anatomical similarities to physeal injuries of poor prognosis.

### Treatment

In acute injuries, the aim of management is to reduce pain, regain function, and preserve growth potential if possible. These goals are most likely achieved by obtaining and maintaining an anatomical reduction of all components of the injury, especially the physeal plate and the articular surface, by open or closed means. A large gap between separated physeal layers tends to fill in with fibrous tissue which has the potential to become ossified and lead to growth disturbance given time and an adequate blood supply. Although the particular methods chosen will vary according to individual fracture patterns, fixation from epiphysis to epiphysis or metaphysis to metaphysis is preferred. Transfixation of the physis itself may cause further damage, but is sometimes unavoidable. Multiple passes across the physis should be avoided, and smooth removable metallic wires are ideal. Treatment needs to be prompt as physeal fractures heal in about half the time of the metaphysis of the corresponding bone.

For the late sequelae of physeal injury the focus is on preventing worsening deformity, and restoring function usually by restoring the correct anatomical relationships between body segments (see later).

### Prognosis

The outcome of physeal injury is dependent on a number of variables (Box 14.2.3).

**Box 14.2.3 Influences on the outcome of physeal injury**

- Anatomical extent of the lesion (classification) and displacement
- Age at time of injury
- Type of physis (slow- or fast-growing, see Figure 14.2.1)
- Effect upon rate of growth (increase, decrease, arrest)
- Duration of growth disturbance (temporary, permanent).

Of these, only the first (the anatomical extent of the lesion and displacement) can be influenced by medical treatment, which can 'reduce' it to some degree. However, even then the prognosis must be guarded. Severe growth disturbance can still result from seemingly benign fracture patterns, for example in Salter–Harris Type I and II distal femoral physeal fractures. This probably reflects the magnitude of the energy inflicted on the physis during the injury, and the tendency of the straight fracture line to cut across the undulating growth plate, thus involving all layers including the germinal layer. Intra-articular fractures of the femoral or radial neck often cause severe growth disturbance even in 'favourable' fracture types because the epiphyseal blood supply is frequently interrupted.

### Complications

The two major complications are joint incongruity and growth disturbance and the two are often interrelated. Joint incongruity can follow the malunion of displaced intra-articular physeal fractures. Such fractures are often associated with displacement at the level of the physis and thus the effects of the joint incongruity become worse with time as the associated growth arrest increases the degree of the deformity. In theory, degenerative change will occur but there is little evidence to support this in the literature.

The physeal response to injury varies. Minor trauma to the physis, such as that arising in association with a diaphyseal fracture, can cause a temporary and usually benign overgrowth. With increasing energy of the insult the cellular response in the physis shifts from hyperactivity to necrosis and the rate of growth slows. Growth disturbance of this type is called a growth arrest, which may be partial or complete.

Complete arrest is uncommon but usually results in a progressive limb length discrepancy, the effect of which varies with the age at which the arrest occurs (Figure 14.2.5). Additional problems arise if the bone affected is one of a pair, for example the radius and ulna.
Temporary cessation of longitudinal growth following trauma is marked by the appearance of a so-called Harris line in the adjacent metaphysis (Figure 14.2.6). The Harris line will appear to ‘migrate’ away from the physis on sequential radiographs once growth resumes, and it should remain parallel to it. If the Harris line and the physis appear to converge however, then a partial growth arrest is occurring.

Partial arrest is more common, and usually results from trauma. The size and location of the bony tether determine the clinical deformity, though all are associated with a degree of shortening. The age at injury and remaining growth potential define the ultimate severity. Three basic categories have been described: central, peripheral, and elongated (Figure 14.2.7). Central arrests tend to cause so-called ‘fishtail’ deformities of the articular surface (Figure 14.2.8). Peripheral arrests cause angular deformity (Figure 14.2.9). Elongated arrests commonly develop after Salter-Harris III or IV fractures of the medial malleolus or lateral humeral condyle. Partial arrests may be associated with a bony bar, but not invariably so; similarly, a radiographically open physis does not guarantee that normal growth will proceed.
Once identified, partial growth arrest may be treated in various ways and a combination of treatments may be necessary, including epiphysiodesis of the contralateral limb, ipsilateral leg lengthening, corrective osteotomy, acute shortening, and bony bar excision depending on the existing clinical problem and the predicted problem at skeletal maturity. It may be better to convert a partial arrest into a complete arrest by surgical epiphysiodesis, and deal with the resulting leg length discrepancy later as in general this is an easier option than correcting major angular deformity.

### Apophyseal injuries

The apophysis is associated with a major muscle attachment and linked to the shaft of the bone by a physeal plate. This traction physis is subjected to tensile forces which serve to shape the bone (Box 14.2.4). In contrast to other physes, these plates are not...
usually perpendicular to the long axis of the bone and only in certain sites do they contribute to joint congruity (proximal ulna, periacetabular, and periglenoid areas). Injury is caused by direct trauma or by a sudden major muscular contraction which disrupts the tendon–physis–bone unit when physeal injury is more likely than tendon rupture. The physeal vascular supply is via its muscle attachments and damage is unusual. If it does occur, the germinal layer of the physis is affected leading to plate closure. Most injuries happen around the time of physiological plate closure; between the ossification and fusion of the apophysis and the peak incidence for injuries is in the adolescent years. The radiological appearances of healing apophyseal fractures can be quite alarming, characterized by florid callus which can take on the appearance of an osteogenic sarcoma. Biopsy of such a lesion is not reassuring as large numbers of mitotic osteogenic cells will be seen, hence the importance of a careful history if diagnostic confusion is to be avoided. At this age, significant growth disturbance does not occur. The major apophyses are listed in Box 14.2.5.

**Box 14.2.4 Traction physis (apophysis)**

- Associated with muscle attachments
- Injury
  - Direct trauma
  - Muscle contraction
- Peak incidence in adolescence.

**Box 14.2.5 Apophyses which may be subject to injury**

- Upper limb:
  - Coracoid
  - Olecranon
  - Medial humeral epicondyle
  - Coronoid process of the ulna
- Lower limb:
  - Greater and lesser trochanters
  - Calcaneal apophysis
  - Tibial tuberosity
- Pelvis:
  - Anterosuperior and anteroinferior iliac spines
  - Iliac crest
  - Periacetabular rim
  - Ischial tuberosity.

The outcome of these injuries is dependent on the degree of displacement of the apophysis and the muscles attached to it. It is thought that muscle strength is reduced when displacement is greater than 1cm although there is little scientific evidence to support this argument and thus open reduction and internal fixation is advocated in certain cases. A symptomatic non-union or malunion is treated similarly or by excision.

**Future directions**

New or improved imaging modalities may identify new physeal injury patterns which may in turn lead to a new classification system that might predict prognosis more accurately than current systems and therefore guide treatment more appropriately.

Distraction osteogenesis can address shortening and angular deformity, and this technique can also be applied across the physis to distract it and encourage new bone formation. It has recently been used to treat physeal bars, with or without excision. However it tends to be reserved for older children as although considerable length can be gained, the physis tends to fuse once treatment has stopped.

Replacing physeal cartilage by transplantation of physeal tissue or iliac apophysis has been attempted with some success in the experimental and clinical settings, but the technique is hampered by a lack of donor sites. Therefore considerable work is now being directed experimentally at attempts to regenerate physeal tissue. So-called mesenchymal ‘stem’ cells harvested from periosteum and embedded in a biocompatible scaffold have been shown to correct leg length discrepancy and angular deformity in an experimental model of a physeal defect in rabbits. The effects of the biological manipulation of physeal cells with cytokines...
such as osteogenic protein-1 (OP-1) are also under investigation, with some favourable results.

**Conclusions**

Physeal fractures usually heal quickly. For acute injuries the aim of treatment is the prompt anatomical reduction of the injured physis in the hope that normal growth will resume after healing. Predicting whether a problem will arise is not easy, although classification systems give a guide. The ultimate outcome of a physeal injury depends on many factors besides the fracture type including the age of the patient and the rate of growth of the physis concerned, and most of these factors are not under the control of the surgeon.

Whilst physeal fractures are common, permanent physeal injury resulting from them is fortunately relatively rare except in certain subtypes (e.g. Salter–Harris IV injuries). There are many other less common causes of physeal injury apart from trauma. The pathophysiological response of the physis to injury is incompletely understood but various responses have been observed including overgrowth, slow-down, growth arrest, and angular deformity. Treatment of these problems involves a variety of techniques to attempt to restore normal anatomy. Regeneration of injured physeal tissue may be available to clinicians in the future.

Fractures of the spine in children

Summary points

- Spinal injuries in children are rare
- Pseudosubluxation above C4 is common in healthy children so the sign needs careful interpretation
- Epiphyseal plates and a high incidence of skeletal variability make the interpretation of spinal x-rays in children difficult.
- Anterior wedging is also normal as is interpedicular widening
- Spinal cord injury without radiographic abnormality (SCIWORA) may occur for up to one-third of spinal injuries in children
- Deformity secondary to trauma tends to deteriorate with growth.

Introduction

Fractures of the spine are rare in skeletally immature children and represent only 2–5% of all spinal injuries (7 per 100 000 population annually). There are characteristic features of spinal injuries in children because of the mechanisms involved and certain predisposing factors. The mechanism of injury usually involves recreational activities. There are also injuries which may occur at birth or secondary to congenital conditions. Non-accidental causes are a very important differential in this age group.

There are ossification centres and synchondroses which have not fused. The paraspinal soft tissue envelope is undergoing development as well. There is differential growth between the soft tissue element of the spinal column and the bony element. The net effect is a bony column which is capable of stretching beyond the limits of the spinal cord and causing injury. There are also the physes of the vertebral bodies which are susceptible to injury. Physeseal damage can result in growth deformities that affect canal dimensions and spinal symmetry. The spinal canal reaches adult size in the first decade. There can be neurological compromise from displaced cartilaginous fragments which are not seen on plain radiographs.

Normal anatomical variations in children

There is a larger head to body ratio in children. It is also common for pseudosubluxation to occur in children above the C4 level. Pseudosubluxation can easily be interpreted as instability and is relatively common in children. About 9% of children between the ages of 1–7 years demonstrate pseudosubluxation between C2 and C3 normally.

Vertebral body translation of up to 4mm is acceptable. Forty per cent of children show excessive anterior displacement between C2 and C3 or between C3 and C4. The spinolaminar line posteriorly should remain intact. There may also be widening of the atlantodens interval when compared to adults. Up to 20% of children aged 1–7 years demonstrate overriding of the atlas on the odontoid process, seen in extension radiography. This may also be defined when more than two-thirds of the anterior arch of the atlas lies above the odontoid.

The prevertebral soft tissue mass should not exceed more than two-thirds of the width of the vertebral body on lateral views in the upper cervical spine. In the lower cervical spine the tissue dimensions can be up to twice as thick. Occasionally a synchondrosis of the odontoid can be misinterpreted as a fracture. Anatomical variations in the lumbarosacral region are not uncommon. There is an abnormal lumbosacral transition in a significant number of patients. This can be in the form of lumbarization of the first sacral vertebra or sacralization of the fifth lumbar vertebra. There can also be segmentation anomalies between the transverse processes of L5 and the ilium. Another incidental finding is spina bifida occulta.

Abnormal anatomical variation in children

The C1–C2 articulation is the most mobile and lies between two relatively stiff joints. This is probably why it is prone to injury. More than 10 degrees of angulation or an atlantodens interval of more than 5mm is considered abnormal in a child. The definition of instability of the lower cervical spine is not well defined in children. In general an interspinous distance greater than 1.5 times normal is considered pathological. Other abnormal signs on radiography include divergence of the articular processes and widening of the posterior disc space.

The immature spine

It is important to recognize the physes in the spine because they can resemble fractures. The atlas and axis vertebrae have their own special physes; C3 and below are all similar.

The atlas has three ossification centres, one anteriorly for the body and two for the two neural arches (Figure 14.3.1). Sometimes the ring is bifid anteriorly. The posterior arch closes during the third year of life, although occasionally it can remain open into adult life. The axis has four ossification centres. Like the atlas it has one for the body and one each for the neural arches, but it also has one for the dens. When viewed anteriorly this resembles the letter H. Occasionally the body has two ossification centres. The physes between the odontoid and the body fuses between the ages of 3–6 years and can resemble a type 2 odontoid fracture. However, it lies well below the level of the articular facets. The lower ring apophysis ossifies in late childhood and does not close until early adult life. The tip of the odontoid has a ‘summit’ ossification centre, which appears between the ages of 3–6 years and fuses by the age of 12. It may persist as an ‘ossiculum terminale’ and should be not confused with an os odontoidenum which is a
separation of the odontoid from the body of the axis.

In hyperextension the arch of C1 may appear to be in the foramen magnum on computed tomography (CT) scan in children under the age of 2. The posterior aspect of the dens may have a defect which is the remnant of the right and left growth centres. This may be seen up to the age of 7.

The lower cervical spine ossifies from three centres, one from the body and one from each of the neural arches. These fuse between the third and sixth years. Each vertebra has cartilage endplates which contribute to growth as in a long bone, and these can fracture across. The inferior endplate is most prone to fracture because the uncinate processes protect the upper growth plate.

The apophyseal rings ossify in late childhood and fuse to the vertebral body at about the age of 25.

It is important to note that surgical intervention may disrupt open physis or synchondroses thereby resulting in asymmetrical growth.

Aetiology

The pattern of injury in children under the age of 10 is quite different from that in older children. The characteristic anatomical features of the upper cervical spine in this age group means that most injuries occur above C4. While injuries in those aged 10 or under are less common, cord injury and death are more common in this group.

The pattern of injury in children over the age of 10 is similar to that in adults, and in general the management is similar. Most of these injuries are caused by high-energy trauma. A less common but significant cause is non-accidental trauma.

Box 14.3.1 Problems in diagnosing spinal injuries in children

- Spinal column injuries are rare in children
- Variations in anatomy exist
- Injuries can arise from differential lengthening of the spinal column.

Clinical features

It is important to establish the mechanism of injury and assess for other life-threatening trauma. Where there is no obvious cause, non-accidental injury should be suspected. It is often very difficult to establish a mechanism of injury from a child who is either very distressed or comatose. A history should be obtained from the ambulance crew, relatives, or eyewitnesses at the scene of the accident. It is important to elicit any history of sustained or transient motor dysfunction as this may be indicative of instability. These children should be immobilized on a specially adapted spinal board avoiding hyperflexion of the neck. An initial ABC assessment should be performed. Any child with major trauma should be suspected of having a spinal cord injury. A neurological examination is done as part of the secondary survey. In the conscious child the presence or absence of limb movement should be noted. Light touch and pin prick sensation should be quantified. A log roll is performed to assess skin integrity, bruising, tenderness, and increased interspinous process gapping. A rectal examination should be performed and the bulbocavernosus reflex assessed for spinal shock.

In the comatose child with a suspicion of spinal cord injury, imaging of the whole spine should be obtained. In the conscious child radiological investigation is directed by clinical examination if the child is fully awake and cooperative.

Assessment of the infant for spinal trauma is an even more challenging prospect. On the whole, a thorough and repeated evaluation is required.

Radiological evaluation

Plain radiography in most centres remains the initial screening method of choice. The views are taken of the whole spine. The cervical views consist of anteroposterior, lateral, and open mouth views. Oblique views may also be appropriate. The lateral view should incorporate occiput to the cervicothoracic junction. The lateral views are also used to determine the Powers ratio although this formula has its shortcomings. Although a single lateral radiograph is sensitive for isolating injuries, 25% of injuries will be missed. Flexion–extension views may help to isolate an area of instability, but should only be carried out under supervision in a
cooperative child. The bony articulations and soft tissues from the occiput to the cervicothoracic junction should be carefully assessed. Multiple-level injuries in the cervical spine are common in children (24%) and radiography should be scrutinized carefully for other injuries. In the thoracolumbar spine both the anterior and posterior columns are carefully assessed for loss of alignment and deformity. Vertebral body height may cause confusion as there is often normal anterior wedging in the immature spine. Secondary ossification centres may look like avulsion fractures. Interpedicular widening should also be noted.

Assessment of radiographs should include the following:

- Interspinous distances
- Spinolaminar line
- The funnel shape made by the spinal canal.
- Radiography is not necessary if the following features are present:
  - Alert and cooperative child
  - No neck pain
  - Normal neck and neurological examination
  - No head, face, or neck trauma.

In all other cases cervical immobilization should be used until the neck has been cleared radiographically.

CT scan is used to assess the extent of bony injury and canal compromise. It can therefore be used to predict stability and guide treatment interventions. In one study two out of 112 patients studied prospectively had injuries which were missed on all examinations except for CT. Children under 4 years of age may require sedation for CT.

Magnetic resonance imaging (MRI) is used to assess for neural and discoligamentous injury. A general anaesthetic may be necessary for children. Three types of MRI change are described in the spinal cord:

- Type I—decreased signal (haemorrhage)
- Type II—increased signal (oedema)
- Type III—mixed signal (contusion).

Patients with type II and III changes have a better chance of recovery.

Differential diagnosis

Congenital defects, skeletal dysplasias, infection, tumours, metabolic, and inflammatory conditions may also present with features similar to a spinal injury.

**General principles of management of paediatric cervical spine trauma**

Immediate immobilization of those suspected of having a cervical injury is mandatory, as the consequences of missed injury can be catastrophic. Even if the child is able to give a history, this combined with clinical examination can be inaccurate.

**Box 14.3.2 General principles of management in spinal injuries in children**

- Under the age of 10 most injuries occur above C4
- Exclude other life-threatening injuries
- Appropriate investigations to confirm diagnosis
- Clinical examination can exclude spinal injury in alert and cooperative child.

Paediatric cervical braces are available but should be supplemented with tape and sandbags in order to adequately immobilize the cervical spine. Establishing an airway in the comatose patient can be difficult due to the inherent dangers of further spinal injury. The cervical spine can be immobilized with a brace or with in-line traction. Braces do not provide secure immobilization and there is a risk of over-distraction with the in-line method. This is a controversial topic. Children under 6 years of age have a relatively large head, and a split mattress technique is best to elevate the thorax and lower the head (Figure 14.3.3). A Minerva jacket has been used in the past for long-term cervical immobilization. Nowadays halo traction and halo jackets are more commonly used, but there is a significant incidence of pin loosening and infection. Lower torque pressures are used and in children less than age 7, 8–10 pins may be used. The halo should be applied under general anaesthetic, and a custom halo vest used. Dural tear can occur with skull perforation. If this occurs the screw should be replaced elsewhere, and usually the perforation will heal within a few days.
Fig. 14.3.2
Posterior cervical line: arrows indicate the points from which the line is drawn to assess any displacement of the axis.

Fig. 14.3.3
Modified backboard.

On the whole, apart from very unstable injuries, the majority of cases are treated non-operatively because of concerns regarding growth potential and long-term deformity.

Upper cervical spine injuries

Injuries in up to 87% of children under the age of 8 will be between the occiput and C3, and the majority of these will occur to the soft tissues rather than the bones (see Table 14.3.1).

SCI, spinal cord injury.

Atlanto-occipital injuries

Atlanto-occipital injuries are frequently fatal and usually occur as a result of high-energy trauma such as a motor vehicle collision. The high mortality is due to the accompanying spinal cord, brain stem, and cranial nerve injuries. Recently, however, there has been an increase in the number of children surviving this injury, possibly due to better early resuscitation measures. The injury may go unrecognized initially because dislocations often reduce and radiographs will be normal or are difficult to interpret. There are...
useful radiographic measurements which are useful in assessing the injury. The Powers ratio represents the distance between the basion of the skull and the posterior arch of C1 divided by the distance between the opisthion and the anterior arch of C1. Abnormality is indicated by a ratio of more than 1. This ratio has its limitations in that whilst it is useful in assessing anterior dislocations it does not have the same accuracy in identifying posterior dislocations. In the presence of a fracture of C1 or a congenital anomaly of the base of skull the Powers ratio is invalid. Symptoms and signs include respiratory distress, cranial nerve lesions, and spinal cord dysfunction. Treatment can be operative by occipitocervical fusion usually down to C2 or non-operative with immobilization in a halo jacket. Reduction by traction is contraindicated.

Occipital condyle fractures are rare. Diagnosis can only be completed with CT scanning, preferably with multiplanar reconstruction. The Anderson–Montesano classification is described in Chapter 12.39.

Fractures of the atlas

Fractures of the atlas are rare in children. They are usually caused by axial forces transmitted through the occipital condyles to the lateral masses of the atlas. The synchondroses of C1 remain open up to the age of 10 and can fail under stress. The transverse ligament may rupture or avulse from its attachment. Neurological deficits rarely occur. Radiographically, open-mouth views should show symmetry of the C1 lateral masses both in relation to the odontoid process and to the lateral masses of C2. CT scanning is essential for diagnosis. Halo-jacket immobilization is usually adequate and surgery is rarely indicated.

Atlantoaxial injuries

These injuries can be traumatic but rare giving rise to transverse ligament deficiencies or atraumatic due to developmental conditions such as Down syndrome, skeletal dysplasia, Klippel–Feil syndrome or os odontidenum (Table 14.3.2). These children in the last group are at increased risk of neurological compromise with minor trauma. Neurological signs such as change in physical tolerance, incontinence, and long-tract or cranial nerve signs should be investigated. Fifty per cent of normal cervical rotation takes place between C1 and C2. The joint surfaces are relatively flat, and stability depends mainly on the ligaments. The spinal canal is relatively large, and Steel’s rule of thirds applies. The spinal canal at C1 is occupied equally by the odontoid process, the spinal cord, and free space. The course of the vertebral artery between C1 and C2 is relatively fixed and therefore excessive movement at this level is liable to compromise blood supply to neural tissue.

Treatment decisions are based on the space available for the cord and the anatomy of the posterior arch of C1. The presence of an excessive atlantodens interval or hypoplastic posterior arch increases the likelihood of neurological injury.

Reduction in extension is recommended. Observation is adequate where the atlantodens interval is less than 10mm, but where this is greater than 10mm, or where there are neurological symptoms or signs, spinal fusion from C1 to C2 is recommended. Immobilization for 8–12 weeks is necessary postoperatively.

Atlantoaxial rotary subluxation
Atlantoaxial rotary subluxation is seen commonly in children. It can occur secondary to local infection, inflammation (e.g., respiratory infection), rheumatoid disease, or trauma.

Atlantoaxial rotary subluxation often occurs after minor trauma and symptoms vary from mild to severe pain. Neurological injury or death is rare. The child may wake with a ‘crick’ in the neck and this sometimes resolves spontaneously. The ‘cock robin’ position is typical (Figure 14.3.4). The chin points in the direction of the side with muscle spasm.

Fig. 14.3.4
Cock robin position.

Radiographic changes are difficult to interpret on plain films (Figure 14.3.5) and dynamic CT scanning is essential. The head is turned maximally to either side. A positive test shows loss of normal rotation between C1 and C2. Plain anteroposterior radiographs show a wider C1 lateral mass on the side which has moved forwards, a narrower C1 lateral mass on the side which has moved backwards, and an obscured facet joint on one side. Plain lateral radiographs show that the wedge-shaped lateral mass lies anteriorly and that posterior arches are not superimposed.

Fig. 14.3.5
C1–C2 rotation.

If symptoms are mild and of less than a week’s duration, a soft collar alone may be adequate treatment. If symptoms are more severe or long-standing, but of less than a month’s duration, halter traction and sedation for a few days usually results in reduction. Some authors recommend Minerva immobilization for 6 weeks if the atlas is displaced anteriorly on the axis. If the condition has been present for 1–3 months it is described as fixed rotatory fixation. Halo traction may achieve reduction. Failure of traction or a history longer than 3 months will usually require open reduction followed by fusion and immobilization. If reduction is not possible, fusion in situ is acceptable. There are various instrumented techniques that have been described.

Odontoid fractures

Odontoid fractures are the most common cervical injuries in children, occurring at an average age of 4 years. They really represent physeal injuries through the growth plate between the odontoid and body of the axis. The growth plate closes at the age of 3–6 years. The injury may follow trivial head trauma or a severe fall or road traffic accident and is almost never associated with any neurological injury. The child will often resist extension of the neck.
Lateral radiographs are usually diagnostic and the angulation is usually anterior. Posterior angulation of the odontoid is seen in 4% of normal children and should not be confused with a fracture. Dynamic CT or MRI scanning in flexion and extension will usually clarify the situation where the diagnosis is in doubt. Diagnosis can be particularly difficult in children with congenital abnormalities, for example in osteogenesis imperfecta or Morquio’s syndrome where the odontoid is dysplastic.

Treatment consists of reduction in extension either simply by head positioning or by halter traction. This should be followed by Minerva or halo-vest immobilization for 6–12 weeks. The results are universally good. Fractures of the odontoid in older children usually behave in a similar manner to adults.

Os odontoideum

Os odontoideum probably represents non-union of an odontoid fracture which has gone unrecognized. It is usually asymptomatic but can be a cause of neck pain, or even occasionally of instability and spinal cord compression. If instability is present, posterior C1–C2 fusion is the treatment of choice.

Hangman’s fracture

Hangman’s fracture (fracture of the pedicle of C2) is unusual in children. Neurological deficit is rare. There are two major causes for confusion in making a diagnosis. Firstly, the synchondroses between the body of C2 and the pedicle ossification centres can be mistaken for a fracture. The synchondrosis normally closes by the age of 7. Secondly, pseudosubluxation of C2 on C3 occurs in up to 50% of children under the age of 8 years. Therefore the lateral radiographs must be properly assessed and, if necessary, further imaging obtained. Reduction should be achieved by positioning; immobilization in a Minerva cast for 6–12 weeks usually results in union. Surgery in the form of spinal fusion is only used if there is non-union or instability. Traction should be avoided because the risk of over-distraction.

Lower cervical spine injuries (C3–C7)

These injuries are not common in children. They can present as injuries to the growth plates which can be difficult to identify on plain radiographs. In the older child they present a similar picture to adults.

Salter–Harris type injuries can occur when the endplate separates from the vertebral body at the level of the physis. These injuries can cause neurologic deficit. Type I SalterHarris injuries are unstable and require surgical stabilization while type III injuries are stable and can be managed in a halo. Compression fractures are the most commonly occurring injury. Other types of injury seen are fracture dislocations, bifacial dislocations, unifacial dislocation, burst fractures, and posterior ligament ruptures. A description of the individual injury patterns and their treatment follows.

Wedge compression fractures

Wedge compression fractures are the most common subaxial fractures. They are stable fractures which heal rapidly in children. They may be difficult to recognize because of varying ossification patterns, and because the vertebrae tend to look wedged normally in children. Fracture healing time is 3–6 weeks, and immobilization in a collar for 2–4 weeks is usually adequate. There may be associated fractures such as anterior teardrop fracture, laminar fracture, or spinous process fracture.

Distraction shear fracture injuries

Distraction shear fracture injuries are rare. They occur through the endplate and they may be associated with birth trauma. Associated quadriplegia is not uncommon. Where neurological deficit is present, reduction and surgical stabilization is advised.

Fracture dislocation injuries

Fracture dislocation injuries are similar to those occurring in adults. They are usually high-velocity injuries. Treatment is by early reduction and stabilization. Late deformity may occur.

Facet dislocation injuries

Facet dislocation injuries are relatively uncommon. The patterns of injury are similar to those in adults, and they occur in adolescents. Dislocations can usually be reduced with traction. Some authors recommend non-operative management in a brace for 6 weeks, whereas others recommend surgical stabilization. If a unifacet dislocation is irreducible or if there is a bifacet dislocation, surgical stabilization with instrumentation and bone grafting is recommended. In children there is a high incidence of fusion extension, when extra laminae or spinous processes are exposed. The surgical exposure should be confined to the area
being fused to avoid this. Whereas wire techniques tend to be inadequate in adults, in children the small forces exerted on the fixation and rapid healing make wire techniques more acceptable (Figure 14.3.6).

Fig. 14.3.6
Wiring of fracture: A) drill holes are made at the base of both spinous processes to be fused (if large enough); B) 18-gauge wire is passed through the lower and upper holes twice and looped around the spinous processes; C) the wire is tightened; D) the laminae are decorticated and corticocancellous graft is placed; E) C2–C3 soft tissue injury with subluxation; F) MRI of same patient showing soft tissue injury at C2–C3; (g) postoperative radiograph showing posterior fusion and wiring.

