SECTION 1 Fundamentals
  1.1 Foundations of clinical practice Thomas Hughes
  1.2 Classification and outcome measures Hemant Pandit
  1.3 The musculoskeletal system: structure and function Parminder J. Singh and Rohit Kotnis
  1.4 Injury and repair Parminder J. Singh and Rohit Kotnis
  1.5 Haemoglobinopathies Paul L.F. Giangrande
  1.6 Prevention of thrombosis in orthopaedic surgery David Warwick
  1.7 Pain and its control Henry McQuay
  1.8 Biomechanics Amy B. Zavatsky
  1.9 Gait analysis Christopher Bulstrode
  1.10 Imaging Joong Mo Ahn, Yusuf Menda, and Georges Y. El-Khoury
  1.11 Complex regional pain syndrome Roger M. Atkins
  1.12 Neuromuscular disorders Tim Theologis
  1.13 Neuromuscular and skeletal manifestations of neurofibromatosis Jeremy Fairbank

SECTION 2 Bone and Soft Tissue Tumours
  2.1 Choice of surgery for tumour: Staging and surgical margins Panagiotis D. Gikas and Timothy W.R. Briggs
  2.2 Amputations, endoprosthetic joint replacement, massive bone replacement, other alternatives William J.S. Aston, Gordon Blunn, and Timothy W.R. Briggs
  2.3 Benign tumours of soft tissues Kesavan Sri-Ram, Anthony McGrath, Eric Yeung, Ben Spiegelberg, Nick Kalson, Barry Rose, Rob Pollock, and John Skinner
  2.4 Malignant tumours of soft tissues Rej S. Bhumbra, Panagiotis D. Gikas, Sammy Hanna, Jakub Jagiello, and Stephen R. Cannon
  2.5 Benign bone tumours Anthony McGrath, Kesavan Sri-Ram, Eric Yeung, Ben Spiegelberg, Nick Kalson, Barry Rose, Rob Pollock, and John Skinner
  2.6 Malignant bone tumours Rej S. Bhumbra, Panagiotis D. Gikas, Sammy Hanna, Jakub Jagiello, and Stephen R. Cannon
  2.7 Metastatic bone disease Panagiotis D. Gikas and Timothy W.R. Briggs

SECTION 3 The Spine
  3.1 Cervical spine disorders Howard An
  3.2 Degenerative disease of the thoracic spine Jayme R. Hiratzka, Robert A. Hart, and Henry H. Bohlman
  3.3 Clinical presentations of the lumbar spine Jeremy Fairbank and Elaine Buchanan
  3.4 Non-operative management of non-specific low back pain (types 1 and 2) Jeremy Fairbank and Elaine Buchanan
  3.5 Cauda equina syndrome Jeremy Fairbank
  3.6 Surgical management of chronic low back pain Jeremy Fairbank
  3.7 Management of nerve root pain (syn: sciatica, radiculopathy) Jeremy Fairbank
  3.8 Management of neurogenic claudication and spinal stenosis Jeremy Fairbank
  3.9 Clinical presentation of spinal deformities Jeremy Fairbank
  3.10 Idiopathic scoliosis Jeremy Fairbank
  3.11 Congenital scoliosis and kyphosis Jeremy Fairbank
  3.12 Neuroumscular scoliosis Jeremy Fairbank
  3.13 Syndromal scoliosis Evan M. Davies
  3.14 Brace treatment in idiopathic scoliosis: the case for treatment Ian Harding
  3.15 Iatrogenic spinal deformity Paul Rhyt Davies and John K. Webb
  3.16 Kyphosis Michael Grevitt and John K. Webb
  3.17 Spondylolisthesis and spondyloysis Dietrich Schlenzka
  3.18 The infected spine Jeremy Fairbank
  3.19 Cross-sectional imaging in spinal disorders S. Gaba, Philip McNee, and Eugene McNally

SECTION 4 The Shoulder
  4.1 The clinical evaluation of the shoulder Tim D. Bunker
  4.2 Pathology of cuff tears Peter Reilly
  4.3 Treatment of rotator cuff disease Lennard Funk and Amol Tambe
  4.4 Biceps Philip M. Ahrens
  4.5 Frozen shoulder Tim D. Bunker
  4.6 Calcifying tendinitis Don Wallace and Andrew Carr

### Section 9 The Foot

9.1 Ankle and hindfoot arthritis
Paul H. Cooke and Andy Goldberg

9.2 Disorders of the forefoot
Andrew H.N. Robinson and Maneesh Bhatia

9.3 Diabetic foot
Andy Goldberg and Paul H. Cooke

9.4 Orthoses of the foot and leg
Jo Mitchell and Paul H. Cooke

9.5 Tendon and ligament disorders of the foot and ankle
Matthew C. Solan and Mark S. Davies

### Section 10 Medical Disorders of the Skeleton

10.1 Metabolic disease of skeleton and inherited disorders
Paul Wordsworth

10.2 Rheumatoid arthritis
Sandeep Bawa and Paul Wordsworth

10.3 Crystal arthropathies
Sandeep Bawa and Paul Wordsworth

10.4 Spondyloarthropathies
Moshiri Atukorala, Sandeep Bawa, and Paul Wordsworth

10.5 Inflammatory connective tissue disease
Catherine Swales

10.6 Osteoporosis
Malgorzata Magliano

10.7 Osteoarthritis
Kassim Javaid and Paul Wordsworth

### Section 11 Infection, Amputation, and Prostheses

11.1 Chronic long bone osteomyelitis
Peter Calder

11.2 Miscellaneous orthopaedic infections
Sally Tennant and Peter Calder

11.3 Amputations and prostheses
Rajiv S. Hanspal and Peter Calder

11.4 Acute osteomyelitis
Peter Calder

11.5 Septic arthritis
Peter Calder

### Section 12 Trauma

12.1 Fracture classification
Thomas A. DeCoster

12.2 Complications of fractures
James Wilson-MacDonald and Andrew James

12.3 Orthopaedic approach to the multiply injured patient
Andrew C. Gray

12.4 Head, thoracic, and abdominal injury in the orthopaedic patient
K. Boffard

12.5 Massive transfusion
K. Boffard

12.6 Blast and ballistic injury
J. Clasper

12.7 Management of open fractures
John McMaster

12.8 Soft tissue coverage
Christopher M. Caddy and Andrew N. Morriss

12.9 Combined vascular and orthopaedic injuries
E. Chaloner

12.10 Limb salvage versus amputation
Gregory M. Georgiadis

12.11 Functional bracing
Augusto Sarmiento and Loren L. Latta

12.12 Principles of plate and screw osteosynthesis
Glenn Clewer and John McMaster

12.13 Principles of intramedullary nailing
David Noyes and John McMaster

12.14 Principles of monolateral external fixation
F. Lavini, C. Dall’Oca, and L. Renzi Brivio

12.15 Principles of circular external fixation in trauma
Martin A. McNally and Maurizio A. Catagni

12.16 Absorbable implants for fracture fixation
O. M. Böstman

12.17 Stress fractures
M. Henry

12.18 Pathological fractures
D.E. Porter

12.19 Management of segmental bone defects
Stuart J.E. Matthews

12.20 Injuries to muscle–tendon units
S.D. Deo

12.21 Dislocations and joint injuries in the hand
Peter Burge

12.22 Flexor tendon injuries
Robert Savage

12.23 Extensor tendon injuries
David M. Evans

12.24 Soft tissue hand injuries
Dominic Furniss and Anthony J. Heywood

12.25 Nerve injuries
Grey Giddins

12.26 Brachial plexus injuries
Grey Giddins

12.27 Replantation
D. Grinsell, D.R. Theile, and W.A. Morrison

12.28 Metacarpal and phalangeal fractures
T.R.C. Davis and J.A. Oni

12.29 Scaphoid fractures
Simon Tan and Mike Craigen

12.30 Instabilities of the carpus
David Lawrie, Chris Little, and Ian McNab

12.31 Injuries to the distal radioulnar joint
David Lawrie, Chris Little, and Ian McNab

12.32 Distal radius fracture
Alistair Graham

12.33 Forearm fractures
Ben Ollivere and Matthew Porteous

12.34 Elbow fractures and dislocations
John R. Williams and Brian J. Holdsworth

12.35 Humeral shaft fractures
Chris Little

12.36 Fractures and dislocations of the shoulder girdle
Gregoris Kambouroglou

12.37 Imaging in spinal trauma
P. McNee, S. Gaba, and E. McNally

12.38 Emergency management of the traumatized cervical spine
Jens R. Chapman and Richard J. Bransford

12.39 Upper cervical injuries
Paul A. Anderson
I would like to give special thanks to James Wilson-MacDonald, Deborah Eastwood, John McMaster, Jeremy Fairbank, and Parminder J Singh who worked unceasingly with me to bring this book to fruition. Their work was ‘Above and Beyond the Call of Duty’ and made the good parts of this book very good. I must take responsibility for the rest!

Thanks also to the team at Oxford University Press - Mandy Hill, Helen Liepman, Anna Winstanley, and Marianne Cronin, as well as to Gayathri Bellan for managing the project with courtesy and patience.

CJKB

Foundations of clinical practice

Summary points

- Conscious and unconscious competency
- Clinical research and the placebo effect
- Trial design and the randomized controlled trial
- Critical review of the literature
- Clinical governance and audit
- Capacity and consent
- Principles of teaching and learning.

Introduction

This chapter aims to describe key knowledge that, while not directly involved in clinical work, is essential for expert clinical practice and therefore should be regarded as equivalent to basic sciences. Like the basic sciences, this knowledge underpins our clinical practice and guides us when faced with new situations.

Surgery and medicine rely on research and innovation to drive improvements in clinical practice. As an expert surgeon, you must know how to assess these innovations and be able to judge objectively whether or not you should incorporate any apparent improvements into your clinical practice.

What is the best treatment?

First do no harm

A common public assumption is that all medical treatment is beneficial. This may be a marker of the success of modern medicine, but some of the major advances of the last 50 years have been the acknowledgement that medical treatments cause harm as well as benefit, and the development of ways of quantifying the relative risks and benefits of treatments. The most recent manifestation of this trend is the current focus on patient safety—preventing harm to patients within the healthcare system.

Another recent trend is an increased focus on the patient as a consumer. There has been a shift towards healthcare provision structured around patient needs rather than simply providing the healthcare that healthcare workers think is best. There are costs and frustrations associated with this approach, but advantages in patient satisfaction and flexibility of healthcare provision. Healthcare evolves to solve patients’ problems rather than the other way round.

For patients to be actively involved in their healthcare, they need to be informed consumers. Therefore part of the healthcare process is to educate the patient about the options available. Patients now have ready access to plentiful information, most of which is not peer reviewed, and may be covert advertising. This can result in health ‘wants’ being confused with health ‘needs’. Surgical practice needs to evolve to meet these challenges.

The problem with structuring healthcare around patient demands is that healthcare, unlike buying a meal or holiday, does not usually result in an immediate objectively good or bad outcome. If you asked a doctor what treatment they would want from a surgeon, they would want a safe, experienced surgeon and anaesthetist operating in a good environment with motivated conscientious nursing staff. They would be in a fairly good position to judge this.

Patients have a limited number of surrogate measures on which to base their assessment of quality (current measures proposed to define ‘good’ healthcare in the United Kingdom (UK) include time on waiting list, hospital cleanliness, and ‘nurse empathy’. Tables of operative results enable comparison of the quantity and timeliness of operations, but not necessarily the outcomes for the patients). Government ratings may have little or no relationship to the outcomes that actually matter most to the patient or society, e.g. freedom from pain, employment, and good quality of life.

In trying to measure healthcare quality, there is a technical aspect (expertise, outcome), an interpersonal aspect (attitude, behaviour), and a service aspect (accessibility, environment). As patients usually cannot objectively judge the technical aspects, they tend to base their decisions on the interpersonal and service aspects, which are more amenable to measurement.