General principles of management of fractures of the thoracic and lumbar spine

Thoracolumbar fractures in infants can be caused by child abuse. Children in the first decade usually sustain injuries as passengers or pedestrians in motor collisions. Beware the seatbelt bruise on the abdominal wall which is usually indicative of major spinal trauma in association with a visceral injury. In children over the age of 10 years, sport and recreational activities are the most common causes.

Clinical assessment is difficult in the very young and in those with multiple injuries. The child may not be able to isolate the site of pain and examination is difficult. A significant fracture may be overlooked. In the emergency department initial trauma resuscitation protocol is carried out to avoid mortality from these other injuries. A thorough secondary survey is carried out to inspect the soft tissues over the front and back of the trunk. Abdominal bruising or the presence of a defect or step posteriorly may point to a thoracolumbar fracture. Serious abdominal injury occurs in 20% of children (50–90% of those with Chance fractures). Signs and symptoms of prolapsed intervertebral disc should alert the clinician to the possibility of slipping of the vertebral apophysis.

The presence of a neurological injury should be established. Where a deficit is present, an assessment to determine whether the injury is complete or incomplete is necessary as incomplete injuries will have a better prognosis. During resuscitation, attention to spine immobilization should be observed at all times to prevent further injury. Further evaluation with plain radiographs is performed although CT is increasingly being used as a first choice investigation. Where there is evidence of neurological injury an MRI scan should be done. Treatment for stable injuries can be with a plaster jacket or orthosis usually fitted to hold the trunk in extension. Unstable injuries require surgical stabilization. Modern instrumentation allows for preservation of more motion segments by using shorter constructs and thereby avoiding the pitfalls of stabilization across several segments. Fracture patterns in the thoracolumbar spine are caused the injury mechanism involved. This is reflected in the classification systems which describe these injuries. Unfortunately these classifications do not serve as a guide for treatment but do allude to injury severity and likelihood of neurological compromise.

Classification of thoracic and lumbar fractures

Fractures are classified by mechanism of injury. As in adult fractures, they can be divided into three broad groups:

- Compression
- Distraction
- Rotation.

The three groups have an increasing incidence of neurological injury and other complications.

Compression

As in adults, flexion injuries are the most common. The discs are more resistant to vertical compression than the bones. The nucleus of the disc causes the endplate to fracture, and nuclear material herniates into the vertebral body. In older children the nucleus of the disc is more viscous and the compression forces are dissipated peripherally; either the annulus is torn and the sides of the vertebrae buckle, or a marginal fracture occurs. More severe forces cause burst fractures similar to those in adults. Flexion
injuries commonly occur at multiple levels in children. Slipping of the vertebral apophysis occurs most commonly in teenage boys. This causes traumatic displacement of the ring apophysis into the spinal canal and disc protrusion. The most commonly injured level is L4. The injury resembles slipped epiphysis of the hip. The symptoms resemble those of disc herniation, and can be acute or chronic. This injury may be associated with Scheuermann’s disease.

**Distraction**

Chance fractures (Figure 14.3.7) occur with hyperflexion and distraction in the posterior column. A fracture occurs across the osseous or posterior ligamentous (soft tissue Chance fracture) elements of a vertebra. The fracture is propagated anteriorly through the anterior and middle columns or in the case of the soft tissue Chance injury through the disc. The most common mechanism is a lap seatbelt injury in a motor vehicle collision. Bony Chance fractures can be treated non-operatively in a plaster jacket or thoracolumbosacral orthosis (TLSO). However, if there is severe kyphosis at presentation or neurological deficit at presentation surgery should be considered. The soft tissue Chance fracture generally has poorer healing capacity if treated non-operatively and therefore surgery should be considered as first choice treatment.

**Rotation**

These injuries usually occur in motor vehicle collisions. The injury passes through the endplate apophysis. Traumatic spondylolisthesis can occur.

**Box 14.3.5 Thoracolumbar spine injuries in children**

- Suspect visceral injury with seatbelt bruising
- Stable injuries treated in orthosis
- Surgical stabilization for unstable injuries
- Preserve motion segments.

**Spinal cord injury without radiographic abnormality**

SCIWORA occurs in about 7% of children with spinal cord injury although it has been said to account for up to a third of spinal cord injuries in children. Neurological loss is more commonly complete in younger children and in thoracic injuries. Thoracic lesions are complete in 92% of those under 8 years compared with 50% of adolescents. Bracing is probably not necessary unless instability has been demonstrated (by definition this will not occur in SCIWORA).

When this condition was originally described, MRI scan was unavailable which has now made the diagnosis somewhat controversial. However, the absence of abnormal cord signal on MRI may indicate good prospects for recovery.

**Neonatal injuries**

Neonatal injuries are seldom reported, possibly because the spine is difficult to assess radiographically as most of it is still cartilage. In traumatic vaginal delivery, neck hyperextension (‘stargazing fetus’) with breech presentation is associated with a high
incidence of cord transection (25%). Treatment is usually limited to a neck support or orthosis, and bone injury rapidly heals.

Child abuse can occasionally cause spinal fracture or spinal cord injury, and is associated with intracranial and intraocular haemorrhages. This has been called 'shaken infant syndrome'.

**Complications**

**Post-traumatic deformity**

The same complications arise as in adults after spinal cord injury (see Chapter 12.45), such as pressure sores, renal tract infection and stones, contractures, etc.

Spinal deformity commonly occurs in children following spinal cord injury. The incidence of scoliosis is related to the age of the child at the time of injury. Ninety-seven per cent of those presenting before the growth spurt may develop scoliosis, compared with 52% presenting after. The onset of scoliosis has been reported in children as young as 3 years. Progression potential depends on the following:

- Age of the patient
- Level of the lesion
- Severity of the spinal cord injury.

Scoliosis is known to deteriorate with growth. The majority of these children will deteriorate and require surgical stabilization in the form of a spinopelvic fusion. Many of them will have seating problems and pressure sores due to pelvic obliquity which is corrected at the time of surgery. Up to 68% of children may require surgical stabilization.

A post-traumatic syringomyelia may develop which manifests as pain, deteriorating neurological function and deformity. Surgical drainage may be required.

**Neurological injury**

Neurological injury may occur in up to 45% of children with spinal injury, but in general this has a better prognosis than in adults. Partial or complete injuries must not be overlooked. Serial observations are useful if neurological status is in doubt. The single most important finding is of a neurological level. Boys are twice as commonly affected as girls, and those aged 10–15 years are at most risk. Ten to fifteen per cent of spinal cord injuries occur in children. In newborn children, neurological injury should be suspected in a floppy infant following a difficult delivery.

Delayed-onset paraplegia has a very poor prognosis.

**Growth arrest**

Significant growth arrest in the spine is rare. The vertebral bodies have great remodelling potential, especially in children under the age of 10 years. Asymmetric damage to the growth plates seldom causes scoliosis because the adjacent vertebrae adapt. Occasionally kyphosis will occur when the endplates are damaged. Spontaneous interbody fusion is rare.

**Box 14.3.6 Special features in recovery from spinal injury in children**

- Post-traumatic deformity common in prepubertal spinal injury
- SCIWORA present in a third of cases
- Syringomyelia can cause progressive deformity
Spondylolysis and spondylolisthesis may have a traumatic aetiology in children.

Acute spondylolytic spondylolisthesis is a rare occurrence following high-energy trauma. The injury usually occurs in the pars interarticularis of L5 but may occur elsewhere in the posterior elements. The deformity often progresses and may cause neurological compromise. These injuries should be treated surgically at an early stage to prevent progression. Grade I deformities can be treated by posterior fusion alone; more severe slips are best treated by anterior and posterior fusion.

Further reading

Summary points

- Dislocation of the shoulder is rare in children but may be mimicked by epiphyseal disruption
- Midshaft clavicle fractures are common and have great powers of remodelling
- Proximal humeral fractures commonly involve the physis and lead to shortening although this is rarely apparent to the patient.

Introduction

Children cannot be considered as small adults, and this is especially true when dealing with injuries around the shoulder. Although one of the most common fractures in both is the clavicle fracture, this is where the similarity ends. Physeal involvement is a factor and the potential for remodelling is considerable. In particular, the pattern and behaviour of fractures of the proximal humerus in children is completely different from that in adults. Shoulder dislocation, a common adult condition, is very uncommon in children. Often epiphyseal fractures in children may appear as joint dislocations.

Anatomy

The three bones of the shoulder girdle—the clavicle, scapula, and humerus—connect with the torso via the sternoclavicular joint. The flat, triangular scapula provides attachment for 17 muscles, and expands into the acromion, which articulates with the clavicle, the coracoid, and the glenoid, which articulates with the humerus. The adult proximal humerus is considered in four parts: the articular head, the greater and lesser tuberosities, and the proximal shaft. In children, the most commonly injured site is the growth plate, and a fracture in the child rarely consists of more than two parts (Figure 14.4.1). In adults, the bony architecture cannot be considered in isolation from the soft tissues, especially the rotator cuff. In children, the growth plates and epiphyses must also be considered, and the rotator cuff is of less importance.

Ossification

The scapula, formed by membranous ossification, is largely present at birth. The coracoid ossifies from two separate centres, fusing by the fifteenth year. By puberty, between two and five ossification centres form the acromion (Figure 14.4.2), which fuses by 20–22 years. Failure of acromial fusion, resulting in an os acromiale, occurs in about 5% of the population, visible on axial view. It may be confused with fracture.
The clavicle develops two ossification centres around weeks 5–6 of fetal life. These fuse within a few weeks of their appearance; failure of this may produce a congenital pseudarthrosis of the clavicle. A secondary ossification centre appears in the medial end of the clavicle in the late teens and fuses by about the age of 25 years. The lateral end occasionally develops a secondary ossification centre at the age of 18–20 years. This is usually small and rapidly fuses to the shaft.

The shaft of the humerus is evident at birth, with the head appearing at 6 months. The greater and lesser tuberosities appear between 2–5 years, fusing by 6 years to produce a conical growth plate with a posteromedial apex, which accounts for 80% of the humeral growth. In children under 6 years, fracture through this growth plate is usually a Salter–Harris type I injury, as before the tuberosities fuse the growth plate is more transverse. In the older child, a Salter–Harris type II fracture occurs through the conical growth plate, retaining the posteromedial metaphysis.

**General principles**

Falls, traffic accidents, and sports are the commonest cause of shoulder girdle injury. However, with any childhood injury the possibility of child abuse must always be considered. In general, most shoulder injuries occur in children over 5 years old, an age at which child abuse resulting in fractures is uncommon. In the under 5s, a proximal humerus fracture is rarely due to child abuse, although all scapular fractures and clavicle fractures in those under 18 months old should be viewed with suspicion. Many of the other fractures seen around the shoulder occur after major trauma, and an appropriate history is available. However, if the mechanism of injury does not fit the history given or there was a significant delay in presentation, child abuse should be considered.

Children under 5 years have tremendous potential to remodel, and significant deformity can be accepted, especially in the proximal humerus. Given the malalignment and shortening that can be accepted even in adults, few of these fractures in children will need operative intervention.

Adolescents should be considered as adults if they are reaching skeletal maturity. The management of their injuries, including the indications for operative treatment, should be the same as those in an adult. In a child of any age, an open fracture must be treated by operative debridement, and stabilization of the fracture site. In children as in adults, polytrauma is a relative indication for surgical treatment.

High-energy trauma around the shoulder is very uncommon in children, so that examples of injuries such as scapulothoracic dissociation, or intrathoracic dislocations in children exist only as isolated case reports in the literature. They will not be considered further in this chapter.

**Epidemiology**

The risk of at least one fracture up to the age of 16 years in a boy is 42%, and 27% in girls. Of these fractures, the clavicle is involved in 8–15.5%, the fourth most common site of fracture in children. Fractures of the proximal humerus account for less than 5%, the fourth most frequent epiphyseal injury. Other fractures around the shoulder account for less than 1% of all childhood fractures.

Infants of 4kg or more are at increased risk of fracture during birth. Ninety-five per cent of birth fractures involve the clavicle by pressure from the symphysis pubis on the anterior shoulder in a cephalic presentation, and heal rapidly. Salter–Harris type I affect the proximal humerus if the arm becomes hyperextended or rotated during delivery.

**Specific injuries**

Sternoclavicular joint
Dislocations of this joint are rare in children and most apparent dislocations, even in adults up to the age of 25 years, represent epiphyseal separations. True dislocations and epiphyseal injuries can be manipulated closed and are often stable. Even if unstable, metalwork is avoided as disastrous results have been reported, including pin migration and infection. Sutures or repair of the periosteal sleeve are sufficient, with 3–4 weeks of sling immobilization as rapid healing and remodelling will occur. Anterior displacement is more common, whilst posterior displacement may be a surgical emergency if vital structures are compromised.

**Clavicle**

Fractures of the medial end of the clavicle were considered earlier.

Midshaft fractures account for 88% of children’s clavicle injuries (Figure 14.4.3), with a mean age of 8 years. The mechanism is a fall directly on to the shoulder with the arm at the side. A direct blow or a fall on the outstretched hand can rarely produce this injury. Greenstick fractures commonly occur, requiring temporary rest in a sling for a short period. Displaced clavicle fractures are very common, but rarely require reduction (Figure 14.4.1). A broad arm sling for 2–3 weeks until comfortable is all that is required. Malunion is very common but rarely causes a functional problem; non-union is very rare in children. Parents should be reassured that the prominent callus will usually resolve over the subsequent months; pressure to remove this ‘unsightly’ lump surgically should be strongly resisted.

![Click to view larger](Fig. 14.4.3)

Midshaft clavicle fracture in a 13-year-old boy.

Open reduction and fixation with wires or a plate may be occasionally required. The indications are similar to those in the adult: open fracture, skin compromise, vascular injury, etc.

Fractures of the lateral end of the clavicle may also be confused with joint dislocations, as discussed later.

**Acromioclavicular joint**

True dislocations of this joint are unusual in children, especially in the younger child. The ligaments around the joint are very strong, and more often the lateral end of the clavicle will fracture, herniating through the thick periosteal sleeve although this may not be apparent on radiographs if it is unossified. The inferior perosteum is left behind, with the conoid and trapezoid components of the coracoclavicular ligament intact, producing a ‘pseudo-dislocation’. This will heal and remodel with conservative treatment, a sling for comfort followed by early mobilization. Rockwood et al. (1984) have classified these injuries.

**Coracoid**

Fractures of the coracoid are usually an epiphyseal separation. In combination with a lateral clavicle fracture, this constitutes a childhood equivalent of an acromioclavicular dislocation and represents failure through the epiphyseal plate before ligamentous injury.

**Acromion**

Acromion fractures are rare in children and are often due to direct violence. An os acromiale may be confused with a fracture. Treatment depends on displacement, and other injuries around the shoulder. Wires, screws, tension band wiring, and plate fixation have all been used and non-union has not been reported in children.

**Scapula body**

These are uncommon injuries and usually represent direct violence. The significance of this injury is the possibility of underlying chest wall and pulmonary contusion rather than the scapula fracture itself. These injuries will almost always be treated conservatively with analgesia, and a sling for comfort. The arm should be mobilized as comfort allows.

**Glenoid**

Glenoid fractures are rare and represent a fracture dislocation of the shoulder. The size and displacement of the fragment must be assessed, and this is best achieved by computed tomography. Minimally displaced fractures respond to sling immobilization, rarely for more than 3 weeks. Indications for internal fixation, usually by a lag screw technique, include large displaced fragments, and an unstable shoulder. Operative approach, method of fixation, and postoperative mobilization will be determined by the fracture pattern and fixation achieved at surgery.
**Glenohumeral joint**

Shoulder dislocation in pre-teen children is unusual, as the ligaments are stronger than the epiphysis; more commonly a Salter–Harris fracture of the proximal humerus will occur. In adolescents as in adults, glenohumeral dislocation is frequently due to a sporting injury. Treatment is along adult lines, with early closed reduction using standard techniques. The recurrence rate is age related, highest in 14–17-year-olds, with a recurrent dislocation rate of 92%, in comparison with 33% for those under 12 years. When traumatic dislocations occur, Bankart lesions are found in 80%, leading to suggestions of prophylactic stabilizing surgery. This is controversial, but if recurrence does happen, surgery is indicated. Surgical patients are less likely to have recurrent instability, but in a study of 66 adolescents, stability improved anyway over 2 years with 90% performing at the same or higher levels of sport and work in both operative and non-operative groups. Another study has found no significant difference was found in functional outcomes between patients who had undergone surgical stabilization and those treated non-operatively.

Atraumatic dislocations can occur in children with joint laxity or connective tissue disorders and can be produced by voluntary muscle activity. Posterior glenohumeral dislocations in children have been reported as case reports.

**Proximal humerus**

Most fractures of the proximal humerus usually occur in the older child or adolescent. Not only are accidents more common at this age, but the perichondral ring may be weaker just before skeletal maturity. The majority of injuries occur through the growth plate; Salter–Harris type II in the older child, and type I in the younger child. Salter–Harris types III and IV are very uncommon injuries of the proximal humerus. No cases were reported in three of the largest series, which in total comprised over 200 patients.

Neer and Horowitz (1965) graded fracture displacement into four groups: group I, less than 3mm; group II, up to 33% of the shaft diameter; group III, up to 67% of the shaft; group IV, more than 67% displacement of the shaft. No specific grading of angulation was made, though noted to be always present in groups III and IV. Varus displacement is most common and is due to the pull of the pectoralis major attaching to the distal fragment which tends to pull it anteriorly and medially. Neer and Horowitz noted residual shortening in nearly 10% of patients of groups I and II at an average follow-up of 4.8 years. This figure rose to 33% of those in group IV, all treated by reduction, nine by open reduction and nine by closed reduction. Despite this, all patients had satisfactory functional results.

Baxter and Wiley (1986) in a review of the treatment of 57 patients, reported that manipulation of a displaced fresh fracture did not improve the final outcome, when humeral growth or function were assessed. Ninety per cent of the 30 patients they assessed more than 2 years after injury had measurable shortening; however, the maximum was 2cm, and none of their patients were aware of the shortening.

Conservative treatment is generally acceptable, not only because of the remodelling potential but also because some degree of malalignment can be accepted around the shoulder. An angulation of 45 degrees and 50% of displacement can be accepted (Figure 14.4.4). In the younger child, 70% angulation and any bony contact should heal with good functional results. The fracture is usually treated in a collar and cuff sling, although rarely a hanging cast may be used in the older child with significant shortening or angulation.

**Click to view larger**

![Fig. 14.4.4](image)

Proximal humeral fracture in typical varus.

If the position is unacceptable, closed reduction is attempted and the fracture held with two or three wires (Figure 14.4.5). These wires can be removed after 3 weeks. The use of cannulated screws instead of wires allows earlier and unimpaired mobilization. Premature closure of the growth plate will occur, but this method of treatment will usually be used in the adolescent approaching skeletal maturity (Figure 14.4.6).
Percutaneous fixation with wires.

Fixation with screws; closure of growth plate occurring.

Open reduction may occasionally be required for soft tissue interposition often the biceps tendon, and this can be achieved through a standard deltopectoral approach (Figure 14.4.7). Fracture stabilization is carried out as described earlier.

Metaphyseal fracture

This may occur with direct trauma, or may occur as a pathological fracture, classically through a unicameral bone cyst (Figure 14.4.8). Displacement is not usually significant; angulation may occur but rarely produces a functional problem. The fractures usually heal rapidly with conservative treatment in a sling. The proximal humerus is the only common site for pathologic fractures around the shoulder.
Fractures of the clavicle or proximal humerus are relatively common injuries in childhood; most can be treated conservatively with excellent functional recovery.

Other fractures are uncommon and an awareness of the basic ossification patterns will further inform a radiographic abnormality. Joint dislocations are very rare in a child; injury usually occurs through an epiphysis near to the joint. Again, a good result can be expected with conservative treatment.

High-energy shoulder trauma or polytrauma need to be treated on an individual basis, following the basic principles of trauma care.

Further reading

Fractures around the elbow are a common occurrence in childhood; however, these fractures require careful assessment and treatment if complications are to be avoided.

**Supracondylar humeral fractures**

These are the most common elbow fractures in children. Although they can occur throughout childhood there is a peak incidence between the ages of 5–8 years. A review of supracondylar humeral fractures noted that the average age was 6.7 years, 60.8% were on the left, 62.8% were in boys, and 1% were open. The usual mechanism of injury is a fall on the outstretched hand with the elbow locked in hyperextension. The natural predisposition to ligamentous laxity in this age group allows this increased hyperextension to cause the olecranon to lever in the olecranon fossa creating a stress concentration at the supracondylar area resulting in the typical extension fracture pattern.

Two per cent of these injuries have a flexion pattern and typically are caused by a direct blow to the posterior aspect of the elbow. Careful consideration of the distal humeral anatomy is needed for recognition since these fractures can be subtle. Displaced flexion fractures have a high incidence of ulnar nerve injury from where it is stretched over the posterior edge of the proximal fragment. Fracture displacement tends to be varus, in contrast with extension supracondylar fractures which may heal in valgus.

**Classification**

The classification described by Gartland (1959) and modified by Wilkins *et al.* (1996) is the most commonly used (Table 14.5.1): this is based on the degree and direction of displacement of the distal fragment on the initial x-rays. In approximately 75% of supracondylar fractures, the displacement of the distal fragment is posteromedial and the lateral spike of the proximal humeral shaft may injure the radial nerve. Whereas when the distal fragment is displaced posterolaterally, the brachial artery is at risk along with the median nerve. The direction of displacement also influences management by either pronating (posteromedial displacement) or supinating (posterolateral displacement) the forearm will help maintain fracture stability from the intact periosteal hinge prior to wiring of the fracture.

**Clinical evaluation**

In completely displaced fractures there will be swelling, bruising, and crepitus apparent and an S-shaped deformity of the elbow may be present. The carrying angle is approximately 15 degrees of valgus but should be compared to the other side as it can vary from 0–25 degrees. Whereas with undisplaced or minimally displaced fractures, swelling and point tenderness may be the only clinical signs present. Puckering of the skin indicates penetration of the brachialis muscle by the proximal end of the humerus which increases the possibility of an open reduction being required.

**Associated injuries**
Nerve injuries have been reported to occur in up to 7% of patients with supracondylar humeral fractures and all the nerves passing across the elbow should be carefully assessed. The most commonly injured is the anterior interosseous nerve since its fibres make up the part of the median nerve closest to the bone; testing for this by flexion of the index finger and thumb into an ‘O’ shape should be undertaken.

The distal circulation of the arm should also be assessed. If a radial pulse is not palpable further investigation can be performed using Doppler or pulse oximetry to assess this but this should not delay the time of operative intervention. Evaluation for compartment syndrome is needed both pre and postoperatively even when there has been no vascular compromise.

 Ipsilateral forearm injuries occur in about 5–10% of patients, but the supracondylar fractures should be treated operatively and stabilized, before treatment of the other fractures.

Radiographic evaluation

When determining the degree of displacement of the fracture on x-ray, several features should be identified (Figure 14.5.1 and Box 14.5.1).

![Fig. 14.5.1](image)

Anterior humeral line (A) and shaft-physeal angle (B). Baumann described the orientation of the shaft and physis of the lateral condyle and observed a normal range of 75–80 degrees; this should be compared to the other side. In addition the integrity of the olecranon fossa needs to be considered.

**Box 14.5.1 Assessment of reduction of supracondylar humeral fracture**

- Anterior humeral line
- Shaft-physeal angle

- Comparison with other side.

Treatment

Treatment of supracondylar fractures is based upon their classification. Type I (undisplaced) fractures need only simple immobilization in a collar and cuff under the clothes for two to three weeks then with advice for mobilization. Swelling can be significant and application of any rigid splintage can create pressure problems and is to be avoided. Complications particularly medial collapse or impaction can occur, leading to varus malunion, and so follow-up evaluation is recommended.

The treatment of type II fractures is by reduction of the extension deformity. Due to the significant incidence of instability then it is the author’s preferred technique for stabilization of these with percutaneous pins.

In type III fractures olecranon screw traction can be undertaken, but this is now rarely used because of the lengthy hospital admission required. Traction is however useful where condition of the skin precludes the presence of wires or where fracture comminution is so severe as to prevent an acceptable reduction being maintained with percutaneous pinning.

Closed reduction and percutaneous pinning

Gentle longitudinal traction should be applied followed by closed reduction of the fracture with flexion and the appropriate forearm rotation under image intensifier control is initially performed. The adequacy of the reduction needs to be assessed using shoot through (Jones view), oblique and lateral views (the latter, particularly in unstable fractures, may demonstrate rotational malalignment but is useful for assessing displacement). Numerous variations of pinning techniques have been described in an attempt to minimize complications. The two most stable constructs consist of medial and lateral pins placed through the supracondylar ridges and into the opposite cortex or two lateral divergent pins. Stabilization using the former technique involves insertion of the lateral wire in full flexion, extending the arm and inserting the medial wire (utilizing a small incision to protect the ulnar nerve) (Figure 14.5.2). Both techniques have their advocates and the main complications of loss of reduction and iatrogenic ulnar nerve injury are technique dependent.
Once stabilized, the elbow can then be assessed for stability and reduction. Radiographic and clinical assessment, as described earlier, should be used.

After closed reduction and pinning, a wool and crepe dressing and non-removable collar-and-cuff sling are worn for 3–4 weeks. Then the pins are removed and an active range-of-motion rehabilitation programme is begun.

Open reduction

Open reduction is required for fractures that cannot be reduced by closed means, open fractures, and in some cases of fractures with vascular compromise. This allows the soft tissue interposition to be treated, following which stabilization can be undertaken in the same manner as for closed reduction with the benefit of direct visualization. Approaches from all directions have been described, the commonest being anteromedial or anterolateral depending upon fracture displacement. Approaching from the same side as the displacement of the proximal fragment, often allows a direct ‘cortical read’ and does not add significantly to the periosteal stripping. Where vascular compromise requires intervention an anterior approach is preferable. Delayed open reduction beyond 10 days has an increased risk of myositis ossificans.

Complications (Box 14.5.2)

Supracondylar humeral fracture complications can be either functional or cosmetic. Functional complications relate to nerve and vessel injury and elbow stiffness. Cosmetic complications are related to inadequate reduction creating malunion.

The majority of nerve injuries are neuropraxic from the injury itself and recover within 3 months of injury. The most common injury involves the anterior interosseous part of the median nerve.

Box 14.5.2 Complications of supracondylar fractures

- **Nerve damage:**
  - ulnar nerve—may be caused by percutaneous pins
  - median nerve—may mask compartment syndrome
  - anterior interosseous nerve—most common

- **Vascular system:**
  - loss of radial pulse with good capillary return and careful observation
  - poor capillary return—urgent exploration
  - loss of circulation after reduction—urgent exploration

- Avascular necrosis of trochlea—produces fishtail deformity of humerus
- Stiffness
- Myositis ossificans
- Deformity
- Cubitus varus (gunstock deformity)
- May have rotatory component.

Ulnar nerve injury most commonly occurs due to medial pin insertion but these recover in almost all cases by 3 months following pin removal.

Vascular injuries are uncommon. If the radial pulse is absent but there is good capillary refill following stabilization of the fracture then observation, especially for compartment syndrome of the forearm musculature, is the preferred management, even if the radial pulse is absent.
pulse was lost during reduction. If the arm is pulseless and capillary refill is poor the fracture should be stabilized and the situation reassessed, and if persistent, observation can still be undertaken since the vast majority of pulses return within 24h without detriment. Close observation should be undertaken with a low threshold to return the child to theatre for release of compartment syndrome and arterial exploration if necessary. The child should be transferred to a unit where facilities exist for vascular surgery.

Avascular necrosis of the trochlear has been reported from vascular injury leading to a fishtail deformity of the distal humerus, symptoms from which are delayed.

Elbow stiffness after this fracture may result in loss of terminal elbow extension. Most patients regain almost complete elbow motion, although this may require several months. Elbow stiffness also can occasionally be caused by myositis ossificans, which usually occurs after delayed open reduction or too vigorous rehabilitation.