The technical aspects such as safety and competence tend to be taken for granted, which is unfortunate because the technical aspects are usually the major determinant of long-term outcome. Moreover, the really important outcomes are difficult to measure. For example, there is a long time lag between a poorly sited or poorly designed joint replacement and its ultimate failure. For these reasons, poor quality work can appear cost-effective if not evaluated carefully, and in a way that considers all costs.

In summary, healthcare quality measurement is vitally important, but often heavily flawed because of the temptation to use surrogate measures that are politically expedient or easy to measure, rather than concentrating on the outcomes that actually matter.
What does the patient want to know?

Performing an intervention such as an operation will have different results in different people. Humans are not linear predictable systems, which is probably why they have survived so long.

There are many different factors that contribute to the operative outcome: type of operation, preoperative function, risks from the operation, surgical skill, and risks from the anaesthetic. The contribution of these factors can be estimated from analysis of different populations of patients who all undergo the treatment, but this would ignore factors unique to that patient and that surgeon.

Imagine that you are the patient. You don’t really care about all this. You want to know: ‘Will this intervention, performed by this person, benefit or harm me, and by how much?’ (Box 1.1.1).

Box 1.1.1 Patients’ questions you should be able to answer

- What is the best treatment?
  How can you be sure?
- What does this test tell you?
  How can you be sure?
- How can I be sure you make good clinical decisions?
- Why should I undergo this procedure?

Competence is being able to answer these questions, but expertise is demonstrated by the ability to defend your decision—to say why. This chapter aims to cover the foundation skills necessary for this expertise.

To answer this, and be legitimately reassuring, it is necessary to demonstrate that:

- You and your anaesthetic and nursing team are safe and competent to carry out the operation and its aftercare
- The operation is appropriate for that patient and condition
- The likely risks are outweighed by the likely benefits.

Only when these conditions are fulfilled is the risk of harm to the patient minimized. Harm may occur in different forms: medical, financial, and social.

Medical harm

Medical harm is the harm directly resulting from the treatment, and may be physical or psychological.

The notion of medical harm has been crystallized in the minds of the UK public by cases such as Harold Shipman and paediatric cardiac surgery in Bristol. Harold Shipman was a general practitioner who murdered approximately 200 patients by giving lethal doses of opiates. Some cardiac surgeons in Bristol in the 1990s continued to perform complex paediatric operations despite overwhelming evidence of very poor results, heroically documented by an anaesthetist, Steven Bolsin, at great personal and professional cost.

Although these differ in being acts of active harm (Shipman) and passive harm (Bristol) in that Shipman set out to harm patients, but in Bristol the harm was not intended, both sets of events have been seen by the establishment as indicators of inadequate self-regulation by the medical profession. Steps such as revalidation and competence-based assessments have been introduced.

Revalidation is designed to identify poorly performing doctors and ensure that they are retrained. Revalidation is very expensive to perform if such assessments are to be both valid and reliable. Revalidation is likely to evolve to a system of re-taking one’s exit exam every 5 years, as in the United States of America (USA).

Continuing Medical Education is an important part of ensuring continuing competence, but the providers of such education often have ulterior motives, and the end product (any benefit to patients) is not measured, just the process.

In addition to compulsory revalidation, league tables of mortality offer a superficial view of competence, and are being implemented for some surgical procedures in the UK, and have been available in the USA for some time.

As doctors, we need to recognize both the ageing of our knowledge, and the changing nature of our jobs. Specialties such as cardiothoracic and vascular surgery have changed completely in 10 years, and technology such as robotics will have an increasing role in trauma and orthopaedic surgery. It is likely that periodic retraining will be a normal expectation and will be written into job plans in the future.

Social harm

By medicalizing a normal human condition, it is possible to create ‘diseases’ where none previously existed. This is obviously good
news if you have a product that cures the ‘disease’. The widespread usage of antidepressants for a rather hazy definition of ‘depression’ medicalized many thousands of people who may have had no more than transient unhappiness. Direct-to-consumer advertising, allowed in some countries, encourages consumers to self-diagnose and approach doctors for specific branded products. These behaviours encourage expenditure on health ‘wants’ rather than health ‘needs’ which disadvantage the poor and less articulate and result in financial harm (see following section).

Back pain is an enormous social burden. In the UK, 50 million workdays are lost each year and 500,000 people are on long-term incapacity benefits for back pain. The advent of magnetic resonance (MR) scanning has enabled everyone to have a diagnosis, but it is likely that this validation of non-specific ‘abnormalities’ has not benefited patients or society.

Financial harm

There is direct financial harm to the patient and society in every illness through lost earnings and inability to participate in social activities. However, in a single healthcare provider system like the UK National Health Service (NHS), there is also an opportunity cost to every treatment.

For example, an opportunity cost occurs if one spends X pounds on drugs for Alzheimer’s disease patients, then one cannot spend X pounds on hip prostheses. The decision about which treatment is the best option is laden with value judgements. Central questions are:

- Does the treatment work as claimed?
- What benefit does the patient or society gain from the treatment?

Conscious competency—the development and ageing of knowledge (Figure 1.1.1)

One starts as a medical student, unaware of how much one does not know—the unconscious incompetent. An awareness of the breadth and depth of knowledge necessary gradually dawns over the course of medical school, making one conscious of one’s incompetence. Through hard work, study, and practical experience in the early postgraduate years, conscious competence is achieved. As the knowledge becomes internalized and practice becomes automatic, we become the unconscious competent—we can do the job, but we don’t always know why we do what we do.

The danger of unconscious competence is that it is easy for this to slip into unconscious incompetence—a process termed ‘occupational senility’. Continuous Medical Education (CME)/postgraduate education helps us to find areas in which we are incompetent and remedy this. Educational skills such as teaching juniors and colleagues ensure that we remain aware of why we do what we do—nothing tests your understanding of a subject as well as having to explain it to someone else.

What is the overall cost of the treatment, and what is the cost of not doing the treatment?

Performing these calculations necessitates value judgements on quality of life, which inevitably have a subjective element.

Engaging in futile or damaging treatment not only causes direct damage and waste, but also deprives another patient of an effective treatment. This makes the continuing presence of homeopathic hospitals funded by the NHS highly illogical, as anything that cannot prove superiority over placebo is just money diverted away from effective healthcare (Box 1.1.3).

Box 1.1.3 Medical business model
To understand the behaviour of device and pharmaceutical companies, it helps to understand their business model.

Developing and testing a new drug or device to the stage when it can be licensed is a calculated high-stakes gamble, costing more than US $1 billion for a new class of drug. There is a substantial risk that defects in the product may be found that will harm some patients. This can lead to not only the loss of the market for that product, but, if handled badly, major damage to the company that makes the product.

Patent laws for drugs and devices give the manufacturer 20 years’ protection from other direct copying, although similar (‘me-too’) products may be allowed to compete. Unfortunately the time to develop and test medical products is rarely shorter than 10 years for a drug, although less for a device. The good news is that once a device/drug is approved for sale, it is generally cheap to manufacture and distribute.

The positive side of this business model is that it favours innovative companies, which should ultimately help patients. An unintended consequence is that once a company has a product licensed, any sales are effectively free money as the cost of production is very low, and the research and development has already been done—it is a ‘sunk cost’—one that can never be recovered. This creates intense pressure to sell as much of the ‘new’ product as possible, whether or not it is a true advance compared to previous products.

From a company’s point of view, it is vital to recoup its initial outlay in research and development as soon as possible, especially if there is a risk that the product may turn out not to be as good as everyone had previously thought, e.g. COX2 inhibitors, ceramic joint replacements.

The pressure for sales results in an uneasy fusion of marketing and research in the later stages of development and testing. As these trials are industry sponsored, conflicts of interest may arise in the trial design and execution. One cannot be too sceptical when critically appraising such ‘research’. Pharmaceutical companies spend twice as much on marketing as on research and development.

Placebo

The placebo (Latin for ‘I will please’) effect is more than just what one attributes the apparent success of the ‘snake oil’ peddled by the quack. It is part of the psycho-social interaction that is present in any therapeutic interaction. It is heterogeneous, and has an interesting history.

The placebo effect appears governed by several factors, which appear additive:

- The patient: the patient’s expectations of success influence the results, e.g. asthmatic patients experience symptomatic relief when using inert inhalers they believe to be bronchodilators
- The doctor: playing the role of an enthusiastic ‘heroic rescuer’ is associated with the highest placebo response, probably due to raising patient expectations. In alternative medicine, the lack of a scientific brake to this runaway enthusiasm goes some way to explain why ineffective treatments ‘work’
- There is also likely to be a credibility factor; this can be exploited by looking like the ‘consultant’ in a private healthcare advertisement—the usual cliché of being [male], avuncular, greyed, white-coated, with some half-moon spectacles
- The doctor–patient interaction: patients with indeterminate symptoms respond better to positive behaviour and a definite diagnosis rather than uncertainty. If the patient has a significant investment, for example, by paying for the service, this is likely to increase their expectations of success
- The disease: chronic diseases with a fluctuating course, subjective symptoms with no objective pathology, anxiety, and common self-limiting diseases are all associated with a high placebo response
- Treatment and setting: tablets four times a day have a higher placebo effect than those twice a day (although possibly less compliance), and red tablets are more effective than white. Elaborate rituals and complex devices increase your chance of a good placebo effect, although this on its own does not justify an MR scan. Surgery itself has a marked placebo effect, demonstrated by the improvement experienced from a sham operation by Parkinson’s disease sufferers in a stem-cell trial, and the efficacy of sham acupuncture.

It is sometimes argued that it does not matter what method is used, as long as the patient gets better. This sounds plausible, but if one is spending public funds on healthcare, one has a duty to ensure best value. Therefore treatments that cannot prove their effectiveness over a placebo should not be publicly funded.

By understanding and enhancing the placebo value in medicine, one can maximize patient satisfaction and the chances of patient compliance, both of which are likely to benefit your patient.

How do I know if I have done any good?

In the 1960s, prior to gastric acid-suppression drugs, gastric freezing was commonly performed. By freezing the gastric mucosa, acid-producing cells were damaged and acid formation was suppressed allowing the ulcer to heal and the patient was cured.

In an era where acid suppression drugs are cheap and effective, it is difficult to understand the disease burden of peptic ulceration to patients and society in general. It was found that reducing the temperature of the gastric mucosa to 5–10°C markedly reduced acid secretion. The exciting new technique of freezing the gastric mucosa was, in effect, a miracle cure for many patients.
duodenal ulcers 6 weeks after having had a gastric freezing operation. More than 2500 gastric freezing machines were sold, and hundreds of thousands of freezings were carried out. Patient satisfaction was high, and a review of the procedure commented that ‘the method is easy and the clinical results are astoundingly good’.

Although more than 100 articles about gastric freezing were produced in the following years, it was not until 1969 that a placebo-controlled trial of gastric freezing was published. This study, with approximately 75 patients in each arm had sufficient power to detect a 20% difference between the treatments, if one existed. There was no difference between the treatment and control groups.

In short, a lot of time and energy and money had been expended on a placebo treatment. In addition active harm was done to patients—fatalities occurred in patients undergoing the treatment—and the financial harm was immense. Without the insight that properly conducted trials provide, doctors are little more than purveyors of snake-oil (Figure 1.1.2).

Why do a trial?