Angular deformities result from inaccurate reduction or subsequent displacement producing a malunion. Cubitus varus (‘gunstock’) deformity is most common. The deformity remains static occurring at the fracture site rather than the joint and there are minimal functional deficits but often a considerable cosmetic deformity. Rarely this can occur in undisplaced fractures which may be a feature of vascular compromise to the lateral condyle.

Correction of cubitus varus is directed at the coronal plane deformity with various techniques having been described (Figure 14.5.3). The commonest technique of a lateral closing-wedge osteotomy may produce a lateral prominence and apparent persistence of the deformity, whereas other techniques attempt to avoid this problem using a dome osteotomy or step-cut lateral closing-wedge osteotomy.

Cubitus varus deformity is rare. Hyperextension occurs when the lateral humeral capitellar angle is not corrected at the time of reduction and this does not improve with growth.

**Lateral condylar fracture**

Fractures of the lateral humeral condyle account for approximately 15% of distal humeral fractures in children, occurring most commonly around the age of 6 years. They can be easily missed radiologically since the metaphyseal fragment appears small but the presence of point tenderness over the lateral condyle with localized swelling should alert the clinician to the possibility of this injury.

**Classification**

Lateral condylar fractures classically were classified by the fracture pattern; Milch (1964) described two types of fracture direction; but practically the best classification is described by Wilkins (1996) and is related to displacement.

**Mechanism of injury**

Two mechanisms of injury have been proposed for fractures of the lateral humeral condyle fracture: a ‘push-off’ mechanism where a fall onto the hand with the elbow flexed causes the radius to push off the lateral condyle; and a ‘pull-off’ mechanism which is more common and occurs when a fall on the outstretched hand with an extended elbow creates a varus moment and the lateral condyle is pulled by the extensor muscles.

**Radiographic evaluation**

In undisplaced or minimally displaced fractures a ‘fat-pad’ sign is present. The metaphyseal fragment is difficult to visualize on the anteroposterior view and on the lateral view will appear falsely small since it is being viewed in profile. In displaced fractures the
Capitellar ossification centre and the radial head are not aligned, distinguishing this from a supracondylar type fracture where this is maintained. Close monitoring of these fractures is required since with displacement operative treatment is required and it is difficult to assess whether there is an intact periosteal hinge stabilizing a minimally displaced fracture.

**Box 14.5.3 Key features of lateral condyle fractures**

- Common but easily missed
- Fracture line hidden in epiphysis and physis
- Muscles attached to distal fragment may increase displacement
- Local tenderness and swelling over lateral epicondyle is diagnostic
- Fat-pad sign commonly visible on radiograph.

**Treatment**

Fractures with less than 2mm displacement can be treated conservatively by immobilization; however they need monitoring to exclude late displacement, in which case fixation will be required. Immobilization is continued until radiographic healing is present.

Fractures with less than 4mm of displacement can be treated by closed reduction and percutaneous pinning with care not to cross the fixation wires at the site of the fracture and a degree of wire divergence is preferable.

For significantly displaced or unstable fractures, open reduction and internal fixation is required. A posterolateral approach in the brachioradialis–triceps interval presents the fracture which is reduced by extension and the metaphyseal fragment is always larger than expected from radiology and can be stabilized with a cannulated small fragment screw into the metaphysis. Excellent results with no complications have been reported with screw fixation. Alternatively two K-wires can be utilized.

**Complications**

The commonest complications of lateral condylar fractures relate to problems of union. In undisplaced fractures treated conservatively delayed union is frequent. Possible causes are poor vascularity of the fragment, synovial fluid in the fracture preventing fracture healing, and the muscle pull of the common extensors.

Non-union is usually due to incomplete reduction of fracture fragments. Non-unions without angulation are usually asymptomatic; however, where angulation remains, a cubitus valgus deformity develops which can lead to a tardy ulnar nerve palsy. Treatment of a non-union depends on functional problems as well as progressive deformity but open reduction with bone graft and internal fixation is required (Figure 14.5.4) and ulna nerve transposition may also be indicated.

**Transcondylar fracture**

Transcondylar fractures of the humerus are a physeal separation of the whole of the distal humerus and occur prior to ossification, typically under 3 years of age (Figure 14.5.5). Since this area is cartilaginous, no fracture may be apparent on x-ray and a misdiagnosis of an elbow dislocation is made. These is a rare injury infrequently reported in the literature. These fractures have also been reported as birth injuries following difficult deliveries and also in child abuse cases.
Clinical and radiographic evaluation

Swelling and hypermobility may be present or in the very young pseudoparalysis of the limb may be the presenting complaint. Assessment of the relationship of the medial and lateral epicondyles and the olecranon as an equilateral triangle exclude the diagnosis of dislocation and should alert the clinician to the possibility of a transcondylar fracture. Radiologically there may be loss of alignment between the radius and ulna and the humerus and the displacement is usually posteromedially. Arthrography or ultrasound may be required to confirm the diagnosis in the operating theatre prior to intervention.

Classification

Three groups are described depending on the degree of ossification present. In group A fractures (up to 12 months of age), the lateral condyle secondary ossification centre is not present and there is no visible metaphyseal fragment. In group B fractures (1–3 years) the capitellar ossification centre is present; a metaphyseal fragment, if present, is very small. Group C fractures (3–7 years) have a well-developed capitellar ossification centre and a large metaphyseal fragment.

Treatment

The recognition of the fracture and its association with child abuse in children under 2 years is mandatory, up to 38% in this age group have been reported to have this mechanism of injury. The fracture is reduced by elbow flexion and pronation of the forearm should then be stabilized using two divergent lateral wires (cross K-wires are difficult to insert medially due to the cartilaginous medial epicondyle) and then immobilized but the adequacy of reduction may require arthrographic assessment. Postoperatively a supportive dressing is required with the limb held flexed by a collar and cuff worn under the clothes for 3 weeks and then mobilization following wire removal. If the fracture has been missed and is more than 5 or 6 days old it will be irreducible and is better left to heal and corrected by osteotomy at a later date if necessary.

Complications

Neurovascular complications are infrequent but cubitus varus is common although generally minor (less than 15 degrees) and is related to the difficulty of assessment of reduction in the absence of ossification of the physeal fragment. This degree of cubitus varus deformity rarely causes functional problems and rarely requires corrective osteotomy. Avascular necrosis of the trochlea can occur after this fracture and tends to occur early with a subsequent varus or fishtail deformity.

Box 14.5.4 Key features of transcondylar fractures

- Easily confused with dislocated elbow
- Associated with nonaccidental injury
- Arthrogram or ultrasound may be needed for diagnosis
- Best fixed with two lateral pins
- Most common complication is cubitus varus.

Medial humeral condylar fracture

Medial humeral condylar fractures are rare, occurring around 8–14 years of age. The fracture involves the trochlea and the distal humeral metaphysis, with the attached medial epicondyle, and is inherently unstable. Up to 40% are associated with elbow
dislocations.

The fracture can either enter the elbow medial to the lateral crista of the trochlea or pass directly through the medial condylar ossific nucleus. Due to the presence of the attached medial epicondyle the fracture is rotated by the common flexors so that the fracture surface presents anteromedially and the articular surface faces posterolaterally (Figure 14.5.6A).

Mechanism of injury

Medial condylar fractures are caused by a direct blow on the flexed causing the olecranon to split the trochlea or where a fall is associated with a valgus stress and the forearm flexor muscles avulse the condyle.

Clinical and radiographic evaluation

Clinically there is medial swelling and tenderness and varus instability. Ulnar nerve function should be carefully assessed. After ossification of the trochlea and medial epicondyle the fracture is apparent on standard radiology and a fat pad sign is also present but before ossification a high index of suspicion is required and alternative techniques such as magnetic resonance imaging (MRI) may be required.

Treatment

Undisplaced fractures can be treated by immobilization in a backslab but must be regularly assessed for displacement. For displaced fractures the preferred option is open reduction and internal fixation via a posteromedial approach decompressing the ulnar nerve, limiting dissection to avoid avascular necrosis. The medial condyle should be stabilized with two parallel pins or a screw (Figure 14.5.6B). Post operatively due to swelling a supportive bandage or back slab is required with immobilization in a collar and cuff for 3 weeks and then mobilization.

Box 14.5.5 Key features of medial condyle fractures

- Rare
- Elbow may be unstable
- Associated with dislocated elbow and ulnar nerve palsy
- Easy to confuse with medial epicondyle fracture
- Difficult to visualize without arthrogram or MRI.

Complications

The common complications are non-union, avascular necrosis of the trochlea causing a “fishtail” growth deformity, and stiffness. Restriction of extension is the most frequent problem. Non-union is usually secondary to delayed diagnosis and treatment or inadequate fixation. Treatment of established non-union requires bone grafting and internal fixation.

Fractures of the capitellum

Fractures of the capitellum are a rare injury at any age, but especially in children. Anterior sleeve fractures have been reported in 8-year-old patients, but capitellar fractures are usually in older adolescents.

These fractures occur following a fall on the outstretched hand, where shear forces are transmitted through the radial head, injuring all or part of the capitellum. Recurvatum and cubitus valgus deformities may be predisposing factors.
The diagnosis of this fracture may be difficult and easily missed, particularly since they can be associated with radial head fractures. Swelling is often minimal about the elbow, with tenderness over the capitellum. A positive fat-pad sign is usually present on standard radiographs. Oblique radiographs or an MRI may necessary for diagnosis.

Two fracture patterns are described (Figure 14.5.7). Type I is a complete fracture of the capitellum, which has a portion of cancellous bone attached to the distal fragment. Type II fractures involve mainly articular cartilage with only a thin margin of subchondral bone.

![Fig. 14.5.7](#)

Types of capitellar fractures: A) type I with a large cancellous fragment; B) type II, almost a pure articular fracture with little or no subchondral bone.

**Treatment**

Open reduction is necessary, if the metaphyseal fragment is large enough this can be reattached and secured with Herbert type screws, via a posterior approach through the lateral condyle but careful dissection is required to avoid avascular necrosis of the lateral condyle. Smaller fragments should be excised and early range of motion exercises undertaken. The complications of capitellar fractures are avascular necrosis of the fracture fragment, loss of motion about the elbow, and early degenerative arthritis.

**Medial epicondylar fractures**

Medial epicondylar fractures are the third most common fracture of the elbow in children, accounting for 11% of fractures about the elbow. This injury most frequently occurs between 9–14 years of age, and is four times more common in boys than in girls. Elbow dislocation occurs in approximately 30% of cases and in half of these the medial epicondylar fragment will be incarcerated in the elbow joint after reduction of the dislocation leading to a block to elbow extension.

**Anatomy**

The medial epicondyle is a traction apophysis with the forearm common flexor muscles arising from its anterior surface and the ulnar collateral ligament also being attached. Ossification of the medial epicondyle begin at 4–6 years of age, and it fuses with the distal humerus by the age of 15 years. Irregularity of ossification can give the nucleus a fragmented appearance, which can be mistaken for a fracture. In younger children some capsular attachments may remain and a positive fat-pad sign may be seen, but in older children the epicondyle is extra-articular.

**Mechanism of injury**

Medial epicondylar fractures can be caused by a direct blow, an avulsion injury due to the pull of the common flexor muscles of the forearm, or with an elbow dislocation where under hyperextension and valgus stress the ulnar collateral ligament avulses the epicondylar. This dislocation may spontaneously reduce prior to presentation. This mechanism of injury also may produce associated injuries to the radial neck and the olecranon.

This fracture can be produced by a sudden isolated muscle contraction, such as the simple act of throwing a baseball (which can also be a chronic condition termed Little Leaguer’s elbow where elbow extension is lost and pain is reproduced by valgus stress, x-rays revealing an irregular and widened physis).

**Box 14.5.6 Key features of medial epicondyle fractures**

- Common
- Usually in boys aged 9–14 years
- Associated with dislocation (30 per cent)
- Fragment may incarcerate in joint (15 per cent)
- Ossific nucleus of epicondyle may be multiple minimizing fracture
- Commonly avulsion of common flexor origin.
Clinical and radiographic evaluation

The elbow is swollen and tender medially and if the medial epicondyle is displaced, it may be palpable and freely moveable. X-rays of minimally displaced fractures may show changes to the smooth physeal edges or a widened physis. In displaced fractures, if the fragment appears at the level of the joint, an oblique radiograph should be performed to exclude incarceration of the fragment within the elbow joint.

Classification

Wilkins et al. combined several classification systems and divided medial epicondylar injuries into acute and chronic injuries. Acute injuries are further divided into (a) undisplaced or minimally displaced; (b) displaced by more than 5mm but proximal to the joint line; (c) incarcerated with no elbow dislocation; and (d) incarcerated with elbow dislocation.

Treatment

Undisplaced or minimally displaced fractures should be treated with immobilization followed by early range of motion of the elbow. For displaced fractures proximal to the joint line good results with non-operative treatment are reported. Although healing in a displaced position occurs this does not lead to any functional deficit or any instability of the elbow joint. In children with high functional demands and a fracture of the dominant arm, fixation can be considered but it is debatable whether this affords any long term benefit.

The only absolute indication for operative treatment is incarceration of the fragment in the joint (Figure 14.5.8). Although successful extraction of the fragment from the joint can be achieved by manipulation in up to 40% by placing a valgus stress on the elbow while supinating the forearm and dorsiflexing the wrist, it is more likely than not that there has been a significant injury to the elbow joint to allow incarceration to occur and that this has been a dislocation that has spontaneously reduced and the fragment is better secured by open fixation affording an element of stability to the elbow joint.

Operatively the fragment is exposed via a medial approach protecting the ulnar nerve. The fragment is always larger than is apparent radiologically and can be secured with a single cannulated screw which will afford sufficient stability to allow early graduated mobilization. If ulnar nerve symptoms are present at the time of fixation, decompression of the nerve should also be performed and this is present in up to 50% of incarcerated cases.

Complications

The most serious complication of this fracture is an unrecognized incarcerated fracture fragment within the elbow joint, this becomes adherent blocking elbow motion. In patients with chronic incarceration of medial epicondylar fractures a thick fascial band binds the ulnar nerve to the underlying muscle causing ulnar nerve dysfunction. Once identified, it should be removed.

Lateral epicondylar fracture

Fracture of the lateral epicondyle is rare, occurring as a traction injury from the pull of the common extensor origin. Localized swelling and tenderness are present and the only treatment required is immobilization and early mobilization; functional deficit rarely occurs. Incarceration of the fragment in the elbow joint has been reported and is the only indication for operative management to reattach the extensor origin.

T-condylar fractures

T-condylar fractures occur in adolescents and have an adult fracture pattern with the fracture starting in the trochlea propagating and dividing the medial and lateral columns. This is caused by the wedge effect of the olecranon splitting the humerus following axial compression or a direct blow on the flexed elbow. Displacement of the fragments occur secondary to the pull of the forearm muscles.
muscles rotating the fragments in two planes.

Gross swelling is present due to the unstable nature of the fracture and radiologically displaced fractures are readily apparent. Undisplaced fractures need careful evaluation to differentiate these from the other forms of distal humeral injury.

Classification

The classification described by Wilkins is well recognized: type I, minimally displaced; type II, displaced with no comminution; type III, displaced and comminuted.

Treatment

Whilst each case should have its treatment determined by the fracture pattern the basic principles of treating this intra-articular fracture should be applied. The articular surface should be restored to congruency; the medial and lateral columns should be restored and stabilized to allow early mobilization because the attached muscles will increase displacement if adequate stability is not achieved.

Type I fractures can be treated with percutaneous pinning. Type II and III fractures require open reduction and internal fixation. The fracture needs adequate exposure by either a triceps-splitting approach, an olecranon osteotomy, or an extensile approach. Initial reduction of the articular surface is performed with stabilization using transverse fixation with subsequent reduction of the medial and lateral columns using wire is the younger adolescents or reconstruction plates at 90 degrees to each other in the older child. In Type III fractures where comminution of the columns is severe the joint surface can be reconstructed and the extra-articular fracture treated by traction to maintain alignment.

Complications

The commonest complications are elbow stiffness and loss of motion, and a degree of this is the usual outcome so the parents should be advised of this. Non-union, avascular necrosis of the trochlea, and failure of internal fixation have all been reported.

Elbow dislocation

Elbow dislocations accounts for 6% of all elbow injuries in children, most commonly occurring once the physes have closed at 13–14 years of age. Up to 50% of elbow dislocations have an associated fracture, typically the medial epicondyle, the lateral condyle, and the radial head and neck.

The presence of an elbow dislocation is readily apparent as the deformity, depending on the direction of displacement and swelling, is usually significant. A detailed neurological examination should always be performed and any deficit documented prior to reduction.

Anatomy

The elbow has little bony stability except when fully extended. The majority of its stability is provided by the collateral ligaments and the joint capsule. The medial collateral ligament consists of anterior (taut in extension) and posterior (taut in flexion) bands. Lateral stability is provided by the radial collateral ligament and the radial head also provides stability to valgus stress. Dynamic stabilizers of the elbow are the forearm flexors and extensor muscles. The brachialis muscle protects the brachial artery and median nerve from injury during elbow dislocation.

Classification

Elbow dislocations are classified according to the direction of dislocation and the status of the proximal radioulnar joint (Table 14.5.2). When the proximal radioulnar joint is intact, the elbow can be dislocated in five directions, the commonest being posterolateral. Disruption of the proximal radioulnar joint leading to a divergent dislocation or radioulnar translocation is rare.

Box 14.5.7 Key features of T-condylar fractures

♦ Grossly unstable elbow
♦ Both columns must be stabilized
♦ Joint surface must be congruent
♦ Open reduction is needed for displaced fractures.

Treatment

In uncomplicated elbow dislocations closed reduction followed by short-term (10–14 days) immobilization is the treatment of choice. Reduction is obtained by one of two methods. In the ‘push’ technique the surgeon’s thumb pushes on the olecranon tip causing reduction. In the alternative ‘pull’ technique the elbow is flexed 70 to 80 degrees traction applied longitudinally to the forearm reducing the dislocation. Placing the arm in supination avoids translocation of the radius and ulna during reduction.

Open reduction is indicated for (a) failed closed reduction, (b) open dislocation, (c) fractures requiring open fixation, or (d) bony fragment incarceration in the joint.

Complications

The most common complication is elbow stiffness which can be minimized by early mobilization, but there is usually a minor loss of extension. Nerve injury occurs in 10%, of which in the majority a neuropraxia and a full recovery is the norm. The ulnar nerve is the most commonly involved, particularly when the dislocation is associated with a medial epicondylar fracture, and exploration of the affected nerve should be considered at the time of fracture stabilization.

Myositis ossificans can occur typically in the brachialis muscle. Its incidence is reduced by prompt reduction, the avoidance of hyperextension, and passive mobilization.

Proximal radioulnar translocation may be unnoticed after closed reduction of a dislocated elbow. In this situation, the radius articulates with the trochlea and the olecranon articulates with the capitellum. In a posterolateral dislocation, if the forearm is hyperpronated at the same time as traction is applied, the radial head can easily pass anterior to the ulna and cause the translocation. Treatment of the translocation requires surgery open reduction.

Recurrent dislocation has either soft tissue or bony components causing the instability. Surgical stabilization using an anterior bone block or transfer of the medial epicondyle proximally to tighten the medial restraining structures can be performed for bone defects. In soft tissue instability triceps tendon transfer or lateral capsular placation are the options of choice.

Box 14.5.8 Elbow dislocation

- 50 per cent have other fractures around the elbow
- Neurologic deficit common
- Elbow should be reduced with forearm supinated to unlock radial head
- Early mobilization reduces stiffness.

Divergent elbow dislocation
With the elbow in extension and a high-energy proximally directed force being applied through the forearm a divergent dislocation can occur. The radius displaces laterally and the olecranon medially. Closed reduction usually can be easily obtained due to the degree of the soft tissue injury, by longitudinal traction releasing the humerus and then compressing the radius and ulna together before flexing the elbow where stability is maintained.

### Pulled elbow syndrome

The classical history is of a sudden longitudinal pull being applied to a child’s wrist or hand (under 4 years of age) with forearm pronation and elbow extension resulting in radial head subluxation. Following this episode the child will be reluctant to use the limb, local tenderness over the radial head and annular ligament is present but swelling is rarely a feature. Supination and flexion movements of the elbow are painful but necessary to reduce the subluxation. If supination alone does not reduce the subluxation then maximal flexion followed by supination should be performed and will usually be accompanied by a characteristic snapping reduction.

### Further reading

Summary points

- Growth plate fractures are common and of these the commonest is a Salter–Harris type II through the distal radial physis. There is considerable capacity for remodelling so reduction may not be needed. Remodelling capacity is inversely proportional to age.
- Elastic intramedullary nails are valuable in the forearm.
- Complications of fractures include malunion, refracture, and cross union.

Distal physeal injuries (Box 14.6.1)

Incidence

Growth-plate fractures comprise 10–25% of all forearm fractures in the paediatric population. When all physeal injuries are studied, the distal radius is considered the most frequently injured single growth plate comprising 17.9–29.7% of all physeal fractures. The distal ulna is less commonly injured and consists of 2.5–4.5% of all physeal fractures. Although radial physeal fractures may occur without visible injury to the ulna, the vast majority of ulnar physeal fractures are associated with a distal radius metaphyseal or growth-plate fracture. The average age of children with distal physeal fractures varies with gender; the peak age of injury in females is at 10–11 years of age while in males it is 12–13 years of age. This disparity is likely due to differences in the age of maximal mean peak growth velocity.

Management

The most common type of growth-plate fracture encountered at the distal radius results in a Salter–Harris type II fracture. The majority of these fractures are minimally angulated and are immobilized without reduction. Gentle closed reduction under adequate anaesthesia is usually successful for displaced fractures sufficient to cause clinical deformity on examination. Treatment guidelines reflect the large capacity for remodelling at the distal radial physis. Fifty per cent apposition is acceptable but may compromise maintenance of reduction. Dorsal–volar tilt of 20 degrees and radial angulation of 15 degrees will remodel as long as 2 years of growth remain and the physis does not close prematurely. The results of treatment are uniformly good given the substantial capacity for remodelling, particularly under ten years of age.

The long-term prognosis into adulthood is also excellent with almost all patients functioning normally even with radioulnar shortening of up to 1cm or an ulnar styloid non-union. If the fracture redisplaces after 7 days, further attempts at reduction should be avoided as evidence suggest that this can result in damage to the physis and subsequent shortening and deformity. Fractures are immobilized in a long arm cast or a well-fitted short arm cast for 3–4 weeks and protected activities are instituted after cast removal. It is recommend that percutaneous pinning after closed reduction, is considered, in cases of instability and severe soft tissue injury resulting in swelling or neurovascular compromise.

Distal ulnar physeal fractures are uncommon and may be difficult to diagnose as the secondary centre of ossification does not appear radiographically prior to the age of 6 years. Ulnar physeal injuries are more likely to result in premature growth arrest than radial physeal injuries. Treatment of these fractures depends on the associated radial injury as well as the ulnar fracture. It has been reported that up to 50% of distal ulna physeal injuries result in growth arrest. However only rarely does this result in symptoms or functional disability.

Distal radius fractures (Box 14.6.2)

Incidence, classification, and diagnosis

Distal radius fractures represent the commonest fracture occurring in the forearm, and there is some evidence that this incidence may be increasing. The peak incidence in boys is 11–14 and in girls 8–11 years of age.

Box 14.6.1 Distal physeal fractures

- 80% of growth at distal physis
- With 2 years growth remaining, up to 20 degrees dorsal angulation and 15 degrees radial deviation is acceptable
- Ulnar physeal fractures have a high incidence of premature growth arrest.

These fractures are classified by type, displacement, and associated fractures. The type is dependent on the predominant force producing the fracture.
Box 14.6.2 Distal radius fractures

- In isolated fractures of distal radius consider Galeazzi and pseudo-Galeazzi fractures
- Loss of reduction more common in:
  - Apex-volar angulation
  - Complete vs greenstick
  - Apposition <50%
- With 2 years growth remaining, up to 20 degrees dorsal angulation and 15 degrees radial deviation is acceptable.

A compression force will result in a torus fracture, whereas a bending force will result in a greenstick or complete fracture. This is important as the former is an inherently stable pattern and it has been shown that they can be safely and effectively treated by a simple ‘futura’ type wrist brace and discharged after the initial visit. Displacement in the majority of cases is dorsal displacement with apex-volar angulation where the periosteum is intact dorsally. Fractures of the distal third of the radius are usually associated with an ulna metaphyseal fracture or avulsion fracture of the ulna styloid. Rarely there is no obvious associated fracture of the ulna. Such a fracture is a Galeazzi fracture. However it has been shown that in many cases such a pattern in children would be better referred to as a ‘Galeazzi equivalent’ or ‘pseudo Galeazzi’ fracture with a radius fracture associated with a fracture occurring through the ulna physis in a bone in which the ulna epiphyseal ossification centre has not yet appeared. These injuries are difficult to diagnose and are missed in up to 41% of cases. The outcome of such an injury has been shown to be poor and if recognized should be treated in a supination cast.

Mechanism of injury

Distal radius fractures with an intact ulna usually follow a fall on an outstretched hand; resultant angulation may also be accompanied with rotational deformity. Apex-volar angulation (the most common deformity) is produced by forced supination and apex-dorsal angulation with forced pronation. Galeazzi fractures usually follow a fall on an outstretched hand with hyperpronation of the forearm.

Management

Distal radius fractures have significant remodelling capacity in the sagittal plane but less so in the coronal plane. Many authors have suggested widely varying limits of acceptable deformity with good outcomes; however, it is our experience that if the arm appears clinically deformed or there is greater than 10 degrees of angulation, reduction is necessary.

Fractures are reduced with a combination of traction, angulation, and rotation of the palm in the direction of the angulation. The fracture is brought out to length, deformity exaggeration and rotation may produce end-to-end contact. If this fails then percutaneous methods using a dorsally inserted pin into the fracture site and levering the distal fragment of the fracture into position may be successful. Typically these fractures are immobilized in short arm casts moulded to produce three-point fixation as they have been shown to be as effective as long arm casts.

Relatively high rates of reangulation in distal radius fractures from 11–62.5% have been reported. Higher rates of reangulation are noted in fractures with apex-volar angulation (supination injuries) and complete fractures versus greenstick fractures. In addition, redisplacement is also commonly seen where bony apposition following reduction is less than 50% or the fracture was initially completely displaced. Although remodelling is substantial (Figure 14.6.1), it is our recommendation that completely displaced fractures should be reduced and plaster cast immobilization should be supplemented with percutaneous K-wire fixation as this reduces the risk of subsequent redisplacement requiring further treatment.
Historically, adult forearm fractures treated non-operatively had poor results from non-union or malalignment and stiffness due to lengthy immobilization required for union. In paediatric fractures, treatment is primarily non-operative due to uniformly rapid healing, the potential for remodelling of residual deformity, and the inherent stability of the fractures once reduced.

Pertinent anatomy and physiology

The radius and ulna are stabilized by the interosseous membrane and by the triangular fibrocartilage complex distally and the annular ligament proximally. The pronator quadratus (distally) and pronator teres (inserting on the mid radius) actively pronate the forearm while the biceps and supinator (proximal insertions) provide supination. The insertion of these four muscles can partially account for fragment position in complete fractures. In complete distal third fractures, the proximal fragment will be in neutral to slight supination while the weight of the hand combined with the pronator quadratus tends to pronate the distal fragment. In complete proximal third fractures the proximal fragment is usually supinated.

Normal growth and implications for remodelling

The distal radial and ulnar growth plates are responsible for 75% and 81% of the longitudinal growth of each respective bone. This is consistent with the often made observation that distal forearm fractures have greater potential for remodelling than do more proximal fractures. Additional remodelling can also be attributed to elevation of the thick osteogenic periosteum after fracture. This peristeal sleeve aids remodelling of residual diaphyseal deformity.