To prove if one treatment is better than another. What sort of trial you do depends on what you are trying to prove:

- A cohort trial involves following groups of patients for a period of time and seeing what happens to them. For example, seeing how long different sorts of hip replacement last in different patients
- A case–control trial involves finding asymptomatic patients who match your symptomatic ones and seeing how they compare. For example, to understand the pathophysiology of osteoarthritis of the hip, you might find symptomatic patients and compare them with matched patients (age, weight, activity) who are not symptomatic
- A controlled trial is one where the active treatment (the one you are testing) is compared with either an inactive one (a placebo) or another sort of treatment, e.g. the current standard. Comparing one sort of hip replacement with another would be a controlled trial
- A ‘blinded’ trial is one where either the patient or the researcher does not know which treatment that patient is receiving. A ‘double-blinded’ trial occurs when neither the researcher nor the patient knows which treatment the patient is receiving. Blinding reduces the risk of bias and this is an important part of trial design
- A randomized trial is one where the patients are randomly allocated to different treatments (Box 1.1.4). If one is going to do a trial, while the process of randomization is important; even more important is that the process by which patients are allocated is concealed from the researcher, e.g. sealed opaque envelopes.

Box 1.1.4 Austin Bradford-Hill (1897–1991)

Sir Austin Bradford-Hill (Figure 1.1.3) pioneered the use of the randomized controlled trial in the assessment of streptomycin for the treatment of tuberculosis. Originally used in agricultural experiments, the randomized controlled trial is now the benchmark by which all interventional medical research is judged.
Trial design

Trial design is more important than trial analysis: if the design of a trial is flawed, no amount of fancy analysis can remedy this. It is vital that you do some background reading and talk to someone with experience of trial design before you start collecting data. Any trial involving human subjects also needs ethical review before it can start.

A literature search should be performed to see whether anyone has already done the trial, but also to generate ideas about how best to perform the trial.

When thinking about how many patients you will need for your trial, you need to consider incidence and prevalence. Incidence is the number of new cases of a condition, e.g. fractured neck of femur. Prevalence is the number of people with a condition at a particular point in time, e.g. back pain. If your disease is uncommon, recruiting a sufficient number of patients to be able to adequately power the study will be difficult.

Ethics and consent (Box 1.1.5)

Any trial will need ethical approval. All NHS Trusts and universities have a structure of ethics committee(s) for approving and monitoring clinical research. These committees are charged with ensuring that all research is of good quality and safeguards the rights of the patients and the reputation of the institution.

Informed patient consent is, excepting a few defined hyperacute situations, an essential component of any research, and the patient consent forms and accompanying information will be carefully scrutinized by the ethics committee.

Bias and confounding

Bias occurs when you fail to measure what you intend to/should measure. This may happen for a variety of different reasons—an example might be if you did a satisfaction survey of patients you saw in outpatients following hip surgery. You might achieve a very good satisfaction score, but by limiting your sample to those who are able to come to your outpatients, this may not be an accurate reflection of the true picture. Bias is therefore the inclusion of an error that distorts the trial in a non-random way (Box 1.1.6).

Box 1.1.6 Common forms of bias

- **Selection** bias: the patients used may not be representative of the usual patient population group. The sickest patients are often excluded from trials
- **Observer** bias: there may be (unconscious) bias in the assessment by observers—minimized by blinding and concealment
- **Measurement** bias: flawed measurement may favour one group over another
- **Confirmation** bias: the tendency to look for factors that confirm rather than disprove our ideas
- **Publication** bias: trials with negative results are less likely to be published.

Confounding occurs when you fail to measure or spot an extraneous factor that accounts for your findings. Say you had a group of patients in whom you measured premature failure of hip prostheses and doughnut consumption, and found a strong relationship.
Does this mean that doughnuts cause prosthesis failure? Or might it be that there is another variable that you have not measured that would explain this—a confounding factor?

Bias can be minimized by blinding, randomization, and concealment, but it is not always possible to randomize and blind in surgery.

Hawthorne effect

The Hawthorne effect is named after experiments done at the Hawthorne factory in the 1920s when factory workers were assembling relays for telecommunications equipment (Figure 1.1.4). Researchers looking for the optimal conditions for factory work increased the ambient light and found that production rates improved. They then reduced the ambient light and found that production rates improved again. Eventually the researchers deduced that the presence of the researchers was the overriding influence on the workers’ performance. Therefore the Hawthorne effect is that just by measuring something, one changes it. Having a control group ensures that the Hawthorne effect does not affect the results.

Box 1.1.5 Ethical principles

♦ Beneficence: do good
♦ Non-malfeasance: avoid doing harm
♦ Autonomy: respect for patients’ wishes
♦ Justice: fairness.

Fig. 1.1.4

The consumer of knowledge can never know what a dicky thing knowledge is until he has tried to produce it.

F.J. Roethlisberger, investigator at Hawthorne.

Outcome measures

Objective or ‘hard’ outcomes, such as death, are preferred in research as there is little debate about their significance. Subjective or ‘soft’ outcomes, such as a change in a pain score, may not be valid or reliable across different populations of patients. If a validated measure of outcome is available, this makes design easier. If any of the measures used are in any way subjective, e.g. fracture angulation or code, it is best to have more than one independent observer and measure agreement between these observers.

If the ‘hard’ measure is rare or difficult to measure, then surrogate measures may be used. Death due to pulmonary embolism following joint replacement is quite rare, but using deep vein thrombosis (DVT) as a surrogate is fraught with difficulty as DVT is very common, but when limited to below the knee, does not seem to be associated with adverse outcomes.

Where are all the randomized controlled trials in surgery?

The gold standard for pharmaceutical research is the double-blind placebo-controlled randomized controlled trial (RCT). RCTs are also the gold standard in surgery, and provide a definitive answer, e.g. for arthroscopic surgery in osteoarthritis. However, RCTs of any sort are uncommon in surgery. This is partly because in order to ensure the full placebo effect in the control group, one must perform a sham operation, and this is ethically and practically difficult. A pragmatic alternative is to randomize based on expertise—if there are two groups of surgeons available with expertise in variants of a surgical procedure, one can randomize patients between these two groups.
Another technique that is used to deal with the difficulty in conducting large RCTs is to use meta-analysis to combine the results of similar small trials.

**Meta-analysis**

In an ideal world, all medical and surgical practice would be based on evidence from well-conducted, multicentre, double-blinded, randomized placebo-controlled trials. Unfortunately such trials are very expensive to organize, and therefore are only performed to answer the most large-scale health questions, e.g. the CRASH (Corticosteroid Randomisation After Significant Head injury) and CRASH2 trials relating to the role of tranexamic acid in patients with major haemorrhage from trauma.

Meta-analysis is a structured review of all the trials relating to a particular research question. It is used when there are many small trials that relate to a research question, but none of them have the power to resolve the question on their own. The quality of evidence from each trial is weighted in a structured and predetermined way to allow a definitive assessment to be made. Meta-analysis may have the power to quantify benefit or harm that smaller trials may not be able to do, particularly if these effects are uncommon.

Careful judgement is necessary to combine the results of several trials in a way that does not prejudice the final result. The Cochrane Collaboration (Box 1.1.7) is an independent organization that organizes and validates meta-analyses of clinical questions.

---

**Box 1.1.7 Archie Cochrane (1909–1988)**

The Cochrane Collaboration (http://www.cochrane.org) is named after Professor Archibald Cochrane (Figure 1.1.5). Regarded as the father of evidence-based medicine, he firstly trained as a laboratory scientist, and then studied medicine before the Second World War.

Through his work on infectious disease he became interested in epidemiology and wrote an influential report on how to improve the NHS.

The report’s stark logic championed the use of the RCT to ensure the best use of NHS funding. The book had a profound effect on medical thinking and policymaking.

---

**Intravenous colloid**

In the 1990s, intravenous colloid fluids, e.g. Haemaccel, Gelofusine were widely used for resuscitation as they were effective at improving a patient’s blood pressure quickly, and the large protein molecules did not leak out of damaged capillaries as quickly as crystalloid. The downside of this is that once they did leak out, they tended to cause resistant tissue oedema, which is bad if the tissue involved is the brain.

In 1998 a meta-analysis performed by the Cochrane Collaboration suggested that colloids gave no benefit over crystalloid fluids, e.g. saline, and appeared to cause harm (up to 5% increase in mortality) in critically ill patients. This, together with their high cost (20 times that of crystalloid), are why colloids are not now used in resuscitation.

---

**How can I use the medical literature to improve my practice?**

The volume of medical literature is vast—there are more than 40,000 biomedical journals, and this number doubles every 20 years.
The quality does not. How can you filter this soup of raw data? How can you work out whether something is true or not? If true, can you apply this new knowledge to your daily practice?

The Bulstrode criteria for medical literature are short and sharp:

- Do I understand it? What is the author claiming?
- Do I believe it? Are there significant flaws in the design, execution, or analysis?
- Do I care? Is this relevant to my practice?

While the first and last of these depend on subjective judgements, the key skill is the ability to read a paper, spot flaws, and be able to judge whether it should change your clinical practice.

Professor David Sackett, one of the originators of evidence-based medicine, developed a set of criteria that expands on the Bulstrode criteria to help you evaluate whether a trial is valid and applicable to your practice (Box 1.1.8).

**Box 1.1.8 Sackett’s tests**

### Was the assignment of patients really random?

If patients were not assigned to treatment and control groups randomly, and/or the assignment not concealed adequately from those treating and assessing the patient, then it is likely that an unacceptable level of bias will be introduced.

### Were all clinically relevant outcomes reported?

If, in a purely hypothetical situation, a new treatment centre starts up next to your hospital and its surgeon malaligns the hip prostheses, a subjective measure such as patient satisfaction on discharge might be good, but a measure of important long-term function such as return to employment or time to failure/revision might be poor.

### Were the study patients similar to your own?

If the patients entering the study were markedly different from your own patients, it may be that the conclusions of the study might not be relevant to your situation. A shoulder reduction technique that has been validated on Japanese patients with an average body mass index of 20 may be less helpful when you are faced with a 200-kg Hell’s Angel with their first dislocation.

### Were the results clinically important?

If a difference was demonstrated by this treatment, was the difference large enough and important enough to justify changing your practice?

### Is the therapeutic manoeuvre feasible in your practice?

It is necessary to think about whether the therapy being tested is viable in your clinical practice. Even if not, you may be able to plan to include it in a future service expansion.

### Were all patients who entered the study accounted for at its conclusion?

If one was running a trial on behalf of a commercial sponsor, and some patients had inconvenient results, some people might be tempted to label these patients as ‘lost to follow-up’ and discount them from the analysis. Trials published now should include a CONSORT diagram: this is essentially a flowchart that demonstrates what happened to all the patients entered into the trial ([http://www.consort-statement.org](http://www.consort-statement.org)). Reputable trials are prospectively registered with published protocols ([http://www.controlled-trials.com](http://www.controlled-trials.com)).

**Evidence-based medicine**

The conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.

The term ‘evidence-based medicine’ was coined by a group of physicians at McMaster University, Ontario, in the 1980s. The aim was to encapsulate the information search and analysis techniques that had been learned from epidemiology in a form that could be used at the bedside. Although this may seem like second nature now, this was in an era before the Internet, PubMed, Google Scholar, and online journals.

One of the problems in traditional medical practice is that doctors tend to carry on doing the things they were taught in medical school. One of the arguments against old-style medical school curricula was that it did not teach the skills for life-long learning.
The integration of the science behind ‘evidence-based’ practice into the medical school curriculum has ensured that future generations of doctors will be able to identify and challenge outdated or dangerous practice from an objective viewpoint.

Levels of evidence

With the many claims and counter claims of patients, healthcare providers, researchers, pharmaceutical and device manufacturers, one needs a league table to be able to work out which evidence trumps others (Table 1.1.1).

<table>

How can I ensure that this evidence is incorporated in practice?

It is all very well having found and assessed the best evidence, but you have been wasting your time if you cannot put it into practice. Approaching people and telling them that their practice is out of date and/or dangerous does not always result in the desired outcome (see Bristol, discussed under Medical Harm earlier).

Unless there is a pressing urgency, e.g. ongoing risk of significant harm to patients, it is necessary to prove that there is a problem with the current system. The way to do this is through audit. Audit is different from research in that audit is ensuring optimal usage of current knowledge, whereas research is about creating new knowledge.