Mechanism of injury

An understanding of the forces leading to forearm fracture is important as reductions are often performed opposite the direction of initial injury. Paediatric forearm fractures typically follow indirect trauma, such as a fall on an outstretched hand. Direct trauma may additionally account for open fractures, severely displaced fractures, and those seen in the proximal forearm. While the final degree of fragment displacement following indirect trauma varies between greenstick and complete fractures, the initial mechanism of injury is usually the same.

### Both-bone forearm fractures (Box 14.6.3)

#### Introduction

Historically, adult forearm fractures treated non-operatively had poor results from non-union or malalignment and stiffness due to lengthy immobilization required for union. In paediatric fractures, treatment is primarily non-operative due to uniformly rapid healing, the potential for remodelling of residual deformity, and the inherent stability of the fractures once reduced.

#### Pertinent anatomy and physiology

The radius and ulna are stabilized by the interosseous membrane and by the triangular fibrocartilage complex distally and the annular ligament proximally. The pronator quadratus (distally) and pronator teres (inserting on the mid radius) actively pronate the forearm while the biceps and supinator (proximal insertions) provide supination. The insertion of these four muscles can partially account for fragment position in complete fractures. In complete distal third fractures, the proximal fragment will be in neutral to slight supination while the weight of the hand combined with the pronator quadratus tends to pronate the distal fragment. In complete proximal third fractures the proximal fragment is usually supinated.

#### Normal growth and implications for remodelling

The distal radial and ulnar growth plates are responsible for 75% and 81% of the longitudinal growth of each respective bone. This is consistent with the often made observation that distal forearm fractures have greater potential for remodelling than do more proximal fractures. Additional remodelling can also be attributed to elevation of the thick osteogenic periosteum after fracture. This peristeal sleeve aids remodelling of residual diaphyseal deformity.

#### Mechanism of injury

An understanding of the forces leading to forearm fracture is important as reductions are often performed opposite the direction of initial injury. Paediatric forearm fractures typically follow indirect trauma, such as a fall on an outstretched hand. Direct trauma may additionally account for open fractures, severely displaced fractures, and those seen in the proximal forearm. While the final degree of fragment displacement following indirect trauma varies between greenstick and complete fractures, the initial mechanism of injury is usually the same.

#### Box 14.6.3 Both-bone forearm fracture

- **Acceptable reduction**
  - <9 years—complete displacement, 15 degrees angulation
  - >9 years—10 degrees proximal angulation or 15 degrees distal angulation
  - Approaching skeletal maturity—no angulation

- Reduce greenstick fractures by rotating in direction of angulation
- Complications: malunion, refracture, cross union, compartment syndrome (rare).

In cases where sufficient force does not completely displace the fracture, an incomplete or greenstick fracture results. A greenstick fracture in one bone may accompany a complete fracture in the other. Radiographically, greenstick fractures demonstrate two-dimensional angulation which in reality is a rotational displacement. Fractures with apex–volar angulation result from an axial force applied with the forearm in supination, those fractures with apex–dorsal angulation result from an axial force applied in pronation. Reducing a greenstick fracture usually requires rotation opposite the direction of the deforming force.

When significant indirect or direct trauma exceeds the resistance of the forearm, complete fractures of both bones will follow. When completely broken by either indirect or direct forces the bones shorten, angulate, and rotate within the confines of the surrounding periosteum, interosseous membrane, and muscle attachments.

#### Clinical evaluation

The diagnosis of forearm fractures is usually self-evident based upon history and obvious deformity. Radiographic evaluation should include anteroposterior and lateral views of the forearm. If the elbow and wrist are not adequately visualized, corresponding views are obtained to rule out radial head dislocation, supracondylar fractures and distal radioulnar joint injury.

Malrotation in complete fractures can be difficult to detect and assess. Malrotation is suspected when cortical, medullary, or bone diameters of adjacent fragments are not equal. Alternatively, malrotation can be gauged from deviations of normal orientation of proximal and distal bony prominences on radiographic analysis.
proximal and distal bony prominences on radiographic analysis. On standard anteroposterior views, the radial tuberosity is seen in profile on the medial side, while the radial styloid and thumb are seen on the opposite side. On the same view, the ulnar styloid and coronoid process are not seen. On standard lateral views the ulnar styloid is seen pointing posterior and the coronoid process pointing directly anterior; the aforementioned radial prominences will not be seen. Another useful method for determining rotation of the proximal fragment utilizes the ‘tuberosity view’. This technique uses a calibration chart to determine the rotation of the proximal radius. The distal fragment can then be manipulated and rotated into a corresponding position.

Adequacy of reduction and results of closed treatment

It is uniformly understood that post-traumatic paediatric angular deformities have a variable remodelling potential; however, it has not been consistently proven that rotational malalignment will also remodel. Many studies have documented better radiographic remodelling in fractures that are distal and in patients less than 9 or 10 years of age. It is important to realize that fracture location and age may not be independent variables.

It is unclear from clinical studies how much malalignment can be accepted. Studies in cadavers have demonstrated clinically significant loss of forearm rotation with residual deformities in the midshaft of the radius and ulna angulation of greater than 10 degrees.

Although several authors have demonstrated decreased remodelling potential in proximal fractures ‘marked loss of function’ is reported infrequently. Some authors have demonstrated little functional loss with decreases of forearm rotation of 35–40 degrees. It must, however, be remembered that loss of pronation can be compensated for by shoulder abduction but supination loss is not well tolerated.

The literature regarding acceptable limits of alignment is confusing and contradictory. It is our view that given the unpredictable nature of remodelling, the unclear relationship between deformity and loss of motion and the difficulty in the assessment of rotation on radiographs that the acceptable limits for alignment in both bone forearm fractures are thus. In fractures at any level in children less than 9 years of age we will accept complete displacement and 15 degrees of angulation. In children older than 9 years of age we will accept angulation in proximal fractures of 10 degrees while more distally it remains 15 degrees. However once a child approaches skeletal maturity no angulation should be considered acceptable.

Management

Greenstick fractures (Box 14.6.4)

Historically, incomplete fractures were treated by completing the fracture and then manipulating the bones into an acceptable position. This approach has the theoretical advantage of increasing the size of the fracture callus and decreasing the risk of refracture. Currently, it is recognized that residual angulation is a result of malrotation and should be reduced with rotation opposite the deforming force. Traction and manipulation of the apex while rotating will often assist in the reduction. The majority of greenstick fractures are supination injuries with apex–volar angulation, and these are reduced with variable degrees of pronation. It can be difficult to remember whether to pronate or supinate the hand based on the direction of the angulation. Most fractures reduce by rotating the palm towards the direction of the deformity. Those fractures with apex–volar angulation are a result of axial load in supination, therefore rotate the palm volarly (pronation). Fractures with apex–dorsal angulations are a result of pronation force, therefore rotate the palm dorsally (supination). It is not uncommon to see a greenstick fracture of one bone and a complete fracture of the other. In these cases we use the same principles of reduction by rotation. After reduction the forearm should be immobilized in the same position that reduced the fracture. Studies have documented redisplacement of 10–16% in greenstick fractures that were not adequately rotated in the cast.

Complete fractures

Complete both-bone forearm fractures are reduced with a combination of sustained traction and manipulation. The fingers are taped to prevent sores and placed in fingertraps with the elbow at 90 degrees of flexion, counter traction is provided with 4.5–6.75kg (10–15lb) suspended from a sling over the distal humerus. The fracture and soft tissues are slowly brought out to length for 10–15min, the arm is allowed to find its own rotation. End-to-end apposition is then attempted with deformity exaggeration and direct manipulation. If attempts to achieve bony apposition are unsuccessful, complete over-riding of fracture fragments is accepted as long as rotation and angulation is within guidelines (Figure 14.6.2).

Box 14.6.4 Greenstick fracture

- Rotate palm in direction of angulation
- Higher rate of re-fracture until 6 months after injury
- Beware plastic deformation without fracture
Fracture alignment in traction is assessed with fluoroscopy or plain radiographs; if adequate, the distal part of the long arm cast is applied and moulded while still in traction. Residual malrotation is addressed prior to cast application by rotating the forearm. Because most displaced both-bone fractures are in the middle region, the hand is placed in a neutral or slightly supinated position; this usually accommodates rotation and angulation. This approach has been supported in other studies that demonstrate little correlation between position of immobilization and end result. Pronation is rarely employed for complete fractures and may result in a functional loss of supination due to soft tissue contracture. Recent studies suggest that immobilizing the forearm in a cast with the elbow extended may result in a lower rate of redisplacement.

Meticulous casting is critical as several studies have documented reangulation in approximately 8–14% of cases. Some have blamed poor cast technique while others have attributed this to residual rotational malalignment. Forearm anteroposterior and lateral radiographs are taken after reduction and immobilization, minimal improvements of residual angulation can be corrected by wedging the cast.

After an adequate reduction and immobilization, patients typically return for a follow-up radiograph at 1–2 weeks after injury. Several studies have documented reangulation during the first 2 weeks. If reangulation is documented, cast removal and rereduction is recommended. Good results of rereduction have been documented if performed within a few weeks of the initial fracture. If no reangulation is appreciated, the cast is continued for 6–8 weeks or until radiographic healing. Patients are released to all activities 3–4 months after injury.

Operative indications and technique

Indications for surgical intervention in paediatric forearm fractures include:

- Open fractures
- Fractures shortly before skeletal maturity
- Irreducible/unstable fractures
- Unacceptable closed reduction
- Failure to maintain a closed reduction
- Multiple trauma/ floating elbow.

Several different techniques are available but the two most commonly applied are open reduction and internal fixation with plates and closed intramedullary nailing of either one or both bones.

As anatomical reduction is usually not needed, we prefer closed intramedullary fixation of one or both bones. Elastic stable intramedullary nailing is now the treatment of choice using a nail 0.4 times the diameter of the medullary canal.

This is introduced into the radius through an oblique drill hole in the distal metaphysis, taking care to avoid the superficial branch of the radial nerve, and through the postero lateral part of the olecranon (Figure 14.6.3). It is considered important to pre-bend the nails so that the maximum curvature occurs at the level of the fracture. Limited open reduction may be required in order to pass the intramedullary fixation. Immobilization with supplemental plaster or fibreglass long arm casts may be required. The advantages of nailing include simplicity of the procedure, union with minimal stress shielding by hardware, easier hardware removal and a better cosmetic result. Studies have shown this procedure is successful and associated with a low rate of complications compared with plate and screw fixation.
Fig. 14.6.3
A) and B) Radiographs of a 5-year-old girl with a proximal both-bone forearm fracture. C) and D) Following closed reduction under general anaesthesia minimal angulation and moderate displacement is noted. This was accepted. E) and F) Due to soft-tissue swelling her cast was split and 2 weeks after closed manipulation she was noted to have loss of reduction with angulation greater than 15 degrees. This was not accepted. G) and H) She underwent open reduction and intramedullary pinning with good alignment and callus formation at 2 and 3 months.

Complications

Malunion

Forearm fractures treated conservatively will rarely present with significant malreduction that precludes activities of daily living. In cases of unacceptable malunion or loss of functional forearm rotation, surgical correction can be obtained with drill osteoclasis and casting or open osteotomy and plating. Both techniques will increase motion; better results are obtained when surgical correction is performed without delay.

Refracture

Refracture can occur up to 9 months after original injury. Greenstick fractures are more likely to refracture than complete fractures, possibly due to weaker union from inadequate callus formation. Refracture is associated with poor clinical outcome. In these cases operative intervention may be indicated to ensure an adequate reduction. Refractures have also followed plate removal in those cases treated with primary open reduction and internal fixation and this may be lower for nail fixation.

Cross-union

Synostosis between the radius and ulna is very rare, but can compromise the results in cases of fracture from very high-energy injury. It is associated with fixation of both bones through a single incision and therefore this should be avoided. Extensive bone formation that restricts pronation and supination can be surgically removed. Restoration of motion following excision is usually poor in comparison with adults.

Plastic deformation of the radius or ulna

Children’s bones are more ductile and an appropriate force applied in the proper direction may result in bending without obvious fracture. Clinically, patients present with pain, tenderness, and diminished pronation and supination. Radiographs will demonstrate slight to marked bowing which extends along the distance of the affected bone (Figure 14.6.4). If bowing is subtle, the injury may be diagnosed with comparison radiographs or a bone scan performed at least 3 days after the injury.
For children under 10 years, reduction is indicated if the angulation is greater than 20 degrees or if significant limitation of forearm rotation is present. Patients older than 10 years would benefit from reduction for deformity greater than 15 degrees or when limited forearm rotation is present. Additionally, plastic deformation must be reduced when the radial head is dislocated (Monteggia equivalent) or redislocation will occur.

Treatment consists of closed reduction under general anaesthesia. A described technique of reduction involves applying a force directly over the apex of the deformity with a sandbag or rolled towel. The force must be applied for a period of several minutes in order to achieve a lasting reduction. Pressure should not be applied over the proximal or distal epiphysis. If this method is not successful, it may be worthwhile to consider open or closed osteoclasis. Following reduction, patients are typically immobilized for 6–8 weeks. This extended period of immobilization may be required due to slightly slower healing resulting from the lack of a significant periosteal reaction.

**Monteggia fracture–dislocations**

**Mechanism of injury and classification**

Monteggia fracture–dislocations involve an ulna fracture combined with radial head dislocation.

Bado (1967) classified Monteggia injuries into four types:

1. **Type 1** injuries have an anterior radial head dislocation with anterior angulation of an ulnar fracture.
2. **Type 2** injuries have posterior or posterolateral dislocations of the radial head with concordant ulnar fracture angulation.
3. **Type 3** injuries have lateral or anterolateral radial head dislocations with radial angulation of the ulna fracture.
4. **Type 4** injuries are essentially type 1 injuries with an associated radial shaft fracture distal to the bicipital tuberosity.

Monteggia equivalent injuries were also described and include plastic deformation of the ulna with radial head dislocation, ulna fracture with radial neck fracture, and radial head dislocation with a radial fracture proximal to the ulna fracture.

In children the anterior (type 1) and lateral (type 3) fracture patterns predominate.

**Clinical evaluation**

It is important to identify nerve deficits as they occur more commonly in Monteggia type injuries. Clinically evident nerve dysfunction has been documented in all major nerves in 3–24% of fractures. Posterior interosseous nerve palsy is the most commonly seen deficit in association with Monteggia injuries due to tethering and compression within the supinator muscle by the arcade of Frohse. The majority of these palsies recover spontaneously within 3–6 months. Exploration may be indicated if no recovery is identified within this time frame.

**Management**

The most important factor for the successful outcome following Monteggia fractures (Figure 14.6.5) is its early diagnosis. A significant number of Monteggia patterns of fracture are missed resulting in pain and loss of function. This is particularly true with greenstick fractures of the ulna which may recoil to a position of minimal displacement that masks the significant initial energy that also produces radial head dislocation and dislocations have been shown to occur up to 3 weeks after the initial injury. Regular radiographic review is necessary for up to 3–4 weeks following such injuries.
Fig. 14.6.5
Radiographs of the forearm obtained 5 weeks after a non-displaced greenstick fracture of the ulna. Dislocation of the radial head had gone unnoticed. A line down the shaft of the radius should intersect the capitellum on all views.

It is essential to assess the radiohumeral integrity on all radiographic views. Regardless of radiographic projection, a line drawn down the shaft of the radius should intersect the centre of the capitellum. Deviation from this relationship indicates dislocation or subluxation and therefore merits intervention.

Most authors believe that in children less than 9 years of age Monteggia injuries should be managed with initial attempted closed reduction. Successful management requires firstly reduction of the ulna fracture, secondly the reduction of the radial head and finally the alleviation of deforming forces.

Therefore type 1 (anteriorly angulated) injuries are reduced by first correcting ulna length by traction and angulation by elbow hyperflexion. Secondly, gentle direct pressure over the radial head may facilitate reduction that is heralded by a gentle snap and placing the hand in supination may stabilize it. Finally these injuries are immobilized in well-moulded long arm cast in supination at 100–110 degrees of flexion. This positioning relaxes the biceps which may be a factor in late anterior radial head subluxation.

Type 2 (posteriorly angulated) injuries are uncommon in the paediatric population and the ulna fracture is reduced with traction and volarly directed force applied at the apex with the elbow in slight flexion. The radial head is reduced by direct anterior pressure and finally these fractures are immobilized in extension following reduction of ulnar alignment and restoration of normal radiohumeral articulation to prevent redisplacement.

Type 3 (lateral angulation) are reduced with a valgus force applied to the apex of the ulna fracture and direct lateral pressure on the radial head. Once reduced, the arm is immobilized in 60–110 degrees of flexion depending on initial radial head displacement. Anterolateral dislocations are better stabilized in more flexion than posterolateral dislocations which are better stabilized in less flexion.

Type 4 injuries are extremely rare and considered unstable. Closed reduction in a manner similar to type 1 injuries may be attempted but these injuries should be considered unstable and operative stabilization is probably needed to prevent radial head instability.

Regardless of injury type, patients should return to the clinic weekly for radiographs to ensure that the radius is still located and the deformity of the ulna has not recurred resulting in redislocation of the radial head. The patient should be maintained in a plaster cast for 4–6 weeks.

Operative intervention will be required in those injuries where the ulnar reduction is unstable, or the radial head is irreducible due to ulnar malreduction or an interposed annular ligament. Type 4 injuries and Monteggia equivalent injuries with radial neck fractures are relatively unstable and require operative stabilization of both radial and ulna fractures in the majority of cases. The ulna is managed with closed reduction and intramedullary fixation using a flexible nail passed distally from the olecranon. The radial head is then checked radiographically for reduction. Open reduction and ligament reconstruction or repair is recommended when the radial head will not reduce in the face of good ulnar alignment. Following repair or reconstruction of the annular ligament, the proximal radius may be further stabilized by K-wire pinning if it continues to be unstable. Because of the risk of pin failure, transcapsular pinning of the radius has been abandoned in favour of pinning the radius to the ulna directly. The postoperative care of Monteggia fractures is similar to that for cases that are successfully managed via closed reduction. Good clinical results can be expected in paediatric patients with Monteggia injuries diagnosed within 2 weeks of injury and treated with surgery.

Radial neck and head fractures (Box 14.6.5)

Incidence

Proximal radius fractures in children usually result in fracture of the radial neck. Radial head fractures have been reported in the paediatric population but are considered to be rare entities. As such, this chapter will not focus on these injuries except to point out that they are usually Salter–Harris type III or IV fractures with potentially higher rates of growth abnormalities and attendant concerns for joint incongruity. Radial neck fractures in children accounted for 5.8% and 8.5% of all elbow fractures. Radial neck fractures are rarely diagnosed prior to age 4 or 5 years as the epiphysis does not ossify until after this. Radial neck fractures typically occur at two different levels—either through the physis with or without an attached metaphyseal fragment (Salter–Harris
type I and II respectively) or 3–4mm distal to the physis in the anatomic radial neck.

**Classification**

Type 1 fractures usually result in lateral displacement of the proximal fragment with angulation that varies in direction and magnitude. The direction of angulation and displacement of the radial fragment is always lateral in relationship to the humerus; however, its angulation relative to the radius depends on the degree of hand rotation upon impact. Type 2 fractures are posteriorly displaced and result from posterior dislocation of the elbow (Figure 14.6.6). In these cases, the radial neck may be fractured following spontaneous elbow reduction or secondary to attempted closed reduction. These fractures are exceedingly rare but are important to recognize as the radial head may be rotated 180 degrees following reduction.

![Click to view larger](image)

**Fig. 14.6.6**
Type 2 fracture of the radial neck. This is easily missed and usually follows spontaneous reduction of a posterior dislocation of the elbow. Closed reduction is attempted by recreating the dislocation followed by distraction and reduction.

**Management**

The majority of authors agree that angulation less than 30 degrees in the paediatric population is acceptable and should be immobilized without attempts at closed or open reduction. Translocation may be accepted when the radial head is less than 4mm displaced.

**Box 14.6.5 Radial neck fractures**

- Angulation <30 degrees is acceptable
- Progressive treatment if >30 degrees
  - Direct pressure ± forearm rotation
  - Percutaneous manipulation
  - Metaizeau technique
  - Open reduction + stabilization (NB avoid damaging blood supply in intact periosteal hinge).

Once a decision has been made to reduce the radial neck fracture we follow a treatment algorithm until the fracture has been adequately reduced and stabilized. Initially we attempt direct pressure over the radial head under fluoroscopy control. Direct pressure is applied to the radial head as the elbow is placed into varus while partially extended. An alternative manoeuvre involves placing the elbow in 90 degrees of flexion with the elbow fully supinated. Pressure is applied to the radial head and the arm is gently pronated to reduce the fracture. If this fails, manipulation is facilitated with the use of a percutaneously placed Steinmann pin into the head of the radius or the fracture site. The pin is then used like a crow bar to lever the radial head into an acceptable position.

If closed reductions fail then we employ the technique described by Metaizeau. This involves the insertion of an intramedullary wire from distal to proximal in the radius; it is passed into the radial head which is disimpacted and by rotating the wire it reduces the fracture. The wire is left in position to stabilize the reduction.

Only if all these methods fail would we consider open reduction. Open reduction is performed through a lateral Kocher approach and caution is directed towards avoiding extensive exposure distally on the neck of the radius. Dissection in this area may disrupt the blood supply which enters proximal to the neck resulting in delayed or non-union and risking the development of avascular necrosis, or may injure the posterior interosseous nerve as it courses through the supinator muscle. Sectioning of the annular ligament may be used to facilitate reduction; however, this structure should also be repaired. If the reduction appears unstable the fracture may be stabilized with an intramedullary wire as for the Metaizeau technique, patients should be immobilized for 3–4 weeks in a long arm cast or splint.

**Results and complications**
Diminished rotation is more commonly seen in children with more severe displacement and angulation, fracture comminution, concurrent associated elbow injury, and in older patients when compared to younger patients.

Some reports have demonstrated poorer results in patients who undergo operative intervention than in those treated via closed means. These studies imply that it is better to accept some degree of malalignment rather than accept the problems of operative treatment in order to achieve an anatomical result. However, superior results have been obtained with the use of the Metaizeau technique.

Complications include aseptic necrosis of the radial head with the majority of series reporting incidences around 5%. Radial head excision in cases of aseptic necrosis may be required due to pain and loss of motion. Occasionally excessive cubitus valgus may follow excision; however, deformity is rarely associated with significant increases in pain, functional limitations, or tardy ulnar nerve palsy. Radial head enlargement has also been commonly reported in several series and may present with pain or clicking during forearm rotation. Proximal cross-union between the radius and ulna has similarly been noted in approximately 3–4% of cases with a higher incidence in patients with associated proximal ulnar injury.

**Further reading**

Summary points

- This chapter reinforces that children are not small adults and the management of these injuries must consider the effect on growth and development.
- Nail bed injuries require microsurgical repair if permanent deformity is to be avoided.
- Every attempt should be made to replace amputated digits, whatever the level of amputation.
- Good results are the common outcome in children’s fractures unless complicated by surgical intervention or infection. However, angulation, rotation, and intra-articular deformities should be corrected where possible.
- All children with deep lacerations of the upper limb should have a general anaesthetic for adequate exploration and repair of the wound.
- A high index of suspicion of nerve injury should exist when assessing hand lacerations, and the outcome of early surgical repair is good.

Incidence and epidemiology

Soft tissue injuries and lacerations are the most common paediatric hand injuries, most of which are the result of the fingertip being crushed. Fractures, followed by burns, bites, and infections are the next most frequent.

The incidence of the various injuries and subtypes of injuries varies with age. Babies suffer scalds, toddlers from soft tissue injuries and crush injuries, with burns also being common in this age group. Older age groups have a higher incidence of fractures, and to a lesser extent lacerations with damage to the underlying longitudinal structures.

Injuries usually occur at home, with a higher incidence in boys.

Examination of children with hand injuries

In young children, it is important to gain the confidence of the child and parents. Time should be taken to allow the child time to look and assess you, whilst you look and assess them. Speak to both the child and parents to obtain the history and establish rapport. It helps to bring a toy, penlight, or other distraction device to draw the attention of the child. If the child is sitting on a parent’s lap, examine them there. Crouch down to their level rather than standing over them.

When possible avoid causing the child any pain. A history of the accident may at times provide sufficient independent reason for surgical exploration making it unnecessary to examine the hand or view the wound prior to theatre. Although wound examination may allow better assessment of injured structures and hence communication, it will not usually change the decision to operate. If a dressing must be removed do this after as much of the examination has already been completed. Examination may require heavy reliance on observation and indirect methods such as the tenodesis effect. Consider examining the child’s unaffected hand to gain their confidence. Much of the examination can be done by observation of the child playing or trying to hold objects. Observe their hand’s posture and movement. Ask them to open or close their fingers of both their hands together. Sensation is extremely difficult to assess even in older children, as they will believe they are feeling something even if they cannot. Trying to assess sensation with them blinded is difficult and unreliable. The wrinkling test following water immersion (denervated areas fail to wrinkle) may be useful, but is time consuming in the clinic. It is much better to observe the hand immediately after any dressing has been removed, as many hands will be moist beneath their dressings and will demonstrate the wrinkling sign. Dryness and sheen of the skin as determined by palpation or by the tactile adhesion test (gently slide a pen against their skin and assess the degree of friction), are often later signs of denervation and may not be that useful in the acute setting.

Movement often provokes pain, hence leave this component of the examination until last. Children can often be encouraged to open and close their fingers. If children are uncooperative then compression of the forearm musculature produces movement of the digits. Failure of movement may indicate a tendon injury. Partial injury can be suspected when there is painful movement. If the injury is distal to the wrist then the tenodesis effect of differential digital tendon gliding on passive wrist flexion and extension can provide evidence of tendon injury or continuity. If there is any doubt then surgical exploration is indicated, as the long-term consequences may be severe.

Dressings

Where dressings are indicated in younger children, it is usually easier to dress the whole hand in a boxing glove type bandage, as this is more difficult for children to remove. Usually, it is not necessary to extend the dressings above the elbow or to plaster them. The additional weight and discomfort of a plaster cast gives the child extra incentive to wriggle out of these extended dressings. A boxing glove bandage wrapped with tape preventing use of the fingers is very effective. To prevent the bandage becoming dirty, wet, or removed, the parents may apply a sock over the bandage, which can be changed as required.
When suturing children’s skin always use absorbable sutures, as this obviates the need to distress the child further by suture removal and avoids an additional anaesthetic. 5/0 or 6/0 Vicryl Rapide is usually rubbed away within several weeks, but may last longer.

**Prevention**

Accident awareness and prevention should be an important part of general health care. Several projects increasing such education are proving successful in reducing injuries.

**Child abuse**

Non-accidental injury (NAI) to children’s hands should be suspected when the pattern of injury does not seem to follow the explanation given by the parents or differs from the explanation given by the child or changes with each telling. Burns are the commonest presentation of NAI in the hand. Recurrent presentations or admissions should alert one to the possibility of NAI.

The consequences of such an accusation are severe, so do seek further opinions, and repeat the history and examination several times over the ensuing days as well as reviewing the records and relevant x-rays before making a diagnosis of NAI.

**Fingertip injuries**

**Crush injuries and distal fingertip amputations**

Crush injuries to the fingertip are extremely common injuries, often occurring when the fingertips of toddlers and younger children become jammed in the hinge side of a closing door. The mechanism is an off-step crushing force that presses on the nail plate on one side and on the pulp on the other. The usual result is a fracture or avulsion of the nail plate, associated with an underlying nail bed laceration, lateral perionychial lacerations, and an underlying tuft fracture of the distal phalanx or a Saller–Harris type I fracture of the distal phalanx physis (Seymour’s lesion). Different patterns of the injury depend on the distribution of the force. Crush injuries most commonly involve the longer ring or middle fingers; however any finger may be injured. Complete amputation including bone is uncommon, but tip avulsion is common.

Deformity of the nail and fingertip is common following conservative therapy (Figure 14.7.1A, B). Operative treatment requires local or general anaesthesia depending on the age of the patient. The operation involves removal of the damaged nail and meticulous repair of the lacerated nail bed and surrounding skin. The nail bed is repaired with the finest absorbable sutures available, usually 7/0 or 8/0 Vicryl, using microsurgical instruments and loupe magnification. Where nail bed loss is present the defect can be closed by excision and direct suture or by using a graft. The graft may be nail bed graft harnessed from the adjacent remaining nail bed, from a toe nail bed, or may be a dermal graft. Once repaired the previously removed nail, silicon sheeting, or piece of foil suture packet is applied as a nail splint, covering the nail bed and maintaining the nail fold. Dressings are applied and left for 2 weeks, following which no dressings are needed. Nail growth will take around 6 months before the result can be assessed (Figure 14.7.1C).