An audit is performed to measure the organization’s performance against agreed standard measures of performance. These might be international or national guidelines (e.g. National Institute for Health and Clinical Excellence, NICE), ‘best practice’, or College standards.

Guidelines are advisory summaries of evidence that are used to guide treatment. They are not supposed to be rigidly interpreted, but if one is going outside their advice, one should have good reasons. Protocols are designed to be rigid: they are standardized routines that can be used to streamline and minimize defects in a process. Both guidelines and protocols have inherent dangers in that they tend to stop people thinking about what they are doing, and may stifle innovation.

Any guideline or protocol must be both exhaustive and exclusive. It must cover all eventualities that will occur, and must reliably exclude other conditions that may look similar. Many protocols, elegantly simple in their first draft, can become so complex as to be unworkable when revised after testing. This is a measure of the inherent complexity within healthcare, which is why we need doctors who have the broad range of knowledge and skills to manage these problems, rather than just technicians.

Make everything as simple as possible, but no simpler.

Albert Einstein.

Audit

Audit is the process by which we ensure that we are meeting the standards that we set ourselves. Audit differs from research in that research is looking for new knowledge. Audit is about ensuring that present knowledge is being used in the most productive fashion. Audit may be used to generate and refine research questions, but is usually used in the context of a quality improvement framework.

Audit can be prospective, but is usually retrospective—at least in the first instance. For example, to audit time to theatre for open fractures, an easy way would be to collect all patients with a discharge diagnosis of open fracture. However, this would miss patients who had died or been transferred. A better way would be to prospectively collect the data on patients who come in through
the Emergency Department with open fractures.

Types of audit:

- Basic clinical audit: throughput, morbidity, mortality, outcome, adverse events
- Patient audit: satisfaction survey
- Notes review
- Benchmarking: comparison between units e.g. TARN (Trauma Audit Research Network—http://www.tarn.ac.uk)

Audit is an important part of Clinical Governance, being the way that clinicians measure their own performance against their peers, and also a structured way of demonstrating necessary service development. Audit data can be compared against agreed standards/national guidelines e.g. NICE/Scottish Intercollegiate Guidelines Network (SIGN)/‘best practice’ from the literature or College.

![Click to view larger](Fig. 1.1.6)

The audit loop.

The most difficult part of the audit loop is usually making the change, and this is why audit usually takes place within the framework of Clinical Governance. This provides the oversight and a mechanism for pushing through the process changes necessary. If the audit requires a questionnaire, time spent researching the format and construction of questionnaires will substantially increase the quality of the information garnered.

Clinical Governance

This rather nebulous term is derived from the notion of Corporate Governance, used in business. Corporate Governance is the process of ensuring that the people who run the company (senior management) act in accordance with the interests of the people that own the company (the shareholders, represented by the Board).

Clinical Governance on the other hand means the process of showing that the work you do is as close to best practice as is feasible, and therefore is a quality assurance process. It was defined as:

A framework through which NHS organisations are accountable for continuously improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish.

From a clinician’s viewpoint, Clinical Governance is important, as apart from clinical adverse incidents it is the only forum in which to demonstrate and resolve problems with clinical service delivery. Clinical Governance incorporates what were Morbidity and Mortality meetings, but should be proactive, identifying problems before they result in significant patient harm, incorporating best practice and a framework for service development/quality assurance.

Diagnosis and investigation

Your decision as to whether to offer a surgical solution to a patient’s problem is based on clinical diagnosis and investigations. An expert should have insight into their own process of assessment, to be able to teach others but also to understand how and why things go wrong.

Clinical diagnosis
Much time, ink, and paper has been expended in pursuit of understanding the process of diagnosis. The short answer is ‘we don’t know’. However, some basic principles seem to be that:

- It takes about 10,000 hours to become an expert at something (chess, golf, orthopaedic surgery)
- Experts use pattern recognition to make diagnoses
- Teaching pattern recognition to non-experts will result in superficial expertise, but without the resilience and depth of knowledge to be able to deal with new situations safely
- Novices either work forwards from the history and examination, or backwards from diagnoses, or both. It may be that the ability to think through problems both forward and backwards is a precursor to expertise
- Problem solving is largely content-specific, i.e., being good at one clinical area does not necessarily imply that someone is good at another
- Clinical vignettes—examples of patients are integrated with the basic scientific knowledge and assembled by novices into mental models of diseases. This ‘case-based learning’ is not a substitute for hands-on learning, but may accelerate the rate of acquisition of mental models.

Clinical reasoning

There is no such thing as clinical reasoning; there is no one best way through a problem. The more one studies the clinical expert, the more one marvels at the complex and multidimensional components of knowledge and skill that she or he brings to bear on the problem, and the amazing adaptability she must possess to achieve the goal of effective care.

Norman (2005).

Why does clinical reasoning go wrong?

Research into clinical reasoning helps us understand some of the processes that underlie clinical decision-making.

- **Framing bias**: this is the context in which you see a patient. If you saw a patient with a hot swollen ankle in the Emergency Department, you might think of a fracture or septic arthritis, but in an outpatient clinic, a rheumatological condition would probably be your first thought.

- **Availability bias**: is all the information necessary to make the decision available?

- **Representativeness bias**: is the information used to make the decision representative of the true situation? We tend to over-weight information from sources we believe reliable and our cultural values may also affect the way we use information to make judgments.

- **Anchor bias**: is the starting point for one’s assessment rational. If one has seen two osteosarcomas in 1 week, this may alter your perception of the likelihood of further such cases, making you more likely to spot one, and may make overdiagnosis likely.

- **Overconfidence**: this can be a response to the lack of certainty in a situation. If the risk inherent in a procedure is ignored because the person doing the procedure regards them as insignificant, this will flaw the consent process and make it invalid.

The courts have made it abundantly clear that risk is what the patient perceives, not what the clinician thinks the patient perceives or should perceive.

If a trainee has persistent problems with poor clinical judgement, then this is usually handled through their training programme. If a colleague shows poor clinical judgement, this should be taken up through the Director/Divisional Director/Medical Director. If these avenues do not resolve the problem, in the UK there is the National Clinical Assessment Service, part of the National Patient Safety Agency (http://www.npsa.nhs.uk).

How do you use investigations?

As investigations have become more complex and are used earlier in the disease process, their flaws have become more apparent and caution is needed in interpreting the results. There are risks and benefits with all investigations but as the treating doctor, there is a duty of care to use them appropriately. Some tests may give misleading results if used in unsuitable groups of patients.

A patient with longstanding mechanical back pain has an MRI scan of their back. An abnormality is noted but is perceived by the radiologist to be the result of normal wear and tear, but is mentioned in the report. The patient and their family may put pressure on
the doctors because ‘something must be done’. An operation may be performed that is both unsuccessful and/or has complications in the surgery, anaesthesia, or recovery period. Significant medical and financial harm has occurred to both the patient and society.

In this situation, the scan could be said to be a false positive—the scan implies that there is a significant abnormality that is responsible for the patient’s pain, whereas in fact this is not the case. It could reasonably be argued that it was not the scan that was a false positive, but the diagnostic process as a whole. The MR scan may be very accurate at finding abnormalities. However, what is required is a scan that can:

- Find abnormalities, but also
- Predict which abnormalities are responsible for the pain, and further
- Predict which of these abnormalities can be surgically remedied.

This is why we need clinicians to interpret these scans in the light of clinical judgement. The ability to weigh all this grey information factors accurately to produce an appropriate treatment plan is one of the hallmarks of an expert clinician.

Both society and individuals seem far more tolerant of false positives than false negatives. It is seen as perfectly acceptable to provide too much treatment rather than not enough, whereas in reality both may result in similar rates of harm in the widest sense.

A good, if politically charged, example of this would be screening for breast cancer:

For every 2000 women invited for screening throughout 10 years, one will have her life prolonged. In addition, 10 healthy women, who would not have been diagnosed if there had not been screening, will be diagnosed as breast cancer patients and will be treated unnecessarily.

Such information is difficult to communicate to the public. By way of contrast, one does not have to open too many newspapers to find sensational reports of a catastrophic ‘missed diagnosis’: these are the opposite: the false negative.

These two situations, the false positive and false negative, can be put into a table together with the true positive and true negative (Table 1.1.2).

<table>
<thead>
<tr>
<th>Test</th>
<th>Reality</th>
<th>True</th>
<th>False</th>
</tr>
</thead>
<tbody>
<tr>
<td>+</td>
<td>+</td>
<td>True +</td>
<td>False +</td>
</tr>
<tr>
<td>-</td>
<td>False -</td>
<td>True -</td>
<td></td>
</tr>
</tbody>
</table>

Apart from the cost, anxiety, and unnecessary investigation that a false positive test entails, there is another form of damage that of which an orthopaedic practitioner should be particularly aware. The radiation dose used in diagnostic testing, particularly in computed tomography (CT), is very large (Table 1.1.3).

<table>
<thead>
<tr>
<th>Diagnostic procedure</th>
<th>Dose (mSv)</th>
<th>CXRs</th>
<th>Background radiation</th>
</tr>
</thead>
<tbody>

<td>40</td>
<td>1000</td>
<td>6.5 years</td>
</tr>
</tbody>
</table>

CT, computed tomography; CXR, chest x-ray; PA, posteroanterior; XR, x-ray.

The use of the ‘scanogram’ (CT head/neck/chest/abdomen/pelvis) in blunt trauma is associated with significant risks of lethal malignancy—approximately 1:500 for children and 1:3000 in adults. Patients have a right to understand the risks and benefits of investigations that are being performed, and the clinician has a duty to ensure they have access to information to make those choices.
**Consent**

Consent is the legal framework used to cover the agreement between a patient and a doctor to undertake a procedure. There are local rules for how consent is obtained and variation between different countries’ legal frameworks; therefore general principles will be discussed.

**Capacity**

For consent to be informed a patient must have capacity to give this consent. The rules governing the assessment of mental capacity have been clarified in English law. The key components of this are:

**Assumption of capacity**

A patient must be assumed to have capacity, irrespective of age/disability/behaviour/beliefs/illness (including mental illness) or the fact that you may disagree with their decision. Each decision as to whether a patient has capacity must be a new assessment, and it is possible that a patient can have capacity in one situation but not another. All efforts must be made to give the patient the maximum chance at establishing capacity.

**Tests for capacity**

The Mental Capacity Act (2005) uses four tests to establish capacity. The patient must be able to:

- **Understand** the information necessary for them to be able to take a rational decision about consent
- **Retain** the information long enough for them to be able to
- **Weigh** the information and be able to
- **Communicate** a decision about the consent to others.

If the doctor’s opinion is that the patient lacks capacity to consent, and it is not an emergency, then medicolegal advice should be sought, through the hospital’s usual channels.

**Emergency situations**

In an emergency, one may do what is necessary to preserve life and limb, but no more. Verbal consent should be sought, but is not essential.

Advance directives may still over-ride life-saving treatments, but only if they specifically include life-threatening situations.

**Advance directives**

Advance directives are now legally binding in parts of the UK. In an emergency, an advance directive may be over-ridden if the patient’s condition is life threatening, unless the directive specifically refers to life-threatening condition being included, e.g. blood transfusion by Jehovah’s Witnesses.

If there is doubt about a local situation, medicolegal advice should be sought.

**Obtaining consent**

Informed consent does not mean: ‘sign here and I will do the operation’. Consent is a two-way process and may need to include negotiation about what will and will not be performed, and a frank discussion of the likely outcomes of these actions. Consent should include an understanding of what will occur if the operation does not take place.

Part of the process of negotiation is to manage the patient’s expectations. If a patient has unrealistic expectations of surgery, this is the time to address this. Failure to understand the risks and likely outcomes is far more likely to lead to dissatisfaction and adverse outcomes for all concerned.