Where avulsion of the fingertip has occurred, the tip frequently contains one or more tiny fragments of distal phalanx tuft. These should be debrided, as if they remain they frequently become infected or resorb. If the avulsed segment is still tenuously attached or is brought in with the patient, it should be replaced. This should be performed within 5h of injury for the maximal chance of success. Once the delay is greater than 5h, the pulp portion should be defatted prior to replacement, returning it as a full thickness...
graft. It is important to debride the recipient bed thoroughly, particularly removing any damaged fat to enhance revascularization of the restored part. When the amputated portion is not retained the defect may be treated conservatively with dressings, by the application of split, full thickness, or composite toe pulp grafts, or by the use of flaps. The indications for these various treatments are similar to those in adults; however, the greater regenerative potential in children dictates a greater dependence on conservative measures. In the case of failure of revascularization of the replaced avulsed segment it should be retained as a biological dressing until healing occurs underneath and the dry eschar separates (Figure 14.7.1D,E).

Fingertip injuries with an underlying distal phalanx fracture should be thoroughly washed under anaesthesia, prior to reduction of the fracture. These fractures are sufficiently stable following the soft tissue repair not to require further stabilization. Wiring may damage the epiphysis, and serve as a portal for infection in these open fractures. A mid shaft distal phalanx fracture is uncommon in children, as the points of weakness produces tuft or proximal phyeal fractures. In the under 5s the commonest distal phalanx physeal fracture is a Salter–Harris type I pattern, eponymously described by Seymour. The child presents with avulsion of the nail plate from the nail fold. The injury appears innocuous but is an open fracture. Seymour fractures should not be treated conservatively as they may become infected leading to destruction of the physis, leading to growth disturbance. Seymour fractures are frequently missed until they present as a paronychial infection. A good lateral x-ray at the time of the original assessment is mandatory, but the only radiological clue may be a widening of the physeal line (Figure 14.7.1F,G).

Amputations

Amputated digits occur infrequently in children. Unlike adults every attempt should be made to replant amputated parts irrespective of the level of the injury or the involvement of a single digit, within limits of technical ability. The outcome of replants in children is more favourable than in adults. With due care to the epiphyses, even growth of the replanted digit can be normal.

Tip amputations are treated depending on the degree, direction, and salvage of the loss. Complete tip amputations at the level of the proximal nail fold should be replanted if the part is salvaged. If replantation fails or should the part be not suitable or unavailable, the tip should be reconstructed making every attempt to maintain length. All the methods used in adults may be used. The results from many procedures is better in children due to greater digit flexibility, a lower tendency to joint contractures, better sensory restoration even in non innervated flaps or grafts, and better cortical re-orientation in neurotized switch flaps. One reconstructive technique that works particularly well in children when the amputated part includes the nail apparatus and revascularization is not possible, is to retain the nail and surrounding skin but discard the phalanx and pulp, replace the nail portion on the end of the finger and revascularize it with a palmar flap such as a cross finger flap (Figure 14.7.2).

Fractures

Hand fractures are one of the most common presenting problems in children, occurring at a rate of 26.4 fractures per 10,000. Hand fractures form 25% of all childhood fractures, with the proximal phalanx of the border digits the most affected. One-third of paediatric hand fractures involve the physis, with 78% being Salter–Harris type II, 13% type III, and 7% type I. Dislocations are uncommon. Although most paediatric hand fractures can be treated conservatively, it is important not to completely depend on growth to correct all displacement.

The differences between adult and child hand fractures include rapidity of healing, pattern of fracture related to the mechanism and zones of weakness along the physis, tolerance of displacement, growth, and variation in the risk of stiffness.

Fracture healing in children occurs in about half the time of adults. This means shorter periods of immobilization but also that delayed presentation generally indicates closed reduction will no longer be possible. The mechanism of injury is likely to be a lower
energy fracture and the fracture pattern reflects the greater deformability of the bone and thickness of the periosteum in children. The incidence of open fractures other than trapped finger injuries is markedly lower in children. Stiffness is less commonly a problem in children due not only to the reduced period of immobility but also the remarkable tolerance of the tissues.

**Physeal fractures**

The physis is the cartilage plate between the metaphysis and epiphysis responsible for longitudinal growth. It is found at the distal end of the metacarpals except the thumb metacarpal, which has its physis at the proximal end like the phalanges. The physis is the weakest link in the digit and hand. Within the physis the zone of chondrocyte hypertrophy (zone III) is the weakest and most likely to fracture in children giving Salter–Harris type I and II injuries. During adolescence, the physeal zones become less distinct leading to more Salter–Harris type III and IV fractures. The pattern of fracture is also influenced by the attachments of the ligaments and tendons. The collateral ligaments of the interphalangeal (IP) joints attach to the epiphysis and the metaphysis at the base of the phalanges, and this protects the physis from lateral forces. However, in the finger metacarpophalangeal (MCP) joints the collateral ligaments inserts only onto the epiphysis of the proximal phalanx, so lateral force produces a Salter–Harris type II or III fracture. The palmar plate inserts into the epiphysis so injury causes a Salter–Harris type III avulsion fracture of the epiphysis.

Physeal growth will correct some deformity in the dorsal and palmar planes but not in rotational or radial and ulnar planes. The degree of correction depends on the proximity of the injury to the physis (the closer the better), the degree of deformity, and the amount of growth potential remaining. Injury to the physis may lead to premature arrest of growth or growth deformity should the injury and growth arrest only involve a part of the physis. The Salter–Harris classification of physeal injuries predicts fracture stability and the potential for growth disturbance (see Chapter 14.2).

Salter–Harris type I injuries (see Figure 14.7.1F) with a transverse slip of the metaphysis from the epiphysis along the plane of the physis are commonest in the distal phalanx of young children with fingertip crush injuries. Reduction after wash out and simple immobilization may be all that is required. Replacement of the nail under the nail fold provides sufficient stabilization. Growth disturbance is unlikely.

Salter–Harris type II injuries with physeal separation and a fragment of metaphysis, is the commonest form of physeal hand injury. These frequently present at the bases of the proximal phalanges with bruising, pain, and deformity. These are generally easy to reduce and are stable after reduction. Reduction can be aided by the use of a pencil placed in the web space to provide a fulcrum on which to exert the reducing force or by flexing the MCP joint to tighten the collateral ligaments and stabilize the proximal segment. Buddy splinting may be all the immobilization required. Growth disturbance is unusual (Figure 14.7.3A).

Salter–Harris type III injuries are physeal separation with a fracture fragment of the epiphysis. These are intra-articular and hence require careful reduction and frequently fixation for a short period, as they may be unstable. Fixation is usually by fine K-wires. These are more commonly seen at the distal phalanx in adolescents and present as mallet finger injuries, or less commonly at the middle phalanx as a central slip type injury causing boutonnière deformity, or of the proximal phalanx of the thumb presenting as a ‘bony game keeper’s thumb avulsion’.

Salter–Harris type IV injuries extend through the physis and are associated with a potential for growth disturbance. These are also intra-articular and careful reduction and fixation is required. Salter–Harris type V injuries are rare and are a crush injury of the physis. They are often not diagnosed until the growth arrest is noted.

What the Salter–Harris classification does not consider is the degree of displacement of the fracture fragments. Growth allows spontaneous correction of some displacement, see Box 14.7.1.

---

**Box 14.7.1 Remodelling potential in the paediatric hand**
Non-physeal fractures

Paediatric hand fractures become increasingly common with adolescence, in association with increasing activity and skeletal maturity. The commonest fractures are fractures of the phalangeal shaft, particularly the proximal phalanx. As mentioned previously, minor angulation (up to 30 degrees up to 10 years of age, and less than 20 degrees in those older) in a palmar or dorsal plane will remodel; however, angulation in lateral planes or rotational deformity will not remodel and thus must be reduced and stabilized, if clinically indicated. Phalangeal fractures without gross displacement are frequently stable postreduction due to the thicker periosteum in children. In these cases 2–4 weeks of buddy strapping or splintage with the hand in an intrinsic plus position is sufficient. However, very displaced fractures indicating a greater degree of periosteal disruption will commonly require fixation. Fixation by closed reduction and fine percutaneous Kirschner wires is adequate (Figure 14.7.4). Additional support by buddy strapping will allow early mobilization. Wires are removed at 3 or 4 weeks, once clinical union is achieved. Wires that are left exposed through the skin can be removed in the outpatient clinic without anaesthesia; however, care must be taken during their tenure that the tips are well protected to prevent injury.

Intra-articular fractures

Intra-articular fractures must be carefully reduced and fixed to prevent long-term problems. These fractures are often condylar fractures of the head of the proximal phalanx. These are easily missed and can result in reduced flexion of the proximal interphalangeal (PIP) joint as the proximal fragment blocks the subcondylar recess. Closed reduction should be attempted to minimize the risk of avascular necrosis of the small fragments. Reduction must restore correct alignment of the articular surface and ensure the subcondylar recess is restored. Occasionally, these fractures are best reduced under direct vision. Accurate relatively stable fixation with minimal trauma to the tiny bony fragments is usually best achieved with small K-wires. With open reduction care must be taken not to devascularize the fragments by preserving any soft tissue attachments (Figure 14.7.5).
Phalangeal neck fractures

Fractures of the neck of the proximal or middle phalanges are often hardest to diagnose and extension of the head or even 180 degrees of rotation may not be appreciated. These fractures need to be reduced and K-wired. The technique involves inserting a wire longitudinally down the distal phalanx, then hyperextend the distal interphalangeal (DIP) joint and pick up the displaced head of the proximal phalanx, then reduce the fracture and pin to the shaft of the middle phalanx (Figure 14.7.6).

Metacarpal fractures

Metacarpal fractures are common in late adolescents. The mechanisms and patterns of injury are similar to those in adults. See Box 14.7.2 for acceptable metacarpal position.

Box 14.7.2 Acceptable metacarpal position

- Younger children <60 degrees of apex dorsal angulation of fourth and fifth metacarpal neck fractures
- Older adolescents < 40 degrees
- Index and middle metacarpals only 10–20 degrees of angulation is tolerated due to the relative stiffness of the carpometacarpal joints.

If an unacceptable degree of angulation exists clinically and radiologically, then reduce the fracture using the Jahss manoeuvre. This consists of flexing the MCP joints and IP joints then pushing dorsally on the PIP joint, whilst pushing down on the metacarpal shaft. Once the fracture is reduced, stabilize it using K-wires or plaster of Paris. Wires are much more difficult to insert into the
metacarpals of children due to the lack of metacarpal head collateral ligament recesses and hence the lack of ‘shoulders’ on which to aim the wires. Consequently there is a much greater risk in children of the wires impinging on the extensor tendons or the MCP joint. This is not too great a problem provided the MCP joint is kept in a flexed position and the wires removed within 3 weeks. As children will tolerate immobilization of their IP joints in a flexed position for 2–3 weeks, maintenance of the reduced metacarpal neck fracture is possible by bandaging the ulnar two digits in a fisted position. This maintains the fracture in a more stable position than gutter splinting. Three weeks is adequate immobilization before protected mobilization is commenced. Protection is provided either by splinting or by buddy strapping.

Metacarpal shaft fractures are treated as in adults, mainly needing reduction to correct any severe angulation and rotational deformity. Intra-medullary fixation techniques such as Bouquet wiring are generally not possible due to the narrowness of the canal. Metacarpal base fractures and carpometacarpal dislocations are uncommon in children, but when they do occur they require closed reduction and K-wire fixation.

Thumb metacarpal fractures

Thumb metacarpal fractures are frequent and are usually found at the proximal metaphysis or physis (Figure 14.7.7). Epiphyseal fractures are usually Salter–Harris type II, with the small Thurston–Holland metaphyseal fragment usually found on the radial aspect. Reduction of these fractures is easy but they are often difficult to stabilize without using K-wires due to the displacing forces. These forces are the radial pull of the abductor pollicis longus on the proximal fragment and the ulnar deviating force of the adductor on the distal fragment.

Outcomes in children’s hand fracture

Good results are almost inevitable in children’s fractures unless complicated by surgical intervention or infection. Avoidance of angulation, rotation, and intra-articular deformities leads to good results in paediatric hand fractures. Malunion is the commonest complication albeit uncommon. If detected before 2 weeks the malunion may still be amenable to closed manipulation. Beyond this period, open exposure and careful unpicking of the malunion should be possible up to the 6- or 8-week stage. Subsequently they should be treated as in adults with opening or closing wedge osteotomies or rotational osteotomies either at the site or distant to the site of the malunion. Care must be taken to avoid damage to any physis. In cases of intra-articular malunion all attempts at intra-articular realignment should be made. Failing that, a pseudarthrosis usually gives adequate function. It is exceptional to consider procedures such as arthrodeses, or arthroplasty.

Joint dislocations in the fingers and thumb

PIP joint dislocations are usually dorsal. Reduction is usually easily achieved and following this the PIP joint is usually stable, requiring only buddy strapping or an extension-blocking splint for 2–4 weeks. Rarely collateral ligament ruptures result in gross lateral instability and require repair. Open reduction may be required in cases of irreducible dislocations due to interposition of soft tissue such as an articular flap or the button holing of the proximal phalanx head between the palmar plate and the flexor tendon.

MCP joint dislocations are rare other than in the thumb. The index fingers are the next most commonly affected, and in this case are often irreducible due to the button holing of the metacarpal head between the flexor tendons and the lumbrical. Open reduction can be performed from either a palmar or dorsal approach, though one must be wary of the displaced digital nerves when approaching from the palmar aspect.

Thumb MCP joint dislocations are less common in children than adults due to the relative strengths of the soft tissues to the epiphysis. When they do occur however the pattern is similar to adults. Both simple and complex dislocations occur. Simple dislocations are amenable to closed reduction by hyperextension of the MCP joint and then with pressure on the base of the dorsum of the proximal phalanx a longitudinal traction and flexion force is gently applied. Complex dislocations require open reduction to free the palmar plate, or the entrapment of the head of the metacarpal between the volar plate and the flexor tendons. The x-ray signs of the proximal phalanx lying almost parallel in line with the metacarpal (as opposed to lying angulated in simple dislocations) or the presence of a widened joint space or with the sesamoid bone lying interposed can predict complex dislocations.

Tendon injuries
These injuries become more frequent with increasing age. The mechanism of these injuries differs from those in adults—most are clean, tidy sharp injuries caused by glass. As the principles of the treatment, particularly the surgical technique of these, are similar to those in adults already presented in previous chapters, this section will concentrate on the differences and special features of these injuries in children.

The major difference is the growth potential and the reduced cooperation with rehabilitation. Growth can be inhibited by lack of movement and scar, and to a larger extent by denervation. Postoperative care is affected by the age and cooperation of the child and rehabilitation is generally limited. However, tendon healing occurs faster and with fewer adhesions than in adults. Hence the results are frequently better, and the complications fewer. The operative techniques and principles are the same, keeping in mind the increased fragility of the structures such as the pulleys. Children’s flexor tendon repairs require special care in their assessment and examination, postoperative care and rehabilitation, and operative indications when complications arise.

Due to the lack of cooperation and compromised examination, all children with deep lacerations of the upper limb should have a general anaesthetic for adequate exploration and repair of the wound. Some preoperative prediction of the injuries can be made by observant examination skills including specialist examination techniques, such as the tactile adherence and immersion test for sensory assessment, and tenodesis and forearm squeezing techniques for assessment of musculotendinous continuity. This will permit discussion with the parents and theatre staff about the likely operative procedure and timing.

**Flexor tendon injuries**

Children’s flexor tendon injuries should be explored as soon as possible, though a delay of a few days is unlikely to affect the outcome. The tendon should be repaired primarily. The mechanism of injury is usually a fall onto glass or whilst clutching a glass, meaning that more frequently than in adults the distal tendon end is found at the level of the laceration making the exposure and repair easier. The smaller tendon structure may prevent the use of a multiple strand core suture tendon repair technique, though this may still be possible if a smaller gauge of suture such as 4/0 is used. The tendon repair strength may be less important in children if immobilization rather than active motion techniques are used for postoperative rehabilitation. Immobilization following repair is the usual postoperative regimen due to the lack of cooperation with exercises and because although children do develop tendon adhesions, once formed the adhesions seem to be more responsive to manipulation and therapy. There is a tendency for long-term absorbable sutures such as PDS to be used rather than non-absorbable sutures, though there is no scientific evidence to support or refute this practise.

In zone 1 injuries, care must be taken not to injure the distal phalanx physis when reinserting the tendon. In zone 2 injuries every attempt should be made to repair both flexor tendons. In situations of delayed repair or untidy injuries requiring detorsion of the tendon end, significant tendon shortening can occur. This would preclude primary tendon repair in adults so as to prevent the quadriga effect, in which one tendon is out of synchronization with the others leading to reduced movement. However, shortened tendon repair is possible in children, as musculotendinous lengthening and readjustment of tension occurs more readily and is far more forgiving. Flexor sheath closure and pulse preservation or reconstruction, are as important as in adults.

Postoperative rehabilitation differs depending on the age and understanding of the child and their parents. Immobilization for 3–4 weeks is as effective in the final outcome. This is probably because complete immobilization is impossible and these children move within the confines of their protective splint or bandage, thereby performing their own protected active mobilization programme. Results deteriorate if they are immobilized for longer than 4 weeks. Children are more likely to spontaneously use their hands once their splints are removed and require less directed therapy to achieve function. Botulinum toxin can be used to weaken the affected muscles so as to reduce the risk of tendon rupture, though rupture can still occur with untended extension.

The results of flexor tendon repairs in children are generally better than those achieved in adults. However, tendon rupture and adhesions preventing movement do occur. Tendon rupture is difficult to assess in children. Assessment is dependent on history, palpation of the tendon, assessment of active and tenodesis movement, and ultrasound examination. An acute rupture detected early may be amenable to direct repair. Frequently the tendon rupture is not detected until a later stage (beyond 2 months) and direct repair is not possible. The situation is then similar to delayed detection of a tendon injury.

The use of immediate or staged tendon grafting techniques is controversial in children. Some believe tendon grafting procedures should only be performed once the child is old enough to participate in rehabilitation programmes. There is little evidence on this subject however, and it is reasonable to perform the tendon graft regardless of age, in order to obtain better function. Children develop hand use patterns during early years, and further digital growth and development are dependent on function, so all attempts should be made for reconstruction of normal anatomy and function in children. Alternatives to tendon repair such as tenodesis or arthrodesis of the DIP joint are contraindicated due to the potential to interfere with growth. Tendon adhesions are uncommon in children. Indications for tenolysis are similar to adults though the timing of the operation is disputed. Tenolysis is recommended when the child is old enough to understand and participate in the rehabilitation programme.

**Extensor tendon injuries**

Closed extensor tendon injuries are rare in children. When they do occur it is essential to exclude epiphyseal fractures, particularly in the closed mallet finger. These are usually Salter–Harris type I in younger children and type III in older children, the latter mimicking the bony avulsion injury seen in adults. Treatment of these is identical to adults, though the challenges involved in maintaining a splint on the child may increase the number that are pinned in extension rather than just splinted. The period of splintage can be reduced by 2 weeks in children.

Delay in the diagnosis of extensor tendon injuries is common in children. Despite the delay the treatment is the same and good results can be obtained in mallet and boutonniere injuries with splintage. Splinting periods in the treatment of delayed extensor tendon injuries in zones 1–5 are 2–4 weeks greater than when treating the acute injury.
Open extensor tendon injuries are more common, usually associated with a crush injury. When there is associated nail bed or epiphyseal injury, operative treatment is indicated. When the injury is a clean tidy laceration over the middle phalanx or the IP joints (extensor tendon zones 1–4), then tendon approximation is possible solely by splinting the finger in extension for 4–6 weeks. The extensor tendon does not retract like the flexor due to the anatomical structure of the extensor tendon at this level. This feature allows direct repair even in cases of delayed detection of extensor tendon division. Where direct repair is not possible all methods of adult reconstruction can be used in the child, with a preference for those that reconstruct the normal anatomy and interfere least with growth and development.

Rehabilitation of extensor tendon repairs depends on the level of the repair. Digital injuries should be splinted for 4 weeks, whereas hand and forearm injuries should be mobilized earlier. Where pins or K-wires have been used for internal splinting, these are carefully protected to prevent them being pulled out or causing injury, early mobilization in a removable splint can be used in cooperative children. Once the splint is removed, the children are allowed to use their hand normally.

Extensor tendon adhesions causing poor movement should be tenolysed following a lengthy trial of mobilization. The results of extensor tendon surgery in children are poorly reported but generally believed to be better than those in adults. Some extensor lag or loss of flexion may occur in 22%.

### Nerve injuries

A high index of suspicion of nerve injury should exist when assessing hand lacerations. Examination of nerve injuries in children is even harder than tendon injuries. If any doubt exists, lacerations should be explored under general anaesthesia. The operative techniques are identical to those previously described for adults. The peripheral nerves are more mobile in children and so less tension is present at the repair site. Consequently, less post operative immobilization is required. Two weeks should be sufficient, if there are no other injuries. The results of nerve repair are much better in children, and this is rewarding surgery. Better results are attributed to better regenerative ability of the nervous system, better neural ingrowth from surrounding areas, and better central cortical reorientation. Children’s superior cerebral ability to develop and adapt probably accounts for a large proponent of their better outcomes. Nerve injuries complicating fractures or tendon lacerations are associated with worse outcomes of all the involved injuries. Tendon transfers of functioning muscles following identical principles used in adult transfers can treat failure of motor recovery. During neural recovery the child will need protection from injuring the insensate portion of the hand.

### Burns (Box 14.7.3)

Hand and upper limb burns are amongst the commonest injuries presenting in children. The mechanism is usually a scald caused by the child pulling a cup of hot liquid off the table. Almost all scald hand burns heal spontaneously, requiring little more than assessment, analgesia, reassurance, dressings, and follow-up. However, not all burns are that simple. The outcome and management depend on the depth and size of the burn. Assessment of burns is based on history and examination. The size of the burn is measured and recorded as a percentage of body surface area and the depth is assessed using the same principles described in Chapter 12.24).

**Box 14.7.3 Burn thickness and healing potential**

- Superficial/epidermal—healed within 48h
- Superficial partial thickness—healed within 2 weeks
- Deep partial thickness—months, leaving scarring and contracture
- Full thickness—will not heal except from edges leaving bad scars/contractures.

### Treatment

**Immediate first aid and resuscitation**

Remove the heat source and cool the burn with running water for 20min. Resuscitation should be given in accordance with Advanced Paediatric Life Support (APLS) protocols.

**Superficial and superficial dermal burns**

Blisters should be debrided as they contain eicosanoids and prostaglandins detrimental to healing and which deepen the burn. Once debrided, desiccation and infection must be avoided, as these will also deepen the burn. Dressings such as paraffin gauze and absorbent gauze are useful in the first few days when the burns are quite productive of ooze. Dressings should be made as light as possible to allow some movement. Once the ooze has diminished, the burn can be dressed with a retention dressing such as Hypafix, Melfix, or Fixomull, adhered directly onto the burn. This dressing can be washed, allows almost normal mobility, and is easily removed, as the adhesive is oil soluble.

**Deep dermal and full thickness burns**

The general rule is that if burns heal within 10–14 days then hypertrophic scarring is unlikely. However, deeper burns that remain unhealed at 14 days have a high risk of developing contractures and hypertrophic scarring. If the burn is obviously deep or fails to
heal within 2 weeks then the burn should be debrided and skin grafted. Debridement should aim to remove all dead tissue but preserve as much dermis as possible. Dermis preservation or reconstruction is the key factor in outcome in terms of scarring and contracture.

Severe burns should be admitted for analgesia, splinting into a functional position, assessment, elevation to reduce oedema, and preparation for surgery.

Children should be followed as they grow, as scars that initially were non-contracting may become tight and cause functionally limiting contractures. These may require surgical revision by excision and grafting, local flaps, or Z-plasties.

**Bites and infections**

Dogs and cats cause most bites in children. The principles of assessment of underlying structures, exploration if indicated coupled with good surgical excision, and primary closure is as true in children as in adults. The infecting organism is usually *Pasteurella multocida* or mixed organisms, sensitive to penicillin or co-amoxiclav.

**Conclusions**

Children's hand injuries are extremely common but most are easily primarily treated with excellent outcomes to be expected. The greatest error is in underestimating the degree of injury. Failure to recognize and treat the injury or failure of treatment can lead to devastating loss of function and growth, which may not be immediately apparent.

Injuries of the pelvis and hip in children

Summary points

- Displaced cervical fractures must be reduced and then fixed with lag screws
- Avascular necrosis remains a significant problem
- Intertrochanteric fractures may be treated closed with traction if an adequate reduction can be obtained and held
- Dislocated hips should be reduced as soon as possible, open if necessary
- Pelvic fractures are associated with a high mortality not so much from bleeding from pelvic veins as from accompanying major trauma to the rest of the body
- The elasticity of children's bones allows for single breaks in the pelvic ring.

Hip fracture

Incidence (Box 14.8.1)

Paediatric hip fractures are rare, comprising less than 1% of all paediatric fractures. These severe injuries frequently have complications that have lifelong significance for the patient.

Anatomy (Box 14.8.2)

The proximal femoral physis contributes the majority of metaphyseal growth in the neck of the femur and to a lesser degree to the appositional growth of the femoral head. The trochanteric apophysis contributes mostly to the appositional growth of the greater trochanter and to a lesser degree to metaphyseal growth.

The metaphyseal and epiphyseal blood supplies of the proximal femur in children are functionally separate until physeal closure (usually at age 14–17 years) except for small penetrating vessels. The terminal branch of the medial femoral circumflex artery, the lateral epiphyseal artery, supplies the majority of the femoral head from childhood into adult life. The anterior portion of the femoral head receives a significant portion of its blood supply from branches of the lateral femoral circumflex artery until age 5–6 years. The obturator artery system supplies a minor contribution to the femoral head through the artery of the ligamentum teres. The dominance of the medial femoral circumflex arterial system makes the child's femoral head vulnerable for avascular necrosis following femoral neck fracture. Fractures closer to the physis and fractures with greater displacement are at greater risk for arterial disruption and subsequent necrosis.

Box 14.8.1 Injuries of pelvis and hip

- Rare
- Complications frequent
- Management difficult
- Associated injuries are common
- Associated with high-energy trauma.

Classification

The most widely utilized classification of paediatric hip fractures is based on the anatomical location of the fracture. The classification divides children's hip fractures as follows (Figure 14.8.1).

- Type I: transepiphyseal fracture (with or without dislocation of the femoral head from the acetabulum)
- Type II: transcervical fractures (displaced or non-displaced)
- Type III: cervicotrochanteric fractures (displaced or non-displaced)
- Type IV: intertrochanteric fractures.
Clinical evaluation (Box 14.8.3)

The patient presenting with a displaced proximal femoral fracture will show a shortened, externally rotated extremity with pain on movement. The symptoms of pain in the hip along with restricted motion should alert the physician to the possibility of a non-displaced fracture.

Box 14.8.2 Anatomy

- Growth-plate injuries may affect growth
- Terminal branch of medial circumflex artery supplies most of the femoral head
- Lateral circumflex artery important until age 6 years.

Investigation (Box 14.8.4)

An anteroposterior pelvis radiograph is standard for the evaluation of a child involved in a major trauma. If a hip fracture is suspected on history/examination or seen on the screening film, further plain radiographs (anteroposterior and lateral views of the hip) are recommended.

Magnetic resonance imaging (MRI) may be helpful in delineating an occult fracture. Ultrasound followed by hip aspiration with or without arthrography can be used to differentiate between fracture and other potential pathology such as hip joint sepsis or synovitis. The aspiration should yield bloody fluid in the presence of fracture.

Management (Box 14.8.5)

Controversy exists over the need for routine anterior capsulotomy and there are differing opinions on whether this procedure decreases the incidence of avascular necrosis.

Box 14.8.3 Clinical evaluation

- Undisplaced—pain without deformity
- Displaced short and externally rotated
- Look for associated injuries.

Type I—transepiphyseal

These fractures can be managed with closed reduction and application of a hip spica cast with the hip in an abducted and externally rotated position. An anatomical reduction must be achieved unless the child is under the age of 2 years, when remodelling of the femoral neck can be anticipated (Figure 14.8.2). In children over the age of 2, if an anatomical reduction cannot be achieved closed, the fracture should be stabilized with percutaneous pins or cannulated screws. Smooth pins are preferred over threaded pins or screws, especially in children with significant growth remaining. If an anatomical reduction cannot be obtained by closed means, open reduction through an anterolateral approach should be performed followed by insertion of pins or cannulated screws. Fixation should be protected with a postoperative hip spica cast.
This 18-month-old patient sustained a type I proximal femoral fracture of the left hip. Treatment consisted of hip spica casting without reduction. A 27-year follow-up shows excellent results. (Courtesy of Dr S.L. Weinstein.)

Type II—transcervical

Type II fractures have been treated with closed reduction and casting with some success but this should be reserved for only truly non-displaced type II fractures. Most of these fractures should be treated operatively. Closed reduction, or an open reduction if an anatomical reduction cannot be obtained closed, is followed by fixation with two to three lag screws placed into the femoral neck short of the proximal femoral physis (Figure 14.8.3). Cannulated or solid screws ranging from 4.0–6.5mm are appropriate depending on the size of the child. Fixation may be supplemented with a hip spica cast.

Box 14.8.4 Investigation

- Anteroposterior pelvic radiograph
- Anteroposterior/lateral radiograph of hip where injury suspected
- Bone scan/MRI if occult fracture suspected
- Ultrasound aspiration/arthrogram sometimes in very young.

Box 14.8.5 Management

- Need for urgent capsulotomy controversial
- Is there displacement requiring reduction?
- Should reduction be done open or closed?
- Is internal fixation required?
Type III—cervicotrochanteric

Non-displaced type III fractures can be treated by application of a hip spica cast depending on the age of the patient. Close follow-up in the cast is mandatory to avoid loss of reduction and resultant coxa vara deformity. Operative treatment is preferred for most type III cervicotrochanteric fractures. The fixation of choice are lag screws inserted short of the proximal femoral physis unless physeal closure has occurred or is imminent in which case the physis may be crossed. Open reduction must be performed if a satisfactory reduction cannot be obtained closed. A supplementary hip spica cast may be used.

Type IV—intertrochanteric fractures

Some intertrochanteric fractures, particularly in younger patients, can be treated with skin or skeletal traction followed by application of a hip spica cast. Close follow-up is necessary to detect loss of reduction. Polytrauma patients, those who fail to obtain an adequate reduction in traction or those who lose reduction, and most patients older than 6 years of age should be managed with operative fixation. Closed reduction is frequently possible, but if a satisfactory reduction cannot be obtained, open reduction and internal fixation is required. In children under the age of 6 years, fixation is with threaded pins or lag screws. If the child is 6–12 years of age, lag screws are recommended or if the patient is large enough a paediatric sliding hip screw can be placed short of the proximal femoral physis (Figure 14.8.4). Children older than 12 years of age should be managed with a sliding hip screw or an angled blade plate short of the physis. Patients treated with only pin or screw fixation need supplemental immobilization in a hip spica cast.

Results (Box 14.8.6)

Type I—transepiphyseal

The results of treatment of type I fractures are generally poor secondary to the frequent development of complications such as avascular necrosis, non-union, and premature physeal closure. Many type I fractures are accompanied by dislocation of the head from the acetabulum and dislocation further worsens the prognosis.

Type II—transcervical

The results of treatment for type II fractures is more favourable than type I but significant numbers will have complications, such as premature proximal femoral physeal closure, non-union, and avascular necrosis. Urgent open reduction and internal fixation with capsulotomy may favourably influence the results, but it appears that the initial displacement of the fracture is the greatest determinant in the development of avascular necrosis.

Type III—cervical trochanteric

Improved results with fewer complications can be expected with type III fractures, although avascular necrosis (30% of cases), non-union, and coxa vara can all occur.
Type IV—intertrochanteric

Avascular necrosis and premature physeal closure are rare in type IV fractures. The quality of reduction obtained will be the largest determinant of the incidence of malunion which is the most common problem following intertrochanteric fractures. Non-anatomical reductions and non-operatively treated fractures have a greater likelihood of developing coxa vara.

Complications (Box 14.8.7)

Avascular necrosis

The rate of avascular necrosis depends on the fracture type. Between 80 and 100% of type I fractures (depending on whether the head is dislocated), 60% of type II fractures, and 30% of type III fractures develop this severe complication. Three patterns of avascular necrosis following paediatric hip fractures have been described (Figure 14.8.5).

♦ Type I: diffuse sclerosis and total femoral head involvement followed by complete collapse of the head
♦ Type II: sclerosis localized to a portion of the epiphysis which is accompanied by minimal collapse
♦ Type III: sclerosis within the metaphyseal portion of the femoral neck from the fracture line to the physis. The femoral head is spared.

![Click to view larger](image)

Fig. 14.8.5

Types of avascular necrosis. (Reproduced from Ratliff (1962).)

The initial fracture displacement is the critical determinant for the development of necrosis. Patients with avascular necrosis fare poorly at long-term follow-up. There are no predictable treatments for avascular necrosis other than hip arthrodesis or arthroplasty when the patient’s symptoms become severe enough.

Non-union

Non-union is more common in neck than intertrochanteric fractures. If non-union is associated with varus deformity, valgus osteotomy is indicated. If the neck–shaft alignment is normal, bone grafting and internal fixation is indicated. This complication can be minimized by obtaining good fixation at the time of initial treatment.

Premature physeal closure

Up to 65% of proximal femoral fractures are complicated by physeal closure. The proximal femoral physis contributes 30% to overall femoral growth and limb-length discrepancy may be more than 2cm.

Box 14.8.6 Results

♦ Type I:
  • Avascular necrosis common (80–100%)
  • Dislocation high chance of avascular necrosis

♦ Type II:
  • Premature physical closure
  • Avascular necrosis (60%)
  • Non-union
  • Initial displacement main prognostic factor

♦ Type III:
  • Results better than types I and II
  • Avascular necrosis 30%

♦ Type IV:
  • Malunion most common complication
Other complications rare.

Box 14.8.7 Complications

- Avascular necrosis:
  - Displacement is risk factor
  - Urgent capsulotomy and fixation may reduce incidence of avascular necrosis
  - Two-thirds have poor long-term results
- Non-union:
  - Type II: 10%
  - Type III: 15%
  - Type IV: rare
  - Treat with valgus osteotomy
- Premature physeal closure:
  - 65%
  - Limb-height discrepancy
- Coxa vara: up to 32% of patients.

Coxa vara

The use of internal fixation decreases the incidence and severity of coxa vara.

Future directions

Historically, treatments for paediatric hip fractures have nearly always been non-operative. More recent series in which operative treatment has been more prevalent, have shown decreased incidence of complications and improved results. Future treatment should focus on anatomical reductions of these fractures and utilization of open approaches if necessary.

Hip dislocations

Incidence and prevalence (Box 14.8.8)

Although the incidence is estimated to be higher than paediatric hip fractures, traumatic hip dislocation in children is rare and comprises about 5% of paediatric dislocations. Posterior hip dislocations comprise the majority of dislocations, although anterior dislocations have been described.

Associated pathology

Patients with a high-energy mechanism of injury must be closely examined and monitored for associated injuries involving the chest, abdomen, and head.

Classification

The dislocation can be generally classified into anterior (obturator, anterosuperior, anteroinferior) or posterior.

Clinical evaluation (Box 14.8.9)

A patient presenting with an anterior hip dislocation will have abduction, external rotation, and extension at the hip while a posterior dislocation will present with adduction, internal rotation, and flexion. Function of the sciatic nerve should be documented prior to reduction of the hip.

Box 14.8.8 Hip dislocations in children

- Rare
- High and low energy
- Usually posterior.
Clinical evaluation

- Anterior dislocation:
  - Abduction
  - Extension
  - External rotation
- Posterior dislocation:
  - Adduction
  - Flexion
  - Internal rotation
- Look for sciatic nerve injury.

Investigation

Any child who has sustained high-energy trauma or has suggestive physical findings, should have an anteroposterior pelvic radiograph. If a fracture of the acetabulum is seen or suspected, Judet 45-degree oblique radiographs should be obtained. If a concentric reduction is not achieved (suggested by widening of the hip joint space on postreduction films) a postreduction computed tomography (CT) scan or MRI is indicated to evaluate for incarcerated osteocartilaginous fragments or soft tissues.

Management (Box 14.8.10)

Closed reduction of the hip should be performed in the emergency department if adequate sedation can be achieved, otherwise the reduction should be performed in the operating room under general anaesthesia. The reduction must be done on an urgent basis, ideally within the first 6h after injury. If the hip cannot be reduced closed or postreduction studies reveal a non-concentric reduction, an open reduction must be performed. A posterior approach is indicated for a posterior dislocation while an anterior approach is best for an anterior dislocation. The obstacle to reduction is usually a button hole through the capsule, interposed piriformis tendon, or osteocartilaginous fragments.

Young children and those with questionable compliance should be managed in a one and one half hip spica cast. Older children can be managed with mobilization when the hip is comfortable with crutch ambulation for 3–4 weeks.

Box 14.8.10 Hip dislocation—management

- Radiographs:
  - Anteroposterior
  - Judet views if fracture suspected
  - CT scan if non-concentric reduction
- Urgent closed reduction within 6h
- Open reduction if irreducible or if closed reduction is non-concentric
- Hip spica or traction/crutches for 3–4 weeks.

Results (Box 14.8.11)

Traumatic hip dislocations without associated fractures generally do well. Higher-energy injuries, associated fractures, and delayed reduction all contribute to a higher number of poor results.

Complications

Avascular necrosis

The incidence of avascular necrosis following traumatic hip dislocation in children is 10% or less and is more common in older children. Reduction of the hip as soon as possible and preferably within 6h of injury should remain the goal to minimize the chances of this complication.

Neurological injury

Injury to the sciatic nerve or its peroneal division is not uncommon. Unfortunately not all of these nerves recover completely and the rate of recovery may not be better than that reported for adults which is only in roughly one-third of cases.
Osteoarthritis

Early degenerative disease after hip dislocation is usually secondary to necrosis. Osteoarthritis is felt to be infrequent in the absence of avascular necrosis, but no good long-term studies on children’s hip dislocations have been done.

Recurrent dislocation

Recurrent dislocation following traumatic hip dislocation in a patient without a hyperlaxity syndrome such as Down syndrome is quite rare. Plication of the posterior capsule should be reserved for patients who fail 6 weeks of hip spica casting after their first episode of recurrent dislocation.

Pelvis fractures (Box 14.8.12)

Incidence and prevalence

Pelvic fractures in children are uncommon. The majority are stable injuries and acetabular fractures are rare.

Anatomy

The anatomy of the pelvis in children differs from the adult secondary to the presence of the triradiate acetabular cartilage complex and the many extra-articular apophyses. The biomechanical properties of the child’s pelvis are also different. The child’s pelvis is more malleable, absorbs more energy prior to fracture, and therefore requires higher-energy trauma to produce a fracture. Even innocent fractures may be caused by high forces and have a significant incidence of associated injuries. The more ductile nature of paediatric bone and the increased elasticity of the joints allows for a single break in the pelvic ring in contrast to the adult where a double break is almost always present. Injury to the triradiate cartilage can result in growth arrest and a deficient acetabulum.

Box 14.8.11 Hip dislocation—results

- Poor results:
  - High energy
  - Fracture dislocations
  - Delay in reduction
- Avascular necrosis 8–10%:
  - Children over 5 years of age
  - Common if reduction delayed
- Neurological injury—20%
- Osteoarthritis—usually secondary to avascular necrosis
- Recurrent dislocation—rare unless hyperlaxity syndrome.

Box 14.8.12 Pelvic fractures

- Usually stable
- Acetabular fractures rare
- Almost always high-energy injuries
- Injury to triradiate cartilage:
  - May be difficult to diagnose
  - May cause growth arrest
- Mortality rate 9–18% (associated injuries)
- Genitourinary injuries common
- Haemorrhage from fracture unusual—look for other sources of blood loss
- Open fracture must be excluded if significant rami displacement
- Vaginal/rectal examination with sedation/general anaesthetic.

Associated pathology

Because of the high-energy trauma required to produce a paediatric pelvic fracture, associated injuries are common. Mortality rates
of 9–18% have been reported. Mortality and morbidity are highly related to associated injuries to the head, chest, and abdomen. Genitourinary injuries including urethral injury, bladder rupture, and vaginal lacerations occur more commonly in the more severe pelvic injuries.

Significant haemorrhage from paediatric pelvic fractures is not as common as in adults. This indicates that other sources for excessive bleeding should be sought. Management of haemorrhage from the pelvic fracture requires resuscitation, stabilization of the pelvis, and, if necessary, selective arteriography and embolization.

**Classification**

The system of Key and Conwell is commonly used and will be the classification system further described here (Table 14.8.1).

<table>

</table>

Although the system of Key and Conwell includes acetabular fractures, the classification system of Judet and Letournel devised for adult acetabular fractures should also be applied to delineate further the extent of the injury and treatment needed.

**Clinical evaluation**

Paediatric pelvic ring injuries most commonly result from motor vehicle collisions or falls from a height. Pelvic injuries sustained in sports competition are usually avulsion fractures. Anterior muscle contraction with the hip in extension and the knee in flexion can result in avulsion fracture of the anterosuperior or anteroinferior iliac spine, whereas avulsion fracture of the ischial tuberosity occurs after maximal contraction of the hamstrings. The patient will complain of pain localized to the area of the injured apophysis.
A thorough general physical examination must be performed secondary to the high incidence of associated injuries. Once the general examination is complete and resuscitation initiated, the bony pelvic landmarks are evaluated for asymmetry and the stability of the pelvis is tested. Range of both hips should be tested. If a pelvic fracture with significant displacement of the rami is present, digital vaginal and rectal examination under sedation or general anaesthesia should be performed to rule out occult open fracture. The neurovascular examination must carefully assess the sciatic, femoral, and obturator nerves, and lumbosacral plexus.

**Investigation**

Pelvic ring fractures should be evaluated with an anteroposterior pelvic radiograph as well as 40-degree caudal inlet–40-degree cephalad outlet pelvic views. If an acetabular fracture is present, Judet 45-degree oblique views should be obtained. If further detail on an acetabular, sacral, or sacroiliac joint injury is needed a CT scan is the study of choice and the common use of CT in trauma assessment may eliminate the need for pelvic radiographs in some cases.

**Management (Boxes 14.8.13 and 14.8.14)**

Initial management of the child with a pelvic fracture is directed at haemodynamic resuscitation and treatment of associated life-threatening injuries. Although massive haemorrhage from pelvic fractures is uncommon in children, if an alternative source for blood loss cannot be found, pelvic external fixation to decrease the pelvic volume and control fracture movement and selective angiography with embolization is indicated. Provisional stabilization of the injured pelvis with a pelvic binder has decreased the need for acute external fixation.

**Fractures without a break in the pelvic ring**

Avulsion fractures about the pelvis require rest and hip positioning to decrease stretch on the involved muscle group. A short period of crutch ambulation with protected weight bearing may be required. Operative intervention is reserved for fractures which result in symptomatic non-union. The results of conservative treatment are generally good.

The plasticity of paediatric bone allows single ramus fractures to occur. These fractures are the most common pelvic fractures in children but are a result of higher-energy trauma than the ramus fractures seen in adults. Isolated pubic or ischial ramus fractures should be treated with bed rest followed by progressive ambulation when symptoms subside.

**Box 14.8.13 Pelvic fractures—initial management**

- Resuscitate
- Treat life-threatening conditions
- Associated injuries common in single/double breaks of pelvic ring.

**Box 14.8.14 Management of pelvic fractures**

- Fractures without break in pelvic ring:
  - Rest
  - Progressive rehabilitation
  - Surgery for symptomatic non-union
- Single break in pelvic ring:
  - Short-term bed rest
  - Protected weight bearing/spica cast
  - Symphysis injuries may be plated
- Double break in pelvic ring:
  - Pubic rami—non-operative treatment
  - Malgaine fracture—traction or surgery
  - Severe multiple—traction or bilateral spica
  - Internal fixation preferable if significantly displaced in older child
- Acetabular fractures:
  - Skeletal traction
  - Displaced fractures require open reduction and internal fixation
- Note few outcome studies.
Fractures of the iliac wing often are accompanied by other fractures in the pelvis which may dictate the treatment required. The isolated iliac wing fracture can be treated with bed rest until comfortable with the hip abducted to relieve stretch on the hip abductor muscles. Once symptoms subside, a programme of progressive weight bearing is followed.

Fractures of the sacrum or coccyx should be treated by ambulation with progressive weight bearing as pain allows. Manual reductions should be avoided since reduction is often lost and there is a risk of rectal tearing with the technique of reduction during digital rectal examination.

**Single break in the pelvic ring**

The elasticity of the child’s sacroiliac joints and symphysis pubis allow for fractures which constitute a single break in the pelvic ring. Single breaks in the pelvic ring usually have minimal or no displacement. Although single breaks in the pelvic ring are stable and often look benign, the physician must remember that significant energy is required to produce these fractures, and associated injuries are not uncommon and must not be missed.

Fracture of the superior and inferior pubic rami on the same side, symphysis disruption, or fracture of the pubis near the symphysis constitute a break in the pelvic ring. These patterns are stable and require only short-term bed rest followed by protected, progressive weight-bearing on the affected side (Figure 14.8.6).

![Click to view larger](image)

**Fig. 14.8.6**

This 12-year-old patient sustained fractures of the ipsilateral rami which healed with protected weight bearing. No posterior injury was present making this a single break in the pelvic ring.

If significant symphysis displacement is present there must be posterior injury at the anterior sacroiliac joint. Widely displaced (over 3cm) symphysis disruptions of the ‘open book’ type are rotationally unstable injuries. Some authors feel the symphysis should be reduced with either external fixation or internal fixation with a plate. Plating is particularly efficacious if laparotomy is performed for abdominal injuries. Some of these disruptions will partially reduce spontaneously during conservative treatment. There is insufficient data about which disruptions will benefit from surgical reduction.

**Double breaks in the pelvic ring**

Double breaks in the pelvic ring are less common than single breaks. They are inherently unstable and usually the result of higher-energy trauma than single breaks. Associated injuries are common.

In double vertical fractures of the pubic rami (straddle fracture) there is often significant superior displacement of the free floating fragment created by the fracture of the bilateral superior and inferior pubic rami. This fracture does not involve the weight-bearing portion of the pelvis and does not require reduction via manipulation or traction. The fracture will usually heal and remodel even when significant displacement is present. Bed rest as necessary for comfort followed by progressive crutch ambulation.

Fracture of the ipsilateral pubic rami with ipsilateral/contralateral fracture of the ilium or dislocation/subluxation of the sacroiliac joint (Malgaigne fracture) is a more severe injury. If significantly displaced, similar to adults, these injuries are commonly treated with reduction and internal fixation of the unstable hemipelvis. There are no good studies to determine how much displacement will lead to a poor outcome without being reduced and fixed. To avoid significant deformities more than 1cm of displacement of the posterior pelvic ring should be considered for surgery.

**Acetabular fractures**

Injury to the triradiate cartilage can cause acetabular growth disturbance which should always be considered in paediatric acetabular fractures.

Small posterior wall fractures that do not result in hip joint instability can be treated with bed rest followed by protected ambulation. Since these usually occur with hip dislocation, the main goal of treatment is to ensure a congruent reduction of the hip.
Skeletal traction can be utilized to obtain reduction of paediatric acetabular fractures. If an adequate reduction (less than 2mm) can be obtained, traction can be used as definitive treatment. However, more frequently children with displaced acetabular fractures through the superior part of the acetabulum or through the triradiate cartilage are treated with open reduction and internal fixation using approaches similar to those used in adults.

Results (Box 14.8.15)

Pelvic fractures without a break in the ring

Avulsions of the anterosuperior or anteroinferior iliac spine do well with rest and conservative treatment followed by a progressive strengthening programme prior to return to sport. Results of treatment of ischial spine avulsions have not been quite as predictable since persistent symptoms at the site are possible.

Single ramus fractures heal reliably. Despite the common presence of comminution or wide displacement fractures of the iliac wing, whether isolated or combined with other fractures, heal with conservative therapy and residual symptoms are rare.

Sacrum and coccyx fractures in children heal without long-term impairment in contrast to the frequent persistent symptoms seen in adults.

Box 14.8.15 Pelvic fracture—results

Type of fracture (pelvic ring)

- Without break:
  - Usually heal without complications
  - Occasionally some limitation of athletic ability

- Single break: usually heal with good function

- Double break:
  - Usually heal well
  - Long-term morbidity due to associated injuries (genitourinary/neurological/vascular/abdominal)
  - Avoid deformities in older children

- Acetabular:
  - Usually satisfactory with traction/open reduction and internal fixation
  - Poor results—non-congruent reduction
  - Type V triradiate fractures.

Single breaks in the pelvic ring

Fractures of two ipsilateral rami, isolated subluxation of the pubic symphysis, and fracture near the pubic symphysis can be expected to have excellent results with a short period of bed rest and progressive protected weight bearing. Isolated fracture near the sacroiliac joint or subluxation of the sacroiliac joint should result in good function after conservative treatment.

Double breaks in the pelvic ring

The results of double breaks in the pelvic ring are not as encouraging as those of single breaks in the ring. This is largely related to the energy of the injury and associated injuries. There is higher morbidity and mortality related to associated genitourinary, neurological, vascular, and abdominal injuries. Straddle fractures generally heal well without sequelae when treated conservatively. Operative treatment to prevent permanent deformity may be chosen particularly in older children.

Acetabular fractures

Conservative treatment of non-displaced acetabular fractures and fractures that reduced acceptably in traction can be good. Poor results are seen in those with non-congruent reductions and type V Salter–Harris triradiate injuries. Operative treatment of displaced transverse fractures of the acetabulum in children can lead to excellent outcomes if a satisfactory reduction is obtained.

Complications (Box 14.8.16)

Many of the complications of paediatric pelvic fractures are related to concomitant injuries to the head, chest, abdomen, long bones, and genitourinary system.

Delayed union and non-union may occur. Non-unions of the rami are frequently asymptomatic. If symptomatic non-union is present, open reduction and internal fixation and bone grafting are appropriate treatments.

Malunion of pelvic fractures may occur including limb-length discrepancy secondary to cephalad displacement of the hemipelvis.
Malunion can be prevented by obtaining and maintaining adequate reduction of the fracture.

Injury to the triradiate cartilage is a rare complication of acetabular injury which may result in premature closure of the physis and resultant acetabular dysplasia. Classifying triradiate injuries can be difficult, especially in type V injuries which are often not detected until physeal growth abnormality is present. Patients with documented or suspected triradiate injury need long-term follow-up to assess for the development of acetabular dysplasia. If dysplasia is seen consideration should be given to acetabular osteotomy or bar resection to prevent subluxation or degenerative changes.

**Box 14.8.16 Pelvic fracture complications**

- Majority due to associated injuries
- Delayed union/non-union up to 5%
- Malunion rarely symptomatic (leg-length discrepancy)
- Triradiate injury:
  - Rare
  - Salter–Harris type I, II, or V
  - Require long-term follow-up
- Incongruity can cause osteoarthritis.

Incongruity of the acetabulum following acetabular fracture can lead to osteoarthritis of the hip. This complication can best be prevented by accurate reduction of the acetabular fracture utilizing open reduction and internal fixation when necessary.

**Conclusion**

Pediatric pelvic fractures are usually secondary to high-energy trauma and carry a high risk of associated injury. The treating physician must be aware of this potential and look for other injuries when a pelvic fracture is seen. The majority of pelvic fractures in children can be treated non-operatively with the exception of widely displaced ring fractures and displaced acetabular fractures.

**Further reading**

Injuries of the femur and patella in children

Summary points

♦ There is considerable scope for remodelling in the child’s femur
♦ Significant overgrowth may correct shortening after a fracture
♦ Below the age of 5 years femoral fractures may be treated non-operatively in a spica or with traction; above the age of 11 years surgical stabilization of the fracture will normally be needed
♦ Flexible intramedullary nails have largely replaced external fixators
♦ Fractures involving the distal femoral physis need careful treatment and follow-up as they may lead to significant growth arrest
♦ Osteochondral fractures accompany a proportion of acute patella dislocations.

Introduction

Fractures of the femoral shaft represent 1–2% of all childhood fractures (Box 14.9.1) demonstrating a bimodal age distribution. Incidence peaks around 2–3 years and with a further peak in adolescence. The rapid increase in cortical thickness from age 5 may account for the reduced incidence. Non-accidental injury should be considered in all age groups but is most likely in younger children. After the exclusion of obvious causes such as car accidents, child abuse has been identified in up to 65% of femoral shaft fractures in children under 1 year old. Towards the end of the first decade, bicycle accidents account for 50% of fractures with the majority caused by car and motorbike collisions in adolescence. Higher energy trauma increases the risk of associated injuries such as hip dislocation or femoral neck fracture, pelvic and knee injuries, or thoracoabdominal trauma. Haemodynamic instability should not be attributed to an isolated femur fracture without careful assessment to exclude other injuries.

Box 14.9.1 Paediatric femur fractures—general

♦ Consequence of child abuse in 30% under 4 years of age
♦ 1.0–1.5cm overgrowth anticipated ages 3–10 years
♦ Can accept up to 15 degrees coronal, 20 degrees sagittal malalignment
♦ The significance of rotational malunion is controversial.

Acceptable deformity, femoral regrowth, and overgrowth

The degree of acceptable deformity at union is in part determined by the anatomical location of the fracture and the age at time of injury (Figure 14.9.1). Girls under the age of 10 and boys less than 12 years generally have significant growth remaining and a long-term study has suggested that up to 25 degrees of midshaft angulation in any plane can remodel in children under 13 years. Generally more than 15 degrees in the coronal plane and 20 degrees in the sagittal plane should not be accepted. Deformity will be more apparent in distal femoral fractures. Remodelling can continue for up to 5 years after fracture union with the majority of deformity correction occurring from physeal reorientation and longitudinal growth, compared to remodelling at the fracture site itself. Rotational deformity is usually well tolerated even with failure to remodel. Absolute values for acceptable angular deformity are not well documented but surgeons should aim for less than 20 degrees of malrotation.

Fig. 14.9.1
A) and B) An 8.5-year-old patient with a diaphyseal femur fracture treated non-operatively with approximately 25-degree malunion in the coronal and sagittal planes; C) 1 year and D, E) 3 years postinjury showing satisfactory alignment and limb length.

Increased growth after femoral shaft fracture is frequently seen, particularly in children aged 3-9 years. The absolute value of
overgrowth reported in studies is unclear with the difference between true overgrowth and compensatory growth in the face of shortening often not clearly differentiated. Stimulation of growth is most prominent in the first 18 months, lasting up to 5 years after fracture and is in the region of 1–1.5 cm. Fractures of the femur on the non-dominant side of the body have been reported to show statistically greater overgrowth. Opinion suggests fracture overlap no greater than 2 cm is desirable in the age group 3–9 years. Older children have less growth remaining to resolve shortening and hence fractures should be stabilized out to length. Younger children with malunited fractures and shortening greater than 2 cm can be observed for a significant period as there will be ample time to perform a contra lateral epiphysiodesis to equalize limb length.

---

**Management guidelines and techniques**

Union of the femoral shaft fractures in childhood is almost inevitable for closed low-energy injuries and a variety of management options can be employed from the non-operative methods of traction and cast immobilization to various forms of surgical stabilization. Complications related to the injury and treatments include infection, compartment syndrome, neurovascular injuries, and fracture non-union with high-energy or open injuries. The commonest problem is that of malunion which may or may not be associated with a limb-length discrepancy. In younger children this complication can resolve with growth.