**What risks need to be disclosed?**

The notion of adequate risk disclosure has changed in the last few years from that of what a doctor deems necessary to what the patient deems necessary. The old legal definition of ‘acceptable medical practice’ (the Bolam test) being defined as acting ‘in accordance with practice accepted by a responsible body of medical opinion’ has been superseded by a patient-focused test—what a reasonable patient would want to know (Box 1.1.9).

**Box 1.1.9 Risk is defined by the patient, not the doctor**

**Chester v Afshar [2002]**

A UK neurosurgeon consented a patient for a multilevel discectomy. Prior to this the patient had been clear that she had wanted to avoid surgery. The patient sustained cauda equina damage during surgery. The court found that the doctor had been negligent by not specifically warning the patient of the 1–2% risk of serious neurological damage, as this would have dissuaded the patient from surgery. The Law Lords commented:
A surgeon owes a general duty to a patient to warn him or her in general terms of possible serious risks involved in the procedure. The only qualification is that there may be wholly exceptional cases where objectively in the best interests of the patient the surgeon may be excused from giving a warning. In modern law medical paternalism no longer rules and a patient has a prima facie right to be informed by a surgeon of a small, but well-established, risk of serious injury as a result of surgery.

**Rogers v Witaker [1992]**

An Australian ophthalmologist consented a patient for surgery. The patient specifically asked about the risk of damage to the ‘good’ eye, and was not told of this risk (approximately 1:14,000). Sympathetic ophthalmia occurred, making the patient blind. The doctor was found to be negligent.

Risks should be disclosed if the risk is more common than 1:1000, or is very serious—death or serious disability. The advice about risks must be recorded on the consent form. Risk should be numerically quantified and documented whenever possible. If a patient enquires about a specific risk they must be advised of the likelihood of this occurring.

Guidance on consent was published by the General Medical Council in 2008, which takes account of these changes and is freely available through their website (http://www.gmc-uk.org).

**Communicating risk to patients**

There are many examples of the public failing to understand medical risk or misinterpreting information, sometimes due to sensational or misreporting of the media, e.g. risks from MMR immunization.

Expression of risk in percentages is a good start, but may not be readily interpreted by patients with linguistic or educational barriers to understanding. Other approaches to help patients understand risk include the use of:

- **Crowd diagrams**: these are a visual representation of a population of patients with a condition and the number of positive/negative outcomes can be demonstrated by shading an appropriate number of these (Figure 1.1.8)
- **Number needed to treat (NNT)**: as illustrated in the breast cancer screening example given earlier. This is an expression of the number of patients that need to be treated (or screened) to give one unit of benefit/harm, e.g. NNT of primary repair for traumatic shoulder dislocation to prevent recurrent dislocation over 10 years is approximately 2. This means that two people have the operation to stop one person from having recurrent dislocations
- **'Bone age' or 'joint age'**: this describes the patient’s condition by using an age-related comparison, e.g. ‘You have the joints/bone density of an 80-year-old’. Although NNT appeals more to doctors rationalizing decision-making, it seems that presenting information in an age-related way personalizes the risk in a way patients can more easily understand.

![Crowd diagram](http://www.gmc-uk.org)

**Teaching and learning**

As an expert clinician, you have a role and a duty to educate. You did not become an expert without the educational input of a large number of teachers. From Figure 1.1.9, as a conscious competent at the end of postgraduate training, you will be at the peak of your educational ability as a ‘conscious competent’.
The danger is the ease of slipping into being an unconscious incompetent—you can do the job, but don’t know why you are doing what you are doing. Regular teaching helps ensure that knowledge and skills are kept up to date. We can all remember inspirational teachers who appeared to effortlessly communicate complex ideas in a fun way. Good teaching does not just happen—it is the result of careful preparation of content, structure, and presentation, and the following section aims to help with this.

The model of learning developed by Kolb is helpful in considering medical teaching. Trainees are generally not short of concrete, i.e. real-life, experiences, but the trick is to teach in such a way as to build on these experiences and incorporate the theory and facts from textbooks into deeper knowledge.

When planning teaching, there should have some overall aim stated—what should the student be able to do/understand at the end? This aim can be broken down into component goals—specific chunks of learning that build together to achieve the aim. Telling students these aims and goals at the beginning of teaching helps them understand how the information is going to fit together into something that will be useful. This increases the chance that teaching becomes learning.

**Practical skills**

The most common teaching an orthopaedic surgeon will do is teaching practical skills, and for this it is helpful to have a minimal structure that helps organize how you transmit the information in a way that is likely to be understood and retained.

- Explain
- Demonstrate
- Imitate
- Practice.

By explaining what you are going to do, and breaking it into stages, you allow the learner to look for the different stages when you put them together as a demonstration. The learner then imitates what you have demonstrated, and then practises this to a level of competence.

**Feedback**

When you are teaching practical skills it is important to be able to help the person you are teaching to improve. If you think back through your training, you will be able to think of times when this has not been done particularly well. A good acronym for this is PQRS:

- **Praise**: insist that the student identifies at least one thing they have done well
- **Question**: ask the student what they would do differently next time
- **Reflect**: ask the student and/or group to explore other ways of improving performance
- **Summarize**: the student should be able to identify one thing they have learned.

**Small-group learning**

While lectures are superficially efficient at teaching, the amount of learning is highly variable, and difficult for the lecturer to gauge. Dividing large groups into small groups for teaching has many advantages:

- Uncertainty and lack of understanding are more likely to be voiced in a small group, and will be either corrected or voiced by the group
- Lazy people are forced to contribute. Quiet people are more likely to contribute (less of a problem with orthopaedic trainees)
- It is possible for the teacher to evaluate how much the student has understood
- It is possible to integrate other skills such as researching evidence and presentation skills.

Small-group teaching is initially quite challenging for many teachers as there is an implicit loss of control of the whole process, and there is a danger the whole thing goes wrong (very rare, providing the task is well structured).

Specific small-group techniques that may be useful are:

- **Problem-based learning**: give small groups of students a clinical problem to solve, and send them away to research it and
produce a presentation based on their research for all the groups

- **Buzz groups**: when you are giving a lecture, create a task or activity that people do, initially on their own, and then discuss with their neighbour(s). Pick a few volunteers to find out the results and incorporate these back into your presentation. This acts as a break, wakes people up, allows you to test that they have understood what you are talking about, and allows you to incorporate the students’ ideas into your teaching.

**Bedside teaching**

Bedside teaching is a particularly difficult skill to do well, yet is the one that has the most chance of inspiring students. A common complaint from students is that they rarely have the opportunity to examine patients with a senior doctor to guide them and give feedback.

Bedside teaching gives an opportunity for the expert to articulate their thought processes so that students may learn how an expert weighs different factors to make decisions. It provides an excellent opportunity to involve the patient both in decisions regarding their management and in the education process, and the evidence is that patients appreciate and enjoy this.

**Crimes against PowerPoint**

The ubiquity of electronic presentation using data projectors has spawned a number of habits that can detract from learning. There are a number of things that you can do to lessen the pain for the audience:

- The productive attention span is about 20 minutes. After this time do something different and interactive like using a buzz group activity
- Format your presentation in PowerPoint 97 and bring on a USB drive and CD, but also email it to yourself as a backup. Beware video in a presentation, as there are many different subformats which are usually incompatible. If you are planning to use video, it is safest to always take your own laptop
- The most readable format of projection text is white or yellow text on a dark background (blue or green). Red text may look good on a screen, but projects poorly. This is particularly important for people with poor vision/colour-blindness. Pure white backgrounds are tiring for the audience and should be avoided
- Use the 6 × 6 rule: do not put more than six lines of six words on each slide. This will prevent you just reading each slide, which is very annoying for the audience
- End with a ‘take home message’ summarizing your talk in three points in nine seconds and (approximately) 27 words. This is the ‘sound bite’ packaging of key information that you want people to remember from your presentation.

**Assessment**

Assessment is the term given to establishing whether the students have learned anything or not. Although this may sound obvious, care needs to be given to establishing the purpose of the assessment. Is the purpose:

- To rank the students in order of performance?
- To establish which students have reached a minimum standard of competence to go on in their training?

Training has generally moved away from the former towards the latter. Assessment should therefore be tied very closely to the curriculum: students should have a very clear idea of what is to be tested and the pass rate should be very high, as only the essentials—the core curriculum—must be tested, but they must be passed.

Teachers are always worried about examination materials, particularly practical (OSCE—objective structured clinical examination) stations getting out into the students’ domain. This is going to happen anyway. The consequences of this can be minimized, and the effect harnessed by giving open access to certain assessment materials. For example, by publishing model OSCE stations with their marking schema, one ensures that the overall performance is much improved, this is: ‘using the tail to wag the dog’.

**Evaluation**

A simple way of evaluating education is to use an anonymous questionnaire. Questionnaires need careful construction to ensure that you receive valid and reliable responses.

**Summary**

Medicine is a science of uncertainty and an art of probability.

Sir William Osler (1904).

This chapter has provided an overview of some of the key supporting skills for expert clinical practice. There is a limited amount of material that can be included in such a textbook as this, and therefore this chapter is little more than a dégustation menu.

The hope is that reading this chapter will equip the reader to go out and negotiate some of the uncertainties that will face them in everyday practice, and also to act as a roadmap for further reading for those who are looking for more information.

Classification and outcome measures

DOI: 10.1093/med/9780198550597.003.0002

Summary points
Classification is needed to:

- Plan treatment
- Communicate between clinicians
- Carry out research.

If it is to be useful it needs to be:

- Clear
- Reproducible
- Relevant.

Introduction
The field of trauma and orthopaedics is ripe with various classification systems and different outcome measures. It is important for a clinician to be conversant with them as they help in communication of ideas, sharing of opinion, and measurement of clinical outcomes. Many organizations perceive them as useful indicators of quality of practice, which is crucial in delivery of quality healthcare. In addition, the day-to-day practice needs to be open to external scrutiny, analysis, comparison for clinical improvement, legislation, and performance assessment by healthcare providers, healthcare system payers, and government and voluntary regulatory bodies. These reasons necessitate the availability of good classification systems and robust outcome measures.

Classification
Classification may be defined as a system whereby one can arrange or organize any number of people or things (seen as a division or a group) based on type, quality, characteristics, etc. (Box 1.2.1).

Box 1.2.1 Classification

- A system for organizing so that high-level decisions can be made
- Should be easy to use, reliable, reproducible, and clinically useful.

Any classification system should be clinically useful, reproducible, validated, easy to use, and, most importantly, have appropriate divisions to separate from each other all the (known) types or grades of the condition, it is meant to classify.

Biomedical studies are either experimental (the investigator assigned the exposures) or observational (investigator did not assign the exposures). An experimental study can be a randomized or a non-randomized controlled trial depending upon whether the allocation to a particular group was at random or not. An observational study can be analytical or descriptive depending upon whether there is a comparison group or not. The analytical studies can be further classified into cohort study (exposure precedes outcome), case–control study (outcome precedes exposure, e.g. identify an outcome and work backwards as to what might have caused the outcome), and a cross-sectional study (exposure and outcome occur at the same time).

Most reports of outcome in orthopaedics are observational studies. Whilst these studies give useful indications of outcome, in most cases they are open to a variety of bias. Bias may be defined as a non-random, systematic error in the design or conduct of a study that may result in mistaken inference about association or causation. In the orthopaedic literature, common types of bias include recall, selection, sampling, and publication bias.

The double blind, prospective, randomized clinical trial (RCT) is the gold standard of an experimental study design (Table 1.2.1). Randomization ensures that allocation to the comparison groups is unbiased. An RCT usually requires large numbers of patients whose diagnoses and severity grading is relatively similar (narrow entry criteria). Stirrat and colleagues in 1992 spelled out some of the problems that can arise with RCTs in surgery: "Placebo operations are unethical. Blinding of the patient is usually difficult if not impossible. Surgical skills vary between surgeons and also the "learning curve" plays an important role when new operations are being compared to existing ones" (Box 1.2.2).