Multiply injured children, head injuries, open fractures and simultaneous ipsilateral fractures of femur and tibia, and the floating knee, are all good indications for surgical stabilization.

The age, weight, and maturity of the child are some of the important factors in deciding the method of fracture stabilization. Presuming children are of average weight and maturity, guidelines are given on the basis of age with a subsequent discussion of the techniques.

**Birth to 1 year (Box 14.9.2)**

Fractures can occur from birth trauma, abuse including neglect, or can be the presenting feature of osteogenesis imperfecta and other metabolic disorders. A Pavlik harness may be used in the majority of children up the age of 6 months with thick periosteum and rapid fracture healing reducing the risk of significant malunion. The potential for remodelling is sufficient to accept up to 3 cm of shortening or 30 degrees of angulation. Spica casts are more suitable in children over 6 months and retained for 4–6 weeks in this age group.

**1 year to preschool (Figure 14.9.3)**

The majority of fractures can be treated with early spica immobilization within 48h of injury and the spica retained for approximately 8 weeks. Temporary splintage or traction may be used prior to spica application. With shortening in excess of 2 cm or significant telescoping of the fracture under anaesthetic an initial period in traction to correct length and alignment may be appropriate. A spica can be applied after fracture haematoma consolidation. Alternatively, incorporation of a traction pin into the spica to maintain length and alignment has been proposed.

**5–11 years**

Ht spica remains an acceptable treatment of low-energy injuries without significant displacement in young patients. However, the loss of independence whilst in a spica combined with the longer time to fracture healing increase the benefits of surgical stabilization. Many schools will not accept a child in a spica, causing a significant interruption in the child’s education. Internal or external fixation techniques are appropriate, with flexible intramedullary nails becoming the usual practice. This facilitates early mobilization and a return to school or social activities for this and older age groups with likely psychological benefits for the child and family. Unstable fragmented fractures can be treated with submuscular bridge plating.

**11 years to adult**

Surgical stabilization is usually indicated. Fractures have a more limited ability to remodel and early mobilization and rapid progression to unsupported weight bearing is desirable. Methods of treatment should aim for less than 10 degrees of deformity in coronal and/or sagittal planes with less than 1.5 cm of shortening. Younger, lighter children are still suitable for flexible intramedullary nails, usually up to weights of 50 kg. However, older children with less potential to remodel malunion and increase weight predisposing to loss of reduction may need early periods of bed rest prior to mobilization and functional bracing to help prevent deformity during fracture healing. Children deemed unsuitable for flexible nails can be treated with plate fixation. Although technically demanding, minimally invasive submuscular bridge plating techniques avoid the disadvantages of soft tissue stripping and large incisions. Successful use of antegrade adult pattern locked intramedullary nails is well described but even using the lateral aspect of the greater trochanter for entry point may not completely avoid the risk of femoral head avascular necrosis.
Traction

Skin or skeletal traction may be used although it is generally a temporary measure as younger children can be treated in a spica and older children with surgical stabilization. Bryant’s or gallows overhead skin traction is not recommended for children over 11kg in weight. Risks include peroneal nerve palsy, compartment syndrome, and skin blistering necessitating frequent examination of the neurovascular status of the limb. Simple longitudinal traction or balanced traction with the knee flexed 45 degrees is often more appropriate. Traction pins should be placed in the distal femur 2cm proximal to the physis under fluoroscopy from a medial to lateral direction to avoid injury to the femoral vessels. The proximal tibia should not be used because of the risk of causing growth arrest and subsequent tibial recurvatum. If skeletal traction is used as a definitive treatment then radiographs should be obtained periodically to adjust the weight and direction of traction in order to maintain fracture alignment. When adequate callus formation is evident the patient can be mobilized in a cast or function brace.

Hip spica

Prior to spica application femoral shortening is assessed by longitudinal compression to confirm the fracture does not shorten by more than 3cm. This has been referred to as the telescope test. The fracture is reduced with traction applied manually directly to the calf and reduction confirmed with fluoroscopy. The popliteal fossa and all bony prominences must be well padded and one and half limb spica applied. Flexion of the hip and knee to approximately 45 degrees is usually adequate to control the fracture position with appropriate moulding of the thigh. Some authors recommend hip and knee flexion of 90 degrees in the spica. Whilst this has undoubtedly been used many times without adverse outcome, there are reports of catastrophic complications with full thickness skin loss and leg compartment syndrome. Initial application of a long leg cast and subsequent completion of the spica may be helpful, but the cast should not be used to apply traction to the leg. Maintenance of fracture reduction should be confirmed at 1 and 2 weeks. Angular deformity can often be treated with appropriate wedging of the cast.

External fixation (Box 14.9.3)

External fixation was previously popular in children inappropriate for spica casts but has been largely superseded by flexible intramedullary nails. There is still a role in patients with fragmented and unstable fracture patterns where control of length and alignment is difficult. Open fractures, significant soft tissue injury such as burns, or the multiply injured patient may be relative indications for external fixation. Pins should be placed in clusters far from the fracture, avoiding the femoral neck and distal femoral physis. Constructs should not be too rigid and dynamized early to reduce the complications of delayed or non-union and refracture after fixator removal. Pin site infection is the commonest complication and usually responsive to oral antibiotics. The need for surgical debridement, intravenous antibiotics, and fixator removal is uncommon.

Elastic stable intramedullary nailing (Figures 14.9.5, 14.9.6)

Elastic stable intramedullary nails (ESIN) have become the mainstay of treatment to stabilize fractures of the femur from the subtrochanteric region to the distal quarter of the shaft. Advantages include avoidance of injury to the blood supply of the trochanter, femoral neck, or head. Limited incisions are used provided the fracture can be reduced by closed methods, using either the nails directly at the fracture site to guide reduction, a traction table, or radiolucent reduction tools applied to the thigh.
• Beware comminution or excessive initial shortening

- Traction followed by spica (3 weeks average):
  - Split Russell skin traction in young children
  - Skeletal in older children.

Fig. 14.9.3
A) Femoral fracture in a 4-month-old male. Injuries such as this in non-ambulating patients should be considered a consequence of child abuse. B) Fractures in this age group may be treated with immediate spica cast immobilization with excellent results.

The majority of fractures are stabilized with two C-shaped nails inserted retrograde from medial and lateral starting points approximately 2cm proximal to the growth plate. Each nail is 40% of the diameter of the femoral canal at the isthmus and present to an identical curvature, approximately three times the diameter of the isthmus, to achieve a stable construct. Nails should cross each other far from the fracture site and not pass around each other in the manner of a corkscrew. Nails are inserted to the level of the lesser trochanter, although subtrochanteric fractures may require nail passage into the femoral neck to achieve stability or an alternative method of stabilization. The fracture is impacted and rotational alignment is compared to the contralateral limb prior to final nail insertion. Leaving 1cm of nail outside the bone facilitates removal and nails should lie flush to the bone to avoid soft tissue irritation. Distal fractures can be treated with a C- and S-shaped nail passed anterograde from below the level of the lesser trochanter. Entry points are on the lateral aspect of the femur with one nail starting slightly distal and anterior to the other. Patients are mobilized protected or non-weight bearing depending on fracture configuration and stability. Full weight bearing is allowed when good callus is present, usually around 6–8 weeks.

The largest elastic nail available is 4mm in diameter; hence femora up to 10–12mm in diameter at the isthmus can be treated using this method. However, consensus suggests that 50–60kg in weight represents an upper limit. The incidence of malunion rises significantly with increasing patient weight and older or heavier children may require either a period of postoperative bed rest and/or bracing to supplement fracture fixation. Additionally, older children will have less growth remaining so are less tolerant of fracture malunion. Flexible nails that allow proximal and distal interlocking screws have been reported but are not in widespread use. There is continued debate over the use of stainless steel or titanium implants. An incidence of malunion with titanium of 23% compared with 6% for stainless steel suggests titanium may be too flexible a material for nails particularly in older or heavier children.
External fixation of paediatric femur fractures should be performed with ‘flexible frame constructs’. A) Large-diameter pins (more than two pins per cluster) with wide pin clusters and close approximation to the fracture increase the structural stiffness of the construct. Smaller-diameter pins placed in narrow clusters away from the fracture site are preferable. B) The second construct and lateral displacement of the fixator may diminish the risk of delayed union and refracture.

Implants are generally removed after fracture union and consolidation, usually at least 6 months postinjury. Refracture after implant removal is uncommon.

Plate fixation (Figure 14.9.7)

Open reduction and dynamic compression plates allow anatomical reduction of fractures without the aid of fluoroscopy and have relative indications in the case of proximal fractures, head injury, or multiply injured patients allowing simultaneous surgery to other injuries. However, this comes at the expense of large incisions and significant soft tissue stripping. Hence flexible nails are more commonly used. Submuscular bridge plating combined with minimally invasive techniques avoids many of the disadvantages of open plate fixation. In association with locking compression plates this technique is an alternative to a locked anterograde nail in adolescents considered too heavy for flexible nails but with an open proximal femoral physis. The technique is demanding particularly as these older patients have a greater need for anatomical reduction of length and alignment. Screw placement is based on similar principles to that of external fixation with six cortices either side of the fracture. The fracture is indirectly reduced by the plate and no interfragmentary compression is applied. Patients can usually bear weight unsupported by 10 weeks. Implants can be removed using the same minimal incisions around 6–8 months after injury depending on fracture consolidation.

Rigid locked intramedullary nails

There is continued controversy over the safety of adult pattern anterograde femoral nails in the treatment of femoral shaft fractures in older or heavier children where there are clear biomechanical advantages. Nails implanted through the piriform fossa have been associated with avascular necrosis of the femoral head at a rate of around 2%. Prior to physeal closure the femoral head blood supply is almost entirely dependant on the lateral ascending branch of the medial circumflex artery. The artery is at risk from nails using a piriform fossa entry point or the medial aspect of the greater trochanter, including inadvertent entry by reaming out the medial trochanter wall from trochanter tip entry. This is a devastating complication with no satisfactory reconstructive option. Coxa valga and thinning of the femoral neck is also reported, which also is likely to represent a vascular insult. Modern nail designs allow a lateral trochanteric entry which avoids dissection near to the artery. Several large series have reported good maintenance of alignment and length with this technique but numbers studied are probably too small to report the true incidence of avascular necrosis with a suitably narrow confidence interval. Overall this remains a controversial device to stabilize the adolescent femur, despite reports of safe usage. Therefore a 1–2% risk of avascular necrosis of the femoral head should be clearly stated if this method is used.

Distal femur fractures

Supracondylar fractures involving the metaphysis but not the physis are relatively uncommon. The gastrocnemius muscle can pull the distal fragment into flexion making it difficult to maintain a reduction with cast alone. Patients can be managed in traction, but usual treatment involves closed reduction using longitudinal traction with the knee flexed and placement of crossed percutaneous pins to stabilize the fracture. Initially a long leg cast is used to stabilize the fracture with possible transfer to a cast brace when early callus is seen. Ideally pins should not cross the physis but it may be necessary to achieve fracture stability. There is a low risk of growth disturbance with smooth pins for approximately 4 weeks.

Box 14.9.3 Operative treatment—indications

- Strong:
• Head injury
• Multiple trauma
• Ipsilateral tibia
• Open fractures

♦ Relative:
  • Age and patient size
  • Psychosocial and economic considerations
  • Unacceptable alignment.

Box 14.9.4 Operative treatment—techniques

♦ Plate fixation—disadvantages include extensive scarring or the technical demands of minimally invasive subs muscular techniques, possible delayed weight bearing
♦ Rigid/reamed nails—disadvantages include trochanteric arrest, 1–2% femoral head avascular necrosis
♦ Flexible nails—disadvantages include length instability, pin migration, supplemental immobilization
♦ External fixation—disadvantages include pin infection, delayed union, refracture.

Distal femoral physeal fractures

Physeal injuries of the distal femur represent 5% of physeal injuries and require significant trauma to disrupt the complex shape of the growth plate which is securely fixed to the metaphysis. The distal femoral physis contributes approximately 40% of the total leg length and 70% of femoral growth at maturity. Fractures with any displacement are at significant risk of growth plate arrest with resultant limb-length discrepancy and angular deformity. Minimally displaced fractures can be confused with knee ligamentous injuries but maximal tenderness to palpation is remote from the joint line. Physeal displacement usually follows the direction of applied force either by direct impact or via ligamentous structures; for example, medial femoral condyle fractures results from a valgus force applied via the medial collateral ligament. It is presumed that less energy is required to cause the fracture than disrupt the cruciate or collateral ligaments.

Distal femoral fractures are seen following obstetric trauma and deformity can usually be expected to remodel with a low incidence of growth arrest. The majority of injuries occur in the age group 11–13 years following sports or road traffic collisions and are Salter–Harris type I or II. Most studies demonstrate worse outcomes in young patients with the greatest fracture displacement and failure to achieve an anatomical fracture reduction. The Salter–Harris grade does not seem to correlate with the risk of growth arrest and type I and II injuries have shown a 50% incidence of growth arrest. Careful follow-up is advised to detect partial or complete growth arrest. Other complications include knee stiffness, ligamentous laxity, and neurovascular injury. Popliteal vessel injury is rare and peroneal nerve neurapraxia generally resolves spontaneously.

Cast immobilization for 4 weeks is usually sufficient for undisplaced, stable fractures although radiographic surveillance for late displacement is required. For displaced fractures a gentle closed reduction is attempted under general anaesthesia. Indications for open reduction include failure to achieve reduction due to muscle or periosteal interposition, open injuries, associated neurovascular injury, and intraarticular fracture extension. Salter–Harris type III and IV injuries require anatomical reduction to reduce the risk of bony bar formation and growth arrest. Surgical approaches should be from the tension side of the fracture (Figure 14.9.10), where the block to reduction is most likely to be encountered. Reduction is stabilized with crossed K-wires (Figure 14.9.9). Placement from proximal to distal avoids transgressing the knee joint. Screw fixation through the Thurston–Holland metaphyseal fragment avoids hardware crossing the growth plate when the fragment is of sufficient size. A long leg cast then applied for 4 weeks.
Fig. 14.9.7
A) Spiral fractures can be length unstable and anatomical reduction more difficult to achieve (B, C). Shortening at fracture union is likely to be compensated for in this 7 year old boy (D).

Fig. 14.9.8
A) A 7-year-old patient with a comminuted subtrochanteric femur fracture associated with closed cranial trauma. B) and C) Fracture stabilization was accomplished with osteosynthesis. D) At 1 year the difficulty in routine hardware removal is evident. (Courtesy of P. Nourbash.)

Box 14.9.5 Distal femoral physeal fractures

- Distal femoral physis contributes 40% of total leg length and 70% of femoral length
- Average age 11–13 years
- Leg-length discrepancy and/or angular deformity in up to 55%
- Reduction and fixation under general anaesthesia
- Open reduction common in Salter–Harris types III and IV and may be necessary in types I and II.
Salter–Harris type I fracture may follow an excessive lateral force. Fracture reduction may be difficult secondary to interposed periosteum. Failure to achieve a closed reduction warrants an open approach in order to remove any obstacles including interposed periosteum.

Distal femoral metaphyseal fractures are prone to malalignment secondary to gastrocnemius pull. Fractures are best treated with closed reduction percutaneous pinning and cast immobilization.

Clinical evaluation after injury screens for signs of growth disturbance and ligamentous laxity until skeletal maturity. Magnetic resonance scans can identify early signs of physeal arrest 3–6 months postinjury. Predicted limb length discrepancy of more than 1cm is an indication for contralateral epiphysiodesis in adolescent patients. Bar excision should be considered with growth arrest in younger age groups.

Patella fractures (Box 14.9.6) and Figure 14.9.12

Fractures of the patella in children and adolescents are uncommon representing 1% and 8% of patella fractures overall. The predominance of fibrocartilaginous tissue and relative increased mobility of the patella probably account for the rarity of this injury. These differences can make diagnosis of a patella fracture more difficult and there is often a tense haemarthrosis preventing palpation of a defect. Abnormal action of the extensor mechanism and loss of function may indicate an injury. Bipartite patella, classically with a superolateral defect, can be painful mimicking a minimally displaced fracture, particularly with incomplete ossification. Sleeve fractures describe an avulsion fracture of the distal cartilaginous part of the patella from the ossification centre, with a significant proportion of the articular surface attached to the distal fragment. The injury is best identified on the lateral radiograph which may merely show patella alta and a small distal avulsion fragment.

Undisplaced fractures with an intact extensor mechanism can be immobilized in extension for 4–6 weeks. Displaced fractures require open reduction to achieve articular congruity and fixation using tension band techniques with wire or non-absorbable suture. Fixation can be supplemented with cerclage techniques and repair of the retinaculum is important. Partial and total patellectomy is described for severely fragmented injuries but should be avoided if at all possible. After suitable cast immobilization, range of motion and muscle strengthening exercises are commenced. Growth disturbance is uncommon after injury with the patella a sesamoid bone, hence growing by apposition.

Acute patella dislocation

Acute dislocations of the patella are generally seen in adolescents and high-level athletes with a significant number having anatomical variation predisposing to the injury. Recurrent or habitual dislocation associated with patella alta, generalized laxity, and
anatomical variation predisposing to the injury. Recurrent or habitual dislocation associated with patella alta, generalized laxity, and genu valgum is discussed elsewhere. Injury commonly occurs from indirect trauma with foot planted and the knee flexed in valgus causing an internal rotation moment. Direct trauma to either the medial aspect of the patella or laterally resulting in knee valgus can cause injury. This damages the medial structures involving the sartorius fascia in the superficial layer, medial patellofemoral ligament (MPFL), and patella retinaculum in the middle layer and medial collateral ligament and joint capsule deep. The MPFL provides between 50–80% of the restraining force to lateral patellar displacement, originating at the adductor tubercle and inserting into the superior half of the medial patella border.

After injury the patella is often relocated otherwise the knee will still be flexed with the patella palpable to one side of the lateral femoral condyle. After suitable analgesia and sedation the knee is extended and gentle medial pressure reduces the patella. Turning onto a prone position helps relax the hamstrings if difficulty is encountered. Considering the similarity in mechanism of injury and likelihood of a large haemarthrosis; the patient should be evaluated for a tear of the anterior cruciate ligament. Radiographs including a skyline view should be assessed for the quality of reduction and the presence of an osteochondral fragment. Damage to the medial retinaculum and the haemarthrosis can cause significant patella tilt on skyline views which reduces as knee swelling resolves.

Osteochondral fractures are reported in 5–50% of acute patella dislocations and their presence may necessitate arthroscopy and evaluation. If radiographs or clinical assessment are unclear then magnetic resonance imaging should be undertaken. Osteochondral fragments more than 2cm in size with suitable osseous component should be fixed using countersunk cannulated screws or divergent bioabsorbable pins, generally through a limited arthrotomy. Acute repair of the MPFL and medial retinaculum is performed and lateral retinacular release may be required. Some authors advise correction of significant predisposing anatomical variants at the same time. In absence of an osteochondral fracture repair of the medial structures is probably unnecessary and doesn’t seem to reduce the risk of further instability compared to non-operative management. Up to 60% of patients over 10 years old have no recurrence of instability after their first dislocation.

Box 14.9.6 Patella injuries

- Patella sleeve fractures best seen on a lateral radiograph with patella alta and a small distal avulsion fragment
- Bipartite patella usually has a superolateral defect
- Osteochondral fractures greater than 2cm should undergo fixation ± repair of medial structures.
**Conclusions**

Femoral shaft fractures in children can be successfully managed using all the methods previously discussed. Fracture pattern, associated injuries, the age, maturity, and the weight of the child influence the choice of management. Ultimately the preferences of the surgeon and family may dominate. Children of 5 years or less can usually be managed in a hip spica and older children with flexible intramedullary nails unless fracture pattern, weight, or maturity makes this method unsuitable. Submuscular plate fixation can be used for most patients unsuitable for flexible nails. The use of adult pattern intramedullary nails inserted through the greater trochanter remains controversial and the risk of femoral head avascular necrosis is approximately 1–2%. Reconstruction following this devastating complication is often unsatisfactory.

Displaced distal femoral physeal fractures require anatomical reduction by either gentle closed manoeuvres or open techniques and stabilization. Surveillance for post-traumatic growth arrest is important.

Patella fractures can often be managed in a similar fashion to adult injuries with tension band and cerclage techniques. Patella injuries should be evaluated for osteochondral fractures presenting as sleeve fractures or avulsion injuries following patella dislocation.

**Further reading**

Summary points

♦ After forearm and digital injuries, tibial and ankle fractures are the commonest fractures in the immature skeleton and the majority of these involve the diaphysis or ankle
♦ Compared to the morbidity seen in adults these are relatively forgiving injuries in children as the healing rate of bone and soft tissues is rapid and remodelling will occur
♦ It is wise, however, to guard against overconfidence in the remodelling potential of certain injuries; for example, angulated mid-diaphyseal fractures, rotational malalignment, and metaphyseal fractures within 2 years of skeletal maturity
♦ Children will tolerate manipulative/cast treatment better than adults as the duration of treatment is usually shorter and rapid rehabilitation is almost the norm with or without physiotherapy
♦ Postfracture overgrowth does occur but is less than that following femoral fractures and seldom clinically significant (over 10mm)
♦ Isolated fibular fractures are of minor importance but need to be taken into account in managing complex injuries involving the distal tibia
♦ It is convenient to discuss injuries according to three anatomical sections: proximal, diaphyseal, and distal.

Proximal tibial injuries

Tibial spine (intercondylar eminence/tubercle)
This is the commonest proximal fracture and is associated with sports injuries, particularly boarding, skiing, and cycling and is, in effect, the child equivalent of an anterior cruciate ligament rupture (Figure 14.10.1). Pain and an acute effusion (lipohaemarthrosis) are characteristic. X-ray classification and treatment is according to displacement (Box 14.10.2).

Fig. 14.10.1
Type II tibial spine fracture. A) and B) Displaced tibial spine fracture. C) and D) Post-fixation tibial spine fracture.

Box 14.10.2 Classification of tibial spine fractures

♦ Type 1: minimally displaced: requires immobilization in an above-knee cast in slight flexion for 5–6 weeks
♦ Type 2: posteriorly hinged: trial of a fully extended above-knee cast and if radiological reduction demonstrated continue with 5–6 weeks of immobilization. If reduction doubtful treat as type 3
♦ Type 3: completely displaced: associated with a broad ‘angel wing’ epiphyseal attachment which is held irreducibly displaced by the underlying intact menisci. It can be difficult to distinguish types 2 and 3. Attempts at reduction of displaced fractures in an extension cast are seldom successful and open reduction is needed.
Open reduction through a 3cm anteromedial arthrotomy is a straightforward procedure. With the knee flexed the fracture is easily reduced under direct vision and is held with an absorbable transepiphyseal suture. In the older child, which most are, the fracture is easily secured with a short cannulated screw taking care not to cross the growth plate. The screw head does not impinge on the notch and does not require removal.

The attached anterior cruciate ligament is almost certainly stretched immediately prior to the avulsion fracture and though residual laxity may be clinically evident, symptomatic late instability is rare.

**Tibial tubercle**

Avulsion fractures are uncommon but when acute mechanical failure of the extensor apparatus occurs it tends to do so distally in children (Figure 14.10.2). This is in contrast to patellar and quadriceps injury seen in adults. There is no relationship to Osgood–Schlatter disease though x-rays may confuse the inexperienced.

![Click to view larger](Fig. 14.10.2)

Displaced tibial tuberosity fracture with internal fixation.

Rarely the fracture extends into the knee joint as a type III Salter–Harris growth plate injury. The fracture is usually displaced.

Treatment is by open reduction and fixation with screws. Growth disturbance is unusual but to minimize the risk of late damaging recurvatum metalwork should be removed after the fracture has healed unless the child is close to skeletal maturity.

**Proximal tibial physeal injuries**

Salter–Harris type II are rare in the proximal tibia. When complete separations do occur there is a reported 10% risk of neurovascular damage to the sciatic nerve and the popliteal artery trifurcation akin to knee dislocations in adults.

**Proximal metaphyseal (Cozen) fractures (Box 14.10.1)**

If undisplaced, an above-knee cast in 10 degrees flexion for 5–6 weeks is effective (Figure 14.10.3). Angulated fractures require initial manipulation under general anaesthesia to within 5 degrees of normal alignment. Interposition of the pes anserinus can prevent closed reduction and open reduction may be needed combined with fixation with crossed 2-mm K-wires in small children or a plate in older children. Above-knee casting is also required.

![Click to view larger](Fig. 14.10.3)
Fig. 14.10.3
Minimally displaced proximal tibial metaphyseal fracture.

As for physeal injuries, the popliteal artery trifurcation is at risk in high-energy displaced injuries so the distal pulses should be checked and the child monitored for compartment syndrome.

Cozen described late valgus deformity developing following early uneventful healing of this fracture. Spontaneous correction may occur though this may take years. Late recurrence of valgus even after corrective osteotomy has been reported and generally it is better to defer correction by osteotomy or hemiepiphysiodesis until late childhood in this unpredictable fracture.

Box 14.10.1 Relevant physeal anatomy

♦ Growth of tibia: proximal physis 60%
♦ Ankle ligaments attach to epiphysis:
  • Physis weak in comparison to ligament
  • Physeal fractures rather than sprains
♦ Distal tibial physeal closure begins centrally then medially and lastly anterolaterally
♦ Beware of vascular injuries in proximal tibial physeal injury.

Diaphyseal injuries

In this heterogeneous group, management is strongly influenced by the amount of energy causing the injury and the age of the patient. For example, management of a 14-year-old close to skeletal maturity with multiple injuries including an open multifragmentary tibial fracture will be very different compared to a 3-year-old with a toddler’s fracture, and therefore this section has been subdivided into low-energy closed injuries and high-energy open injuries.

Low-energy closed fractures—non-operative management

Toddler’s fractures (Figure 14.10.4) are common and characterized as follows:

♦ Usually found at 1–3 years
♦ Low-energy spiral fractures of the distal tibial diaphysis
♦ Caused indirectly by simple trips and twisting injuries
♦ Diagnosis delayed as the clinical presentation is unimpressive with an otherwise well toddler simply reluctant to weight bear and no traumatic episode recalled
♦ Delayed presentation and inadequate history may give rise to concern about non-accidental injury
♦ Degree of displacement and angulation minor
♦ Treat with above-knee walking cast in 10 degrees of knee flexion
♦ Predictably good prognosis.

Fig. 14.10.4
Toddler’s fracture. Can be radiologically subtle. May be missed or misinterpreted as vascular marking. Callus at 2 weeks is the giveaway.
Falls and road traffic collisions are common throughout childhood and more energy results in displaced fractures (Figure 14.10.5) but these isolated closed injuries can be treated in a similar way to toddlers’ fractures.

- Reduction and application of an acceptable full-leg cast can usually be achieved in the Emergency Department using sedation and/or inhalational analgesia. This will stabilize the fracture better and minimizes handling of the injured limb in a frightened or uncooperative child
- Complete cast acceptable if child admitted for elevation and observation for compartment syndrome
- Ankle equinus is unimportant in children’s fractures as late ankle stiffness will not be a problem and may help maintain reduction
- Check radiographs at 1, 2, and even 3 weeks postinjury are needed as late displacement may occur. Plaster wedging can correct angular deformity but it is often better to reapply and mould a fresh cast under general anaesthetic
- Surgery is the better option when casting fails to achieve or maintain satisfactory alignment. A guide to the amount of displacement and angulation permissible is shown in Table 14.10.1.

![Fig. 14.10.5](image)

Displaced tibial shaft fracture manipulated into acceptable position and held in an above-knee cast.

It may be argued that these criteria are strict but orthogonal anteroposterior (AP) and lateral x-rays may underestimate the degree of deformity if it lies in an oblique plane.

Advice about weight bearing is often ignored and if children can weight bear they tend to do so. Children younger than school age struggle with crutches but cope with a small walking frame or simply use a buggy. It is worth considering reducing an above-knee cast to a below-knee one when fracture callus is visible on radiographs. This will help older children who appreciate a lighter, less restrictive cast but young children dislike such interventions and are better left to heal in their existing cast which in most cases would be removed 2 or 3 weeks hence.