Box 1.2.2 Types of study

♦ Observational: good for creating hypotheses, weak for drawing conclusions
♦ Cohort: exposure precedes outcome
♦ Case–control: outcome precedes exposure
♦ Cross-sectional: simultaneous exposure and outcome.

Outcome measures

Outcome measures are vital to the setting of standards of care and their measurement, as well as in the assessment of disease or injury severity. The British Paediatric Association Outcome Measures Working Group defines an outcome measurement as a subtype of health status measurement where changes in the measure are known (or at least believed) to be largely attributable to a health service intervention.

Outcomes can be binary (death), continuous (change in blood pressure), a count (number of episodes), or a score (knee society score, Oxford hip, knee, or shoulder score). Also, the outcome can be objective (mortality rate) or subjective (pain, quality of life). To assess outcomes, condition-specific and general questionnaires are widely available, but their sensitivity to change and validity is open to question (Box 1.2.4).

Box 1.2.4 Outcome measures

♦ Binary, continuous, count, or score
♦ Objective vs. subjective
♦ Doctor-based vs. patient-based
♦ Needs validity, reliability, and reproducibility.

An outcome measure should be quick, simple to use, reliable, specific to the question being investigated, cost-effective, and applicable. In most cases, this ‘ideal’ instrument does not exist, although many measures have come into general use without meeting these criteria (Box 1.2.3).

Box 1.2.3 Essential properties of ‘good’ outcome measures

♦ Validity
♦ Reliability
♦ Agreement
Outcome measures may be broadly classified into those used to measure doctors’ assessment, and those used to measure the patient’s own assessment of their problem. In most cases, it is appropriate and perhaps necessary to record both types of outcome. These two measures tend to assess different aspects of a condition and should normally be presented as separate outcomes. In the past, patient-based outcome measures have been dismissed as being too unreliable (subjective test vs. objective data) but in fact these assessments tend to follow closely the main indication for the original indication.

Two essential requirements of an outcome measure are that it measures what it is supposed to and that this measure is made with the minimum of error. The former is called ‘validity’ and the latter ‘reliability’. Content validity examines the ability of the instrument to measure all aspects of the condition for which it was designed so that it is applicable to all patients with that condition. One problem with increasing the content is that the reliability tends to decrease; however, validity at the expense of some reliability is the rule.

Another important issue with an outcome measure is ‘agreement’. Various reliability coefficients are available. An intraclass correlation coefficient (ICC) should be used for continuous data to measure agreement between or within methods or raters. The Pearson correlation is based on regression analysis and is a measure of the extent to which the relationship between two variables can be described by a straight (regression) line. Pearson’s product moment correlation coefficient tends to over-estimate the agreement and is unable to distinguish data when there is a systematic error. It is always worth plotting the results to find systematic biases when comparing data. The best way to plot the data is by placing the mean of points on the x-axis and the difference on the y-axis. This method has been extended by Altman and Brand for normally distributed data to include lines at two standard deviations above and below the mean line, these being termed the ‘limit of agreement’.

If the instrument is being assessed for its reliability as a clinical test, then sensitivity, specificity should be used. These are derived from the proportions of a 2×2 table.

An outcome instrument should be able to detect changes with time and this is termed as ‘responsiveness’. It is important to ensure that the instrument can detect a clinically important change, even if this is quite small. This has two implications—firstly the clinically important change should be and can be defined and secondly this change must be considered while designing an experiment so that power calculations can be made accordingly.

Outcome measures can be substantive (what one really wants to know) or surrogate (what one often ends measuring instead). For a substantive measure (e.g. time taken for an implant to fail), the follow-up is usually prolonged, and during the life of the study one tends to lose participants either due to withdrawal (by patient or surgeon) or due to an adverse event (death, physical or mental impairment) or inability to keep track of patient’s movements (lost to follow-up). For these reasons, surrogate measures are commonly used in clinical practice. However, one has to remember that the association between the surrogate and substantive outcome may be altered by the intervention and also unless the trial is powered to detect a difference in the substantive outcome, the effect of the intervention on the surrogate outcome may determine the clinical practice which can prove to be harmful.

Inclusion of health-related quality of life (HRQL) is increasing in popularity as an outcome measure after any intervention. There are two key dimensions to it: primary (physical, psychological, social, etc.) and additional (neuropsychological, personal productivity, pain, etc.). HRQL provides a method of measuring intervention effects as well as the effects of the untreated course of diseases, in a manner that may be helpful to both the investigator as well as the individual. Most outcome measures tend to assess one or more of HRQL.

Another commonly used measure in orthopaedics is ‘survivorship analysis’ (Box 1.2.5). This is important in studies where participants are entered over a period of time and therefore have various lengths of follow-ups. These methods permit the comparison of the entire survival experience during the follow-up and may be used for the analysis of time to any dichotomous response variable such as a non-fatal event or an adverse effect. The graphical presentation of the total survival experience is called the survival curve and the tabular presentation is called the life table. Two commonly used methods are Kaplan–Meier and Cutler–Edere method. For a Kaplan–Meier estimate, one needs to know the exact time of entry into the trial and also the exact time of the event or loss of follow-up. In this method, the follow-up period is divided into intervals of time so that no interval contains both deaths and losses. In addition, one makes two assumptions. Firstly, it is assumed that at any time patients who are censored have the same survival prospects as those who continue to be followed. Secondly, it is assumed that the survival probabilities are the same for the subjects recruited early and late in the study. For some studies, all that is known is that within an interval of time, a known number of deaths and losses occurred amongst the known number of participants at risk. In such cases, the Kaplan–Meier method can not be used. In the Cutler–Edere method, the assumption is made that the deaths and losses are uniformly distributed over an interval to overcome this problem.

**Box 1.2.5 Survivorship analysis**

- Allows study of patients who enter a study over a period of time
- Uses a life table to present results
- Relies on a valid end-point measure in terms of relevance and reliability
- Can be used for studying longevity of implants.

For expressing survival data of a particular implant, the life-table method is usually used. In this method, generally the cumulative...
survival is calculated at regular time intervals (usually yearly). The life-table method has advantages as it reports number of implants followed, number of failures, loss to follow-up, and confidence intervals. Establishing patients who are lost to follow-up are important in interpreting a survival analysis. Each individual lost may have been a failure and may therefore have dramatically altered the final result of the analysis. This can be addressed by including a worst-case scenario calculation in all survival studies to display the possible results of the loss to follow-up on the study. Confidence intervals give some sense of uncertainty in the estimated treatment or intervention effect. In a survival study, wide confidence intervals suggest that the numbers at risk were small and the results must be treated with caution. The method of Peto is usually used to calculate confidence intervals.

This brief chapter can not summarize all the relevant classification systems and outcome measures used in trauma and orthopaedics. The reader should refer to standard orthopaedic textbooks for the same. An excellent in-depth critique on this subject is available in *Outcome Measures in Orthopaedics and Orthopaedic Trauma*, by Pynsent et al.

**Further reading**

Summary points

- Structure of bone is comprised of cells, matrix, and water
- Bone consists broadly of three surfaces (periosteal, endosteal, and Haversian) and two membranes (periosteum and endosteum)
- The blood supply of bone is derived from four main routes (nutrient, metaphyseal, epiphyseal, and periosteal arteries)
- There are three main types of cells in bone (osteoblast, osteocyte, and osteoclast)
- The matrix is a composite material consisting of an organic and an inorganic component
- Two types of bone formation are intramembranous and endochondral ossification
- The skeleton is also involved in the vital homeostasis of calcium and phosphate.

Introduction

The human body is composed of cells and surrounding matrix. The cells are important in determining active functions of the tissues. The matrix determines the mechanical properties of the tissue and its structure is adapted to cope with the stresses it is exposed to. Tissues such as bone whose main function is support (a mechanical property) have a high ratio of matrix to cells. Tissues such as muscles (functional) are mainly cellular. This chapter describes the make up of bone and joints in more detail. In addition, the embryology and its role in calcium homeostasis is detailed.

Bone

Structure

Bone is tissue formed by the deposition of mineral within a collagenous framework. The mineral consists of hydroxyapatite and type I collagen (90%). The dry weight of bone is 70% mineral and 30% organic. The wet weight of bone is 70% mineral, 22% organic, and 8% water. The organic components of bone consist of 98% matrix and 2% cells.

Bone is a dynamic composite material whose structure is designed to cope with and respond to loading. It is continuously being resorbed and laid down, and this appears to serve two important functions. Firstly, it allows the skeleton to remodel in response to changes in demand and loading. Secondly, it prevents fatigue fractures developing under repetitive loading. At the microscopic level, bone consists of two forms: woven and lamellar.

Woven bone is considered immature bone or primitive bone and is normally found where rapid new bone formation occurs such as in the embryo and new born, fracture callus, and in the metaphyseal region of growing bone. Woven bone contains no uniform orientation of collagen fibres, which gives it isotropic mechanical properties. In other words, the mechanical behaviour of the woven bone is similar regardless of the direction of the applied forces. Lamellar bone begins to form one month after birth. By the first year, it is actively replacing woven bone as the latter is resorbed. By the age of 4 years, most normal bone is lamellar bone. Therefore, lamella bone is more mature bone that results from remodelling from immature woven bone. The collagen fibrils are arranged in parallel sheets called lamellae. The highly organized stress-oriented collagen of lamella bone gives it anisotropic properties; that is, the mechanical behaviour of lamella bone differs depending on the orientation of the applied forces.

Woven bone and lamellar bone are structurally organized into trabecular (spongy or cancellous) and cortical (dense or compact) bone. Trabecular bone is mainly found at the epiphysis and metaphysis and in cuboid bones such as the vertebrae. The surface area to volume ratio of trabecular bone is ten times that of cortical bone. Trabecular bones principally resists compressive forces and responds up to eight times faster than cortical bone.

Trabeculae are needed where there are tension forces. For example, the proximal end of the femur has large compressive forces on the medial side and tension forces on the lateral side where the abductor muscle inserts. Trabecular patterns designed to cope with compression fan out from the calcar up to the articular surface of the femoral head. On the lateral side, a second set of trabeculae at right angle to the first arch up and across from the lateral cortex to counter the tension forces (Figure 1.3.1). The line of the trabeculae appears to be partly determined genetically but is also modified by the loads passing through the bone. This response is known as Wolff's law and stated in simple terms says that bone responds to changes in the magnitude and direction of load by remodelling the shape and thickness of the cortex and of the trabecular pattern inside.
The trabecular pattern of the neck of the femur is designed to provide maximum strength in the calcar where compression is greatest and through the top of the femoral neck where tension forces will be largest.

In contrast, cortical bone, which makes up 80% of the skeleton, is found in the diaphysis of long bones. Cortical bone is much stronger than cancellous bone and is subjected to bending and torsional forces as well as compressive forces. Cortical bone is made up of multiple layers of lamella bone and woven bone, with vascular channels located mainly in woven bone.

The basic unit of cortical bones is known as the Haversian system or osteon. This consists of concentric layers or lamellae surrounding a central Haversian canal. Haversian canals contain blood and nerves and communicate with the medullary cavity by Volkmann's canals. The capillaries in the central canal are derived from the principal artery of the bone or the epiphyseal and metaphyseal arteries. Each lamella consists of highly orientated, densely packed collagen fibrils which run in different directions. The collagen fibrils often interconnect with each other and between the lamellae which increases bone strength. Lamellae are lined with osteocytes which communicate via canaliculi. Osteons are major structural units of bone and are bound to each other by cement lines which define the outer boundary of each osteon. These thin layers of organic matrix mark sites where the resorption of bone stops and new bone formation begins. They separate, as opposed to bind, adjacent matrix lamellae.

Bone consists broadly of three surfaces (periosteal, endosteal, and Haversian) and two membranes (periosteum and endosteum). Periosteum covers the outer surface of bones except in the regions around synovial joints and is comprised of an outer fibrous and inner cambium layer. The inner layer contains cells that are capable of becoming osteoblasts and can also form hyaline cartilage. The outer layer has fewer cells and more collagen. It continues into the joint capsule and thereby connects one bone to another. Some ligaments and tendons insert into the outer layer. Periosteal cells can resorb and form bone in response to local stimuli. The periosteal blood vessels supply the outer third of the cortex. Sharpey's fibres anchor the periosteum to bone.

The central portion of long bones (the diaphysis) is mainly concerned with resisting compression and resisting bending and torsion and the shape approximates to a thin-walled tube (like a bicycle frame) (Figure 1.3.2). Muscles, tendons, and ligaments are bound firmly to the bone structure by fibre anchors deep in the cortex of the bone. These collagen anchors are cemented to the bone with hydroxyapatite (Figure 1.3.3).
Blood supply of bone

Bone is a highly vascular organ that receives up to 10% of cardiac output. The blood supply of bone is derived from four main routes (nutrient, metaphyseal, epiphyseal, and periosteal arteries). The arterial blood flow is centrifugal in direction (endosteum to periosteum). Venous blood flows in the opposite direction. Periosteal stripping of bone deprives it of venous drainage and collateral arterial supply. With aging, the periosteal blood supply diminishes in importance.

The blood supply to the epiphysis relies on penetrating vessels that ascend along the periosteal and perichondral layers and enter through the groove of Ranvier. The blood supply can be vulnerable to disruption following a physeal injury and can lead ultimately to avascular necrosis of the epiphysis. Following closure of the physis at skeletal maturity, anastomosis develops between the epiphyseal and medullary system.

The articular cartilage of the joint itself has no blood supply, but the epiphyseal vessels terminate in a capillary net in the bone immediately beneath the articular cartilage (the subchondral bone). However, the main supply of oxygen and nutrients to the articular cartilage is by diffusion through the synovial fluid and not from the subchondral vessels (Figure 1.3.4).

Nerve supply of bone

The periosteum is well innervated, but the only nerves entering the bone marrow appear to be unmyelinated sympathetic fibres which travel in the walls of the nutrient vessels, and dispense with them. It is these fibres that presumably mediate the deep aching which comes from bone when there is raised intraosseous pressure, as occurs in osteoarthritis, avascular necrosis, and bone marrow oedema.

Cellular constituents of bone
Bone cells assume specialized forms in order to perform diverse functions including formation and resorption of bone, mineral homeostasis, and repair of bone. There are three main types of cells in bone (osteoblast, osteocyte, and osteoclast) which are derived from different stem lines. Undifferentiated cells in the endosteum, periosteum, and Haversian canals differentiate into osteoblasts when stimulated.

**Osteoblasts**

Osteoblasts line the bone surface and produce matrix. Their shape is altered by their functional state: when active they resemble a cuboidal shape, and when in a static phase they adopt a flattened appearance. They possess hormone receptors for parathyroid hormone and a well developed endoplasmic reticulum. Osteoblasts have a variety of functions (see Box 1.3.1).

**Box 1.3.1 Functions of osteoblasts**

- Control bone formation
- Secrete organic bone matrix
- Regulate electrolyte influx
- Release mediators that control the function of osteoclasts
- Secrete and process type I collagen
- Aid in the formation of microfibrils and maturation of the collagen matrix.

**Osteocytes**

Osteocytes make up more than 90% of the bone cells in the mature human skeleton and are surrounded by an organic matrix that can mineralize. They have a single nucleus and long branching cytoplasmic processes.

An osteocyte originates from an osteoblast and is, in effect, an osteoblast encased in calcified matrix. The canaliculi provide its nutrients and its metabolic activity is much reduced compared with osteoblasts.

**Osteoclasts**

These are bone lining cells responsible for bone resorption and resemble giant multinucleated cells. In contrast to the other bone cells, osteoclasts share a haematopoietic stem-cell precursor with cells of the monocyte family. These precursor cells may be found in the marrow or circulating blood. At their bone attachment, they possess a brush border which secretes lysosomal enzymes that degrade matrix components. Bone resorption creates Howship’s lacunae in cancellous bone and cutting cones in cortical bone. Osteoclasts are rarely found in normal bone. On cancellous or periosteal surfaces, they create a depression referred to as Howship’s lacuna. In dense cortical bone, they lead cutting cones that tunnel the bone creating resorption cavities.

**Bone matrix**

The matrix makes up 90% of the volume of lamellar bone and is a composite material consisting of an organic and an inorganic component. The inorganic component contributes 65% of wet weight of the bone. The organic component, principally collagen, gives bone its form and its ability to resist tension, while the inorganic or mineral component primarily resists compression. Demineralized bone is flexible, pliable, and fracture prone. The matrix serves two main mechanical functions (see Box 1.3.2).

**Box 1.3.2 Functions of the matrix**

- To prevent tissues from being torn apart (tension)—tensile forces predominate in tissues such as tendons and ligaments
- To stop tissues from collapsing (compression)—often found in bones and the intervertebral disc.

The main constituent of the matrix is water, which is held in equilibrium with the intracellular water by the osmotic pressure of the salts it contains. Where the matrix needs to resist compression, large hydrophilic feather-shaped molecules—proteoglycans—hold the matrix together (Figure 1.3.5).
Proteoglycans—long feathery molecules covered in negative charges which are highly attractive to water molecules (hydrophilic) and create the turgor pressure in the matrix.

Organic matrix

Collagens, predominantly type I, make up 90% of the organic matrix. The other 10% consists of glycoproteins and proteoglycans. Proteoglycans consist of a central protein core to which the negatively-charged glycosaminoglycans, either keratin sulphate or chondroitin sulphate, are attached. The negative charge attracts cations into the matrix to neutralize. A high osmotic pressure is created leading to the matrix continually attempting to draw in water. This will occur until it is resisted by tension arising in the fibrous network, leading to an equilibrium. However, to resist shear and maintain form requires the addition of collagen (Figure 1.3.6). There are also a small number of non-collagenous proteins that may influence matrix organization and bone mineralization. These include osteocalcin and osteonectin.

Structure of collagen

Collagen is the most common protein in the human body and consists of 19 different types. Common to all is a long triple helix made up of three helical alpha chains twisted around each other to form a superhelix. The structure allows collagen to resist stretching although it can be compressed easily. Collagen is laid down in bundles and layers wherever distraction forces may be significant (Figure 1.3.7) and can be thought of as being similar to the reinforcing steel rods found in concrete skyscrapers. The combination of an incompressible matrix (proteoglycans and water) with collagen creates a composite structure whose strength and mechanical properties far exceed those of its individual components. Depending on the arrangement of the collagen fibres, the matrix can specifically resist compression (articular cartilage), tension (the annulus of the intervertebral disc), and distraction (ligaments).
Collagen—one triple helix of strands made from tropocollagen molecules. Each type of collagen has a characteristic repeating pattern of amino acids usually involving glycine, hydroxyproline, and proline. Collagen is very strong in tension. However, in order to resist bending, one further component is required in the composite—hydroxyapatite—a rigid crystal of calcium and phosphate (a form of ceramic), which converts a strong but flexible matrix into the rigid and unyielding structure of bone. The hydroxyapatite crystal is weak in tension but very strong in compression. When mixed into a composite it resists bending. The crystals are only 25µm long but are laid down in layers, creating bone, which for its weight is one of the strongest composite materials known.

Inorganic matrix

The inorganic matrix performs two essential functions (see Box 1.3.3).

Box 1.3.3 Functions of the inorganic matrix

- An ion reservoir: about 99% of the body’s calcium and 85% of phosphorus are associated with bone mineral crystals. Bone therefore helps in maintaining their extracellular fluid concentrations within ranges critical for normal physiological function, including nerve function and muscle contraction
- Gives bone most of its strength and stiffness: the calcium-phosphate crystals in the matrix create a rigid material able to withstand forces imparted by normal activity.

Mineralization of bone

The formation of solid calcium phosphate in the organic matrix represents a phase transformation. Solid calcium phosphate first appears as a poorly crystalline apatite, whose crystallinity increases with time. Mineralization of bone collagen fibrils occurs in an organized fashion with progressive mineralization within hole zone regions in the collagen fibrils. Mineral continues to accumulate and gradually increases the density of the bone and its stiffness. The abnormal mechanical properties of bone in patients with osteomalacia or rickets illustrate its importance. In this group, the osteoid fails to mineralize, the bone weakens, and is more prone to skeletal deformities and pathological fractures. In osteoporosis there is a general reduction in bone mass. Thick trabeculae become thinner or may disappear altogether. The radiographic result is a coarsening of the main trabecular pattern. The reason for this paradox is that the main trabeculae may become slightly thinner in osteoporosis but do not disappear, but the small cross-trabeculae disappear and allow the main trabeculae to stand out even more clearly than before, making the bone look stronger rather than weaker on radiographs (Figure 1.3.8).
In osteoporosis there is generalized loss of bone. The thick longitudinal stress-bearing trabeculae become thinner, and thin cross-bridging trabeculae disappear altogether. On radiography the loss of the cross-bridges enhances the definition of the longitudinal trabeculae, making the bone look stronger not weaker.

Embryology of the musculoskeletal system

The differentiation and organization of the embryo starts with the formation of the notochord during gastrulation. It is at this stage that ectoderm cells become programmed to form neural tissue. The signal to start forming the notochord appears to arise from a layer of dorsal mesoderm in contact with the ectoderm, which induces the ectoderm to infold and form the neural tube. The limb buds start to form shortly after this. They are produced by rapid division of mesoderm cells (the progress zone) which bulge out as a result of their fast growth. The thin layer of ectoderm lying over the end of the limb bud, called the apical epidermal ridge, seems to stimulate proliferation of the mesoderm beneath. Removal of this apical epidermal ridge at an early stage prevents limb formation altogether. Removal of the apical epidermal ridge late on in limb-bud formation results in normal proximal limb development but absent digits and other distal structures. The apical epidermal ridge seems to control the longitudinal growth of the limb.

The anteroposterior differentiation of the limb is controlled by an area of mesenchyme along the posterior margin of the limb bud, known as the zone of polarizing activity. The apical epidermal ridge, the underlying mesenchymal progress zone, and the zone of polarizing activity all work together to produce the normal limb. Cells left behind from the progress zone at any early stage are destined to become part of the proximal limb. Those which leave the progress zone later make up the distal part of the limb.

The gene controlling the ability of one group of cells to initiate differentiation in another is known as Sonic Hedgehog in humans. Activation of this gene in responsive cells seems to be mediated by retinoic acid. The signal sent out by the cells in which Sonic Hedgehog is active appears to be fibroblast growth factors 2 and 4, and possibly bone morphogenetic protein 2.

Formation of bone

The formation of bone tissue during development and in adult life is the responsibility of osteoblasts. The two types of bone formation are: intramembranous and endochondral ossification.

Intramembranous ossification

This process is responsible for forming the flat bones of the skull and parts of the mandible and clavicle. Precursor cells in vascular connective tissue enlarge, differentiate, and secrete thin strands of osteoid. Within a few days, mineralization commences and the tissue is referred to as primitive woven bone. Recognizable trabeculae form and remodel to mature lamellar bone. The fibrous tissue between the trabeculae is replaced by marrow.

Endochondral ossification

Ossification is preceded by a cartilage anlage or template. Cartilage cells hypertrophy and secrete matrix vesicles at a genetically predetermined time and site (primary ossification centre). The matrix calcifies and the chondrocytes die. Blood vessels enter the space and bring osteoblast precursors which differentiate and lay down mineralizing osteoid on the previously mineralized cartilage matrix. This method of laying down bone within a cartilage anlage is known as endochondral ossification and occurs almost everywhere in the human body apart from the skull and the clavicle (Figure 1.3.9).
Fig. 1.3.9
Formation of bone at 10 weeks from a condensation of mesenchyme. This is followed by the formation of a cartilage model (anlage). The cartilage cells then die (apoptosis) and bone is laid down in place of the cartilage.