As a rule-of-thumb, most low energy, closed children’s diaphyseal fractures require 6–8 weeks’ cast splintage though toddlers’ fractures are usually sufficiently healed in about 4 weeks. Seeing the child walking comfortably in clinic and fracture callus on x-ray indicates that the cast can be removed.

It is important to warn parents that it takes a few days for confidence to be regained and for weight bearing to resume.
Knee and ankle stiffness seldom occur and formal rehabilitation is not needed. Sport should be prohibited until the child can walk normally and run with confidence, perhaps a further 6 weeks.

**Low-energy closed fractures—operative management**

In the last 20 years, intramedullary nailing in adults has become very popular. In children, however, proximal physis damage at the nail entry point needs to be avoided as anterior growth arrest and tibial recurvatum may result.

When closed treatment has already failed or is not a practical proposition, for example, in multiply injured patients, there is a variety of fixation devices that can be used. The role of each is dependent on the fracture type and the surgeon’s training and experience. Relative indications, advantages and disadvantages of each are summarized in Boxes 14.10.3–14.10.6.

**Box 14.10.3 Elastic intramedullary nailing (Figure 14.10.6)**

- Over 7 years
- Minimal intervention
- Quick to insert (with experience)
- Very good fracture control
- Segmental fractures difficult
- May well require removal especially if nails ends palpable/irritate
- Infection rare and usually minor/superficial
- Supplementary below-knee cast for 4 weeks.

**Box 14.10.6 Plating**

- When used usually applied for metaphyseal injuries but possible in the diaphysis
- Unpopular in diaphyseal fractures as other methods less invasive.

**High energy, open injury**

After open finger injuries this is the commonest open fracture in children. The Gustilo and Anderson classification helps define the prognosis and is useful for communication. The full extent of injury may only be apparent at formal debridement. High-energy unstable ipsilateral tibial and femoral fractures (‘floating knee’) injuries are difficult to manage without surgical stabilization of one or, preferably, both.

**Box 14.10.4 External fixation, monolateral fixator (Figure 14.10.7)**

- Minimal intervention
- Easy technique to learn, very quick to apply
- Good fracture control
- Adjustable (general anaesthetic)
- Requires 3–4cm diaphysis/metaphysis proximally and distally for screw fixation

Fig. 14.10.6
Displaced tibial shaft fracture (A) treated with flexible intramedullary nails (B).
Infection at screw sites common but superficial
- Pock mark scarring at screw sites
- Can remove in clinic
- Difficult to know when to remove
- Stress shielding and late fracture rate
- Malunion.

**Box 14.10.5 External fixation—circular frame**

- Complex devices, more time to assemble and apply
- Minimal proximal/distal bone needed to obtain sound fixation using transfixation wires
- Excellent fracture control, even segmental fragments, and possibility to adjust incrementally in all planes in clinic/at home (especially the Taylor Spatial Frame)
- Usually reserved for complex/high energy/revision surgery cases (Figure 14.10.8).

---

**Fig. 14.10.8**
Open multifragmentary diaphyseal fracture with bone loss (same case as Figure 14.10.7). Failure to consolidate in a monolateral fixator treated by segmental bone excision and bone transport using a circular frame resulting in union.

---

**Fig. 14.10.7**
Open multifragmentary diaphyseal fracture with bone loss (A). Primary stabilization in a monolateral fixator (B).

Grades 1 and possibly 2 can be treated without surgical stabilization but where facilities and expertise exist, surgical stabilization is preferable. The management strategy is the same as for adult open fractures, except:

- Adult type transphyseal intramedullary nailing contraindicated
- Superior age-related healing of soft tissues and bone
- Less debridement may be required in children
- In younger children judicious use of a windowed cast is adequate.

---

**Distal tibial and ankle injuries**

Distal tibial metaphysis
Fractures are usually greenstick pattern and the large majority are minimally displaced. Closed reduction and immobilization in a long leg cast allows correction of any deformity. High-energy displaced injuries with soft tissue compromise may require stabilization with crossed percutaneous wires (2mm), external fixation or even plating (Figure 14.10.9).

Severe open injuries including open ‘grinding’ injuries from road abrasion require plastic surgical assessment and the circular frame is a useful stabilizing device. Remodelling will correct minor translational deformities; rotation, however, will not and angular deformities should not exceed 10 degrees.

These injuries merge with those described in the following section on ankle and growth plate injuries.

**Ankle and distal growth plate injuries**

These are injuries of older children and adolescents. The predictable way the tibial physis fuses in the last 2 years of growth dictates injury patterns around the immature ankle as the open part of the physis is more vulnerable than adjacent bone (and ligaments). Fusion begins centrally then medially and lastly anterolaterally. It is also thought that the characteristic medial prominence seen on AP x-rays (‘Kump’s bump’) confers some stability to that part of the physis and also modifies fracture patterns.

Injuries involving a partially fused physis are sometimes referred to as transitional fractures.

These distal injuries are the most complex group to consider and in an attempt to clarify discussion is in terms of:

- Mechanism of injury
- Salter–Harris type (intra- vs extra-articular)
- Adolescent Tillaux fracture
- Triplane fracture
- Fibular injury.

**Mechanism of injury**

A modified Lauge–Hansen classification was devised by Dias and Tachdjian (1978) (Figure 14.10.10), to describe mechanisms of injury and resulting characteristic x-ray appearances.
Children seldom report anything other than a twist or fall and the value of recognition of the x-ray appearance is that it allows the fracture to be reduced by reversal of the injuring force. This is helpful in children as closed treatment and splintage of the foot and ankle in an over-corrected non-plantigrade position is much better tolerated than in adults where a policy of open reduction/internal fixation renders such fracture pattern analysis largely redundant.

**Salter–Harris type I and II injuries**

- Salter-Harris type I and II tibial injuries do not cross the weight-bearing joint surface and are non-articular. Manipulation under general anaesthetic is usually easy.
- Stable reduction held in an above-knee cast for about 5 weeks.
- Check x-ray at 1 week. Patients are allowed to weight bear when comfortable.

Interposition of the thick and elastic periosteum is a well-recognized cause of failure of closed reduction and requires open reduction. At surgery it is simple to split the infolded periosteum longitudinally and lift it out of the fracture gap.

Where there is doubt about stability or the ability of a cast to maintain reduction, crossed transphyseal 2mm K-wires can be used.

Healing is rapid and a delay of more than 1–2 weeks risks physseal damage if a forcible reduction is then attempted. In this case it may be preferable to accept a non-anatomical reduction and consider a late elective corrective osteotomy.

The distal tibial growth plate is particularly vulnerable to growth disturbance after injury with reports of up to 50% late growth arrest even in Salter–Harris type I and II injuries. Growth disturbance may not become evident until 18 months postinjury but since the majority of injuries occur around adolescence the effects are mitigated.

When partial growth plate arrest occurs in younger children, typical angular deformities develop and require treatment (Figure 14.10.11).

![Partial distal tibial growth arrest resulting in a varus ankle and relative fibular overgrowth.](Click to view larger)

Often the best solution is to ablate both the distal tibial and fibular growth plates and perform a corrective supramalleolar osteotomy. Depending on the age of the child and amount of shortening, some lengthening may be required. This may be done as a secondary procedure towards skeletal maturity or as part of a one-stage reconstruction using a lengthening device.

**Medial malleolar fracture/Salter–Harris type III or IV injury** (Figure 14.10.12)

- Supination–inversion injuries before the medial physis has fused.
- Aim is anatomical reduction of joint surfaces.
- Reduction of the closely adjacent physis is important to reduce the risk of growth disturbance by a physeal bar.
- Open mini-arthrotomy/closed reduction of displaced fractures and stabilization with percutaneous cannulated 4.0-mm screw(s).

Whilst there is a generally held view that the intra-articular reduction should be within 2mm at most (the authors included) there is little clinical evidence to support this ‘2mm displacement rule’.

It is unclear whether a gap is of greater significance than a step though it would seem intuitive that a step would be more likely to predispose to late joint degenerative change than a ‘level’ gap.

If there is doubt or difficulty in reduction then open reduction is needed. If the fracture line is steeply oblique then intraepiphyseal fixation with a 4.0-mm cannulated screw is an excellent method. More horizontal fracture lines require transphyseal fixation into the metaphysis. Tension band wiring is a useful option for smaller fragments or when the malleolus has split during attempted screw fixation.
Occasionally diagnostic confusion arises from an accessory area of ossification at the tip of the medial malleolus.

**Adolescent Tillaux fracture/Salter–Harris type III injury (Figure 14.10.13)**

Similar management as for type III medial malleolar fracture.

This is a Salter–Harris type III avulsion injury of the anterolateral portion of the epiphysis. They tend to occur in older adolescents shortly before the end of growth as this portion of the epiphysis is the last to fuse. External rotation of the talus in the mortise puts tension on the anterior tibiofibular ligament which avulses a substantial intra-articular fragment of the epiphysis.

**Triplane fracture/Salter–Harris type IV injury (Figure 14.10.14)**

This describes the sagittal, axial, and coronal planes that the fracture line follows. The mechanism is as for Tillaux fractures but a more complex pattern occurs because the patient is younger and a larger part of the lateral physis remains open and vulnerable to injury.

This injury pattern is typified on plain x-rays by a Salter–Harris type III fracture on the AP view and a Salter–Harris type II on the lateral. Computed tomography (CT) scanning has clarified the pathoanatomy of what is in reality a group of injuries with fracture lines not always following the typical pattern and, for example, two-, three-, and even four-part fractures can occur. The CT scan also allows accurate preoperative planning for screw placement.

As for the Salter–Harris type III and IV intra-articular fractures described earlier, closed manipulative treatment is possible but where significant displacement (>2mm) persists, open reduction and screw fixation of the epiphyseal fracture is indicated. The posterior metaphyseal component is, of itself, unimportant but persisting displacement indicates that the articular surface has not been reduced.

If the injury is treated closed a check CT at 1 week is preferable to plain x-rays.

**Salter–Harris type V injury**

These are rare following ankle trauma.

**Fibular fracture (Figure 14.10.15)**
Salter–Harris type I injuries are common though often misdiagnosed as lateral ligament sprains as the x-rays seldom show obvious displacement. Ankle ligament injuries are relatively uncommon in children. Minimal splintage required for pain relief.

- Isolated displaced Salter–Harris type II injuries are rare and probably merit closed reduction and below-knee cast.
- Displaced fractures associated with tibial fractures usually reduce when the tibia is reduced.
- High-energy complex metaphyseal injuries with residual fibular shortening and ankle incongruence may require open reduction and fixation.

### Miscellaneous conditions

**Corner or ‘bucket handle’ fractures (Figure 14.10.16)**

These are subtle but important injuries to recognize. These represent small avulsion fractures of either the proximal or distal metaphyses and are usually seen in infants subject to violent twisting injuries. They are generally recognized as a strong indicator, some say pathognomonic, of non-accidental injury.

**Tibial pseudarthrosis/prepseudarthrosis**

Rare, associated with neurofibromatosis, typical anterolateral bow and radiological features. Simple splintage is used before fracture. Complex surgery always required for fracture, sometimes Symes amputation needed.

**Osteogenesis imperfecta (Figure 14.10.17)**

One of the most common bone dysplasias usually with typical ‘gracile’ bones on x-ray. Fractures unite in normal way but repeated fractures together with progressive deformity hinder mobility and intramedullary nailing with extending rods helps.

---

**Click to view larger**

Fig. 14.10.14

Imaging in three planes and three-dimensional reconstruction helps understanding of this three-part triplane fracture and screw placement.

---

**Click to view larger**

Fig. 14.10.15

SH type 2 distal fibular physeal injury, minimally displaced and easily overlooked, especially SH type 1.
Stress fracture

Rare and sometimes bilateral. Subtle presentation and may cause concern initially because of x-ray appearance suggestive of tumour or infection. Magnetic resonance imaging is both sensitive and specific. Consider ‘shin splints’ or chronic compartment syndrome in the differential diagnosis.

Compartment syndrome

Always consider when pain is out of proportion to injury even in open fractures. Proceed to emergency pressure measurements in theatre and wide four compartment fasciotomies if pressure greater than 30mmHg or within 20mmHg of diastolic.

Further reading

Foot injuries in children

**Summary points**

- The child’s foot is very supple but when injuries do occur conventional imaging is not as valuable as it should be because of the late ossification. Accessory centres of ossification complicate matters
- Transchondral fractures are not easily seen on conventional x-rays
- Lawnmower injuries (shredding of the forefoot) should have a slightly more tissue-preserving approach than in adults
- Lacerated tendons in the hindfoot need repairing if foot growth is to be normal.

**Introduction**

Children’s feet are very supple and consist mainly of soft non-osseous tissues. Significant injuries are rare, as forces applied to the foot are invariably transmitted up the limb leading to a fracture more proximally. With growth and ossification of the skeleton, the stiffness of the foot increases and fractures occur more regularly.

A thorough assessment of an injury requires a full clinical history, a careful physical examination, and appropriate investigations. Interpretation of children’s radiographs may be difficult without a full understanding of the array of minor growth variants and the multitude of sesamoids which may occur (Figure 14.11.1). It is important to appreciate the potential damage that might arise from an injury and ensure that the clinical site of tenderness is correlated with the abnormality on the radiograph.

![Click to view larger](Fig. 14.11.1)

Accessory ossicles and sesamoid bones of the foot and ankle. (Reproduced from Mann and Coughlin (1993).)

Subtle radiographic abnormalities may hide a serious injury to the soft tissues which could have a devastating effect on the development of the foot and its function. Recent advances in imaging techniques have improved our understanding of these injuries but they are an adjunct to, not a substitute for, good clinical judgement.

**Calcaneum (Box 14.11.1)**

Until recently, calcaneal fractures in children have been reported infrequently and in general terms it was felt that the injury was benign, required minimum treatment, and was invariably associated with a good outcome. In the adult population, computed tomography (CT) scans are considered essential for the thorough assessment of calcaneal fractures and they have become an important influence on the choice of treatment and the assessment of outcome. In the child over 10 years of age, fracture patterns are similar to those in adults (see Chapter 12.56) and appropriate management can be instigated (Figure 14.11.2).
In the young child, the ossific nucleus of the calcaneum is not the same shape as the cartilage anlage and the lateral process of the talus is underdeveloped. Thus the forces applied to the immature calcaneum cause fracture patterns which differ from those seen in the adult. The anatomical differences also account for the smaller Bohler's angle found in the uninjured child. Many fractures in this age group are extra-articular. Involvement of the anterior process may be difficult to identify on plain radiographs. Unfortunately, delay in diagnosis is common and a high index of suspicion is required.

Conservative treatment is usually recommended with good results reported for both intra- and extra-articular fractures. Displaced avulsion fractures of the tuberosity or indeed of the apophysis itself, particularly when associated with soft tissue compromise or loss of Achilles tendon function should be treated by closed or open reduction and internal fixation.

Talus (Box 14.11.2)

The cartilaginous structure of the young child’s talus is resistant to compression and this combined with the lower body mass of a child means that injuries to the talus are rare. They usually occur through the neck of the talus and are thus extra-articular injuries (Figure 14.11.3A). A high index of suspicion is required in this as in many other injuries in childhood as the initial radiographs may seem normal. Forced dorsiflexion is the mechanism of injury and even in undisplaced fractures there will be tenderness distal to the anterior ankle joint. If there is less than 5mm displacement and less than 5 degrees malalignment the position can be accepted. If displacement is greater than this then reduction by either closed or open means should be performed with internal fixation from the posterior aspect.

The risk of avascular necrosis is the major concern with fractures of the talus and the risk is related to the site of the fracture and the degree of displacement. The risk should be low in undisplaced fractures. However, avascular changes can occur even in undisplaced fractures. Weight bearing may have been detrimental in these cases and indeed, restricted weight bearing is recommended for all cases where avascular change is suspected. In adults the presence of the ‘Hawkins sign’, a subchondral lucency in the dome of the talus, is a good indicator of bone viability. The absence of the Hawkins sign in children may not necessarily be indicative of avascular necrosis. Magnetic resonance imaging (MRI) is the method of choice for the detection and definition of avascular change.
Calcaneal fractures

Different fracture patterns in young children
Adolescents follow adult patterns—consider fixation
Young children:

- Fractures usually extra-articular
- Fractures often involve the anterior process of the calcaneum
- Delay in diagnosis is common
- High index of suspicion required
- Good results with conservative treatment.

Other fractures of the talus are rare. Anatomically, fractures of the talar body should be associated with a worse prognosis but there is little evidence to support this statement. Basic principles of fracture management should be applied as they would in an adult.

Talar fractures

- Fractures usually occur through the neck
- Initial radiographs may be normal
- Mechanism of injury is forced dorsiflexion
- If <5mm, displacement treat conservatively
- Greater displacement requires reduction
- Major risk is avascular necrosis:
  - Related to site and displacement of fracture
  - Related to early weight bearing
  - Absence of Hawkins sign not indicative of avascular necrosis in children.

The os trigonum is an accessory centre of ossification for the posterior process of the talus which first appears in girls aged 8–10 and in boys aged 11–13 years. It usually fuses to the talar body approximately a year after its appearance but if it fails to do so it may be mistaken for a fracture of the posterior talar process.

Transchondral fractures of the talus

Various terms such as osteochondritis dissecans and osteochondral fracture have been used to describe this condition which presents in adolescents as a chronic ankle sprain or activity-related stiffness. The lesions occur either on the posteromedial or anterolateral aspects of the talar dome. Most studies report a predominance of medial lesions in approximately 75% of cases but those on the lateral side are often associated with an injury with a torsional component to it. The posteromedial lesion is often deeper and cup-shaped compared with the thinner, more wafer-shaped anterolateral lesion. The fracture is unlikely to heal if the fragment is displaced from the talar body as fibrous tissue becomes interposed between the two injured surfaces. The cartilage, nourished by the synovial fluid, grows whilst the osseous fragment becomes avascular and dies.

Anderson et al. have modified Berndt and Harty’s staging system for transchondral fractures of the talar dome based on the MRI findings in such injuries (Table 14.11.1 and Figure 14.11.4). Initial radiographs may be normal so if a transchondral injury is suspected further investigation must take place. An isotope bone scan will confirm damage in the region of the talus. Helical CT scans visualize bone damage well and are useful in detecting acute transchondral fractures and MRI highlights areas of soft tissue injury. MRI identifies the stage of the lesion which in turn dictates which treatment is most appropriate. Anatomical variants can be confusing and lead to the appearances of pseudodefects. In the presence of an abnormal radiograph, further investigation is unnecessary. Arthroscopy is useful in differentiating between incomplete and complete separation of the fragment.

Fig. 14.11.4
Diagrammatic representation of Table 1 to show the staging system for transchondral fractures of the dome of the talus.

Treatment aims to achieve stable union of the fracture, and if this appears unlikely, excision of the fragment and healing of the defect with fibrocartilage is allowed. In early cases, symptomatic relief and occasionally healing can be obtained by immobilization in either a weight-bearing or a non-weight-bearing plaster cast. Arthroscopic assessment and management of the lesion has become popular but a child's ankle is small and care must be taken not to inflict further damage with the instruments. Arthrotomy is still preferred by some, especially for the posteromedial lesion, although care must be taken with the transmalleolar approach in the skeletally immature patient in order that physeal damage does not occur. Stage 2a and 3 lesions may be treated by drilling of the fragment whilst in stage 4 lesions the loose fragment is excised, the defect debrided, and the base curetted or drilled. Some advocate direct autogenous bone grafting of the symptomatic medial lesion to replace the necrotic subchondral bone and promote the ingrowth of viable bone to support the talar surface. Degenerative change occurs in approximately 50% of cases.

Other tarsal bones

Significant fractures rarely occur other than in association with major foot injuries. Minor fractures are seen more commonly and may divert attention from the more subtle radiographic features which might indicate a major injury such as a peritalar dislocation.

The accessory navicular is a congenital anomaly in which the tuberosity of the navicular develops from a separate ossification centre. The radiographic appearances can be of a synchondrosis, an isolated ossicle, or an elongated cornuate process. The accessory navicular may be mistaken for a fracture and can be associated with localized pain and flat feet in the adolescent when the cartilaginous synchondrosis is subjected to tensile forces and fails.

The cuboid is susceptible to a crushing abduction mechanism between the fourth and fifth metatarsals, and the anterior calcaneum—the nutcracker fracture. This seldom occurs in isolation, and the coexistence of other midfoot injuries should be sought. Untreated, the shortened lateral column can result in an acquired flatfoot deformity. Non-operative treatment is acceptable in the majority of cases; however, displaced fractures require reduction and bone grafting.

Tarsometatarsal injuries

Such injuries do occur in the paediatric population and although overall they are of lesser severity due to the smaller applied forces, the mechanisms of injury are similar to those in adults. Wiley has described the pathoanatomy associated with these injuries and highlighted the significance of the ligament which runs from the medial cuneiform to the base of the second metatarsal, which is important in maintaining the metatarsal within the mortise formed by the cuneiforms. Anatomical reduction is essential and must be achieved by either closed or open means with suitable fixation as indicated. The apparently undisplaced joint injury should be assessed for stability but in suitable cases conservative management can be used.

A variation of the classic Lisfranc injury may occur in younger children when a plantarflexion force wedges the oblique first cuneiform-first metatarsal epiphysis between the first and second metatarsals. This has been termed the ‘bunk bed’ injury (Figure 14.11.5).
14.11.5. Radiological changes are subtle in the young child and buckling of the cortex of the first metatarsal may be the only sign.

**Fig. 14.11.5**

“Bunk-bed” fracture. Diagram to show the direction of force and the subsequent injury with displacement of the first cuneiform and part of the first metatarsal epiphysis between the first and second metatarsal.

### Forefoot fractures

#### Metatarsal fractures

These injuries are relatively common and conservative treatment is the rule. However, although children have extensive capabilities of remodelling this is not infinite and some fractures will require more aggressive management with the use of finger traps for a manipulative reduction and the use of K-wires for fixation. Open reduction is rarely indicated. Soft tissue swelling or injury may necessitate hospital admission with monitoring of the compartment pressures as appropriate. An apparently solitary fracture of the base of the second metatarsal should raise the possibility of a paediatric Lisfranc injury where the subluxation has reduced spontaneously.

### Non-accidental injury

Fractures of the metatarsals and the phalanges consistent with a mechanism of forced hyperextension are subtle but important injuries in children who have been abused.

#### Fractures of the fifth metatarsal base

Avulsion fractures of the base of the fifth metatarsal occur relatively frequently and this is the classical site where radiological variants are confused with fracture patterns. The diagnosis is confirmed on radiograph where the fracture line is noted to be perpendicular to the long axis of the bone. The attachment of the peroneus brevis tendon is often blamed for the avulsion injury but the tendinous portion of abductor digiti minimi and the lateral cord of the plantar aponeurosis may also be implicated in the pathology. Treatment is a weight-bearing cast for a time appropriate to the child’s age. The fracture must be distinguished from sesamoids, within the tendons of peroneus brevis and longus (see Figure 14.11.1), and from the apophysis which lies parallel to the shaft of the metatarsal and is not apparent before the age of 8 years. The apophysis unites to the metatarsal shaft by the age of 12 in girls and 15 in boys.

Fractures at the junction of the proximal diaphysis with the metaphysis occur in the adolescent. A stress injury often predates the fracture in which case operative reduction and fixation with bone grafting may be required.

### Phalangeal injuries

Fractures and joint dislocations do occur and treatment is based on clinical grounds. Reduction may be required particularly with the proximal phalanx of the great toe. Rotational deformity should be prevented. The ossification centre of the proximal phalanx of the hallux is frequently bipartite and may be mistaken for an intra-articular fracture.

### Stress fractures

With the current trend for an increasingly active lifestyle, stress fractures are becoming more common in the paediatric population. They occur most frequently in the metatarsals. An appreciation of this injury and its frequency is important otherwise the clinical and radiological signs can be worrying and biopsy will be necessary to exclude a neoplastic growth. Localized tenderness without obvious bruising or swelling is observed and a high index of suspicion is necessary. The stress fracture itself is a relatively benign
lesion and the aim is to restore the child to his or her normal activity level. There is rarely any concern regarding growth disturbance. Fractures are most common in the adolescent with the relatively less flexible foot who is beginning to participate in intensive sports training. Treatment varies with the duration and severity of symptoms. A simple restriction of activities may be all that is necessary or a plaster cast may be applied. Operative treatment may be necessary if there is an underlying abnormality.

**Soft tissue involvement**

**Open fractures**

The principles of management for open foot fractures in childhood are the same as those for the adult and for open fractures at any site. Fractures involving the physis should be anatomically reduced. This is easier to achieve at the initial visit to the operating room for wound debridement but should not be performed if the risk of osteomyelitis is high.

**Lawnmower injuries**

These are any injury where there is significant damage to both the soft tissues and the bones associated with a crushing force. It may be difficult to judge the extent of the soft tissue damage at the time of injury and the decision whether to amputate an injured extremity or to save it requires considerable experience. A thorough debridement of dead tissue at the time of injury is essential although a conservative approach to tissue of doubtful viability is justified in children. A plastic surgical opinion should be sought as many of the advances in the management of these devastating injuries have occurred due to advances in plastic surgical techniques; particularly in the choice and timing of soft-tissue reconstruction. At the initial assessment it is important to document the extent of the injuries and the anticipated problems such as physeal or joint damage and loss of tendon function in order that treatment can consider both short-term goals and long-term development and function. Broad-spectrum antibiotic cover is required as wound contamination is inevitable with multiple organisms which are similar to those seen in farmyard accidents. Wounds must be examined every 48–72h and intra-articular and transphyseal injuries reduced and stabilized.

In general terms, shredding injuries and injuries to the posterior and plantar surfaces do less well. Amputation of at least part of the forefoot or toes is common with amputation rates varying from 39–67%. Limb salvage must always be considered and the decision to amputate can often be delayed until the second visit to the operating room, when the viability of previously doubtful tissue can be reassessed. Split-skin grafting is the most common method of achieving soft tissue cover. Even on weight-bearing areas such grafts do surprisingly well. In cases where there are exposed bone, tendon or neurovascular structures a rotational or more commonly a free vascularized flap must be considered. The long-term outcome of free flap reconstruction in 91 cases has shown a lower incidence of trophic ulcers in muscle flaps with a cutaneous component compared with skin-grafted muscle flaps, and overall flap survival of 95%. Immediate tendon reconstruction can be successful and lead to fewer overall operations.

**Soft tissue lacerations**

The Achilles tendon and the tendons of tibialis anterior, tibialis posterior, and peroneus longus are important for foot shape and function. Damage to these tendons often leads to a severe and progressive deformity with foot dysfunction. Such damage should be recognized promptly and treated by appropriate tendon repair and postoperative splinting. Lacerated flexor or extensor tendons to the toe may not be repaired but in such cases the affected toe should be strapped to its neighbour to prevent deformity. Satisfactory function usually returns. Most surgeons feel that tidy lacerations to extensor hallucis longus should also be repaired.

**Compartment syndrome**

Compartment syndrome is not a common problem in children but the diagnosis should be considered in any child who has had a crush injury to the foot with swelling and pain on passive motion. The potential morbidity of chronic pain and loss of protective sensation in the foot following an unrecognized compartment syndrome is a high price to pay for poor clinical judgement. Adults with a compartment syndrome are expected to have a concomitant serious bony injury but in children this is rarely the case. In suspected cases, pressure measurements should be made in the central and interosseous compartments and the readings related to the child’s diastolic blood pressure. Treatment of an established compartment syndrome is prompt decompression of all nine compartments of the foot via either a dorsal or medial approach (Figure 14.11.6).
Non-traumatic causes of foot pain

In addition to the above injuries, non-traumatic causes of foot pain in the active child must always be considered (Box 14.11.3).

Box 14.11.3 Other causes of foot pain

- Infection:
  - Puncture wounds
  - Calcaneal osteomyelitis
  - Tuberculosis

- Tumours
- Plantar fasciitis
- Tarsal coalition
- Calcaneal apophysitis
- Juvenile inflammatory arthritis
- Osteochondroses:
  - Kohler’s—navicular
  - Freiberg’s infraction—metatarsal heads.