As ossification of the primary centre commences, the periosteal sleeve lays an outer shell of bone which will become the cortex. In a long bone, this process starts in the centre of the diaphysis and spreads leaving only the bone ends as cartilage (epiphyses). At the junction of the cartilage and bone, the cartilage is organized to form a specialized structure referred to as the growth plate or physis. Osteocytes become incarcerated in rings of bone laid down around blood vessels, creating a pattern of interlinking rings with a Haversian canal running down the centre (Figure 1.3.10).

Fig. 1.3.10
Osteocytes become incarcerated in rings of bone laid down around blood vessels, creating a pattern of interlinking rings with a Haversian canal running down the centre.

At differing times throughout the skeleton, secondary ossification centres are formed in the epiphyses in a similar fashion to the primary centres. Growth of the epiphysis occurs using endochondral ossification at the junction of the bone with the articular cartilage (secondary growth plate).

The ossification of the bone spreads out from the ossification centres, each of which forms at a characteristic age and can be used to age skeletons by radiography. The last areas to ossify are the epiphyseal plates, where longitudinal growth of the bone will continue until adulthood (Figure 1.3.11). The diameter of bones also increases during growth through bone laid down under the periosteum. Remodelling may also continue on the inner cortex enlarging the diameter of the medulla in proportion to the dimensions of the rest of the bone.
In cortical bone, ossification continues in rings around each blood vessel. Each layer of bone laid down around the vessel has the collagen arranged at a certain orientation. The osteoblasts lay down collagen in organized lamellae to form an osteoid seam about 10mm thick. The next layer will have its collagen at a different orientation, creating a layered effect which is exceptionally strong. Ten to fifteen per cent of osteoblasts become incarcerated within the lacunae as osteocytes. In the centre of these sets of concentric rings the blood vessels flow in the Haversian canal (Figure 1.3.10).

The osteoid which has not yet been mineralized is about 10µm thick. Each layer of osteoid takes about 10 days to mineralize. An unusually thick layer of osteoid suggests that there may be a problem with bone mineralization such that it cannot keep pace with osteoblast activity (osteomalacia). In the adult there is a dynamic equilibrium between osteoclastic activity (resorbing bone) and osteoblastic activity (new bone being laid down) (Figure 1.3.12).

Remodelling

There are three main functions of remodelling (Box 1.3.4)

Box 1.3.4 Functions of remodelling

- Replacement/repair of old/damaged bone
- Reinforcement due to altered stresses
- Calcium homeostasis.

The control of remodelling is very precise. The amount of bone formed in each remodelling unit must precisely match that which has been resorbed. If this does not occur, the trabecular bone volume will change.

Both compact and cancellous bone are composed of individual basic multicellular units separated by cement (reversal) lines. This pattern is the result of bone remodelling activity involving organized groups of osteoclasts and osteoblasts. Osteoclasts are large multicellular structures with a large volume of cytoplasm. In cortical bone, following an activation stimulus, a group of osteoclasts form a cutting cone in the bone (a tunnel which is drilled into old bone) for up to 2.5mm. This resorption activity is followed by a short reversal phase when macrophages remove any debris. In the cavity created, osteoblasts line the walls of the cavity and lay down concentric lamellae of osteoid on the previously resorbed bone surface (Figure 1.3.13). The end result is the mature, mineralized, Haversian system (osteon) with a central vascular channel.
A cutting cone in mature bone. Osteoclasts are cutting into old bone, resorbing as they go. Behind them, osteoblasts are laying down new bone communicating via cytokines.

In cancellous bone, osteoclastic resorption to a depth of approximately 50µm occurs, followed by osteoblastic activity to replace the resorbed bone. The resultant bone packet is bounded by a cement (reversal) line and the trabecular surface.

There is a close link between the activity of the osteoclasts and of the osteoblasts, maintaining a constant mass of healthy bone and keeping the plasma levels of calcium and phosphate at the correct level. This linkage is probably mediated by cytokines which pass between the two cell types, osteoclasts (removing bone), and osteoblasts (rebuilding). If osteoclastic activity outstrips osteoblastic activity, a progressive reduction in bone mass occurs. This is known as osteoporosis. If this is rapid then plasma calcium and phosphate may rise (as in myeloma and other bone-lysing tumours). Excessive activity by the osteoblasts increases bone mass and removes calcium and phosphate from the plasma.

Bone growth and the epiphyseal plate

Growth plates consist of a series of histological layers which represent the stages that bone goes through when it is produced. At the front of the epiphyseal plate, there are relatively undifferentiated and quiescent reserve cells, ready to be activated and move the epiphyseal plate forward. This is the reserve cell layer. In this quiet area, the epiphyseal artery supplies nutrients to the growing epiphyseal plate. Immediately behind the resting cell layer are cells which are rapidly dividing and separating, driving the resting layer and the epiphysis forward.

This layer creates the cells needed to produce the matrix of the epiphyseal plate. This is known as the proliferative layer. Cells are budded off and they remain behind and mature as the proliferative layer continues forward. The cells grow larger and start producing matrix. Columns of cells are produced; those closest to the proliferative layer are still small and young, and those further back are larger and older (hypertrophied) and surrounded by the cartilage matrix that they have produced. This region is known as the hypertrophic zone.

Finally, even further from the advancing front, the hypertrophied cells start to die (apoptosis) and the cartilage matrix calcifies (the calcification layer). New blood vessels from the nutrient artery of the metaphysis grow into the back of this zone and from their sides, cells appear which remove the calcified cartilage and start to lay down new endochondral bone.

From the orientation of the epiphyseal plate it can be seen that any fracture of the proximal side is, in effect, a simple fracture of new bone which can heal normally. Injury to the distal part of the epiphysis cuts off the blood supply to the cells about to create the next phase of the plate and effectively stops the plate’s forward movement (Figure 1.3.14).
horizontal to resist shearing forces. The deeper layers are vertical to provide struts for the hydrostatic pressure which serves as a shock absorber.

**Joints**

**Embryology**

Joints initially appear in the embryo as condensations of mesenchyme. At around 8 weeks there appears to be a line along which cell death occurs. A cleft is created which develops into the joint. In the typical diarthrodial joint the cells around the cleft contribute to the synovium and articular cartilage.

**Articular cartilage**

Articular cartilage is a tough, elastic tissue that covers the ends of bones in joints and enables them to move smoothly over one another. It is also a shock-absorbing tissue that protects the more rigid underlying bone. It consists of specialized hyaline cartilage ranging in thickness depending on the joint and receives its oxygen and nutrients through the synovium.

The collagen fibres in the articular cartilage are arranged on the surface as a mat to resist shearing. Deeper down they are vertical. This assists in the load-bearing function of the cartilage because there is a high concentration of proteoglycans between the collagen fibres which draw in water and create the turgor pressure of the cartilage. This pressure constrained by the vertical collagen fibres converts articular cartilage into a hydroelastic suspension system which cushions and spreads load across its joint surface. The indentation of the outer layer of articular cartilage as a load moves across it squeezes out synovial fluid lying within the articular cartilage. This creates a fluid lubrication layer between the articular cartilage surfaces, which explains the low coefficient of friction of the articular surface (Figure 1.3.15).

![Click to view larger](image.png)

Fig. 1.3.15
The structure of the intervertebral disc in relation to function. Sheets of collagen laid in oblique sheets (like plywood) allow some movement but resist expansion. The central nucleus pulposus has a high concentration of proteoglycans that create a hydrostatic pressure which resists compression and acts as a shock absorber.

Articular cartilage is mineralized at the junction between cartilage and bone. A mineralization front advances through the base of the hyaline articular cartilage at a rate which depends on cartilage load and shear stress. Variations in mineral deposition density of the mineralizing front, lead to multiple "tidemarks" in the articular calcified cartilage. The cartilage is penetrated by vascular buds, and new bone is produced in the vascular space in a process similar to endochondral ossification at the physis. A cement line demarcates articular calcified cartilage from subchondral bone.

**The synovial membrane**

The inner membrane of synovial joints is called the synovial membrane, which secretes synovial fluid into the joint cavity. This fluid forms a thin layer at the surface of articular cartilage and seeps into irregularities in the cartilage surface. The fluid within articular cartilage serves as a synovial fluid reserve. During normal movements, the synovial fluid held within the cartilage is squeezed out mechanically (so-called weeping lubrication) to maintain a layer of fluid on the cartilage surface.

The synovial membrane consists of a thin layer of lining cells lying on a subintimal layer of fat and fibrous tissue and lacking a basement membrane. The intimal cells or synoviocytes consist mainly of two classes of cells. One group appears to be mainly synthetic and probably produce hyaluronate for the synovial fluid as well as nutrients for the cartilage cells. The second group are macrophage-type cells which clear detritus created by the movement of the joint.

Synovial fluid is made of hyaluronic acid and lubricin, proteinases, and collagenases. Synovial fluid exhibits non-newtonian flow characteristics. The viscosity coefficient is not a constant, the fluid is not linearly viscous, and its viscosity increases as the shear
Fibrocartilage

Fibrocartilage is the most common form of cartilage by weight and is characterized by a dense network of type I collagen commonly arranged parallel to tensile forces. Under the microscope, it consists of fibrous connective tissue arranged in bundles, with cartilage cells in between. The cells resemble dense irregular connective tissue but may be distinguished from them by their surrounding concentric striated area of cartilage matrix, their lacunae, and by their less flattened appearance.

Fibrocartilage is a tough material that provides high tensile strength and support and contains more collagen and less proteoglycan than hyaline cartilage. It is most present in areas subject to frequent stress such as intervertebral discs, the symphysis pubis, and the attachments of certain tendons and ligaments. In the annulus of the intervertebral disc, in combination with the proteoglycan rich nucleus pulposus, it provides a very strong load-bearing joint with a limited range of movement in all planes. The amount of fibrocartilage increases with age as hyaline cartilage transforms into fibrocartilage.

Calcium and phosphate homeostasis

The skeleton is also involved in the vital homeostasis of calcium and phosphate. Both ions are important for normal physiological function. Calcium is needed for neuromuscular conduction, especially in the myocardium and plays an important part in the clotting cascade. Phosphate ions have an equally important role as one of the ions that buffer the pH of the body fluids. Bone mineral homeostasis is tightly controlled by the synchronized action of the vitamin D3 metabolites, parathyroid hormone, and calcitonin. These hormones regulate the dietary absorption of calcium, bone mineral resorption and deposition, and renal secretion and reabsorption of calcium and phosphorus.

Homeostasis of these ions can be influenced in four main ways (see Box 1.3.5).

Box 1.3.5 Ion homeostasis

- The intake may be disturbed (usually because of poor diet—dietary rickets)
- Regulation may be affected by inappropriate levels of parathyroid hormone, calcitonin, or vitamin D
- The kidneys may be unable to resorb calcium and/or phosphate so they are lost from the body (renal rickets)
- The bone may be destroyed and ions released by destructive processes (myeloma and other bone tumours).

Any disease process may affect more than one of these four causes of dysfunction, so that the final result in terms of whether the serum calcium is raised or reduced and whether the phosphate is affected in the same way or not depends on the actual disease and the body’s response to it. However, if both calcium and phosphate are raised, their solubility product may be exceeded in which cases calcium phosphate may be deposited spontaneously in the tissues.

Injury and repair

Summary points

♦ Types of injury—traumatic and overuse
♦ Importance of determining the energy involved in an injury
♦ The relevance of mechanical load curves
♦ Types of fracture healing—how and why they occur
♦ Healing in articular cartilage, tendon, ligaments, peripheral nerves, and brain tissues.

General concepts

The musculoskeletal system (also known as the locomotor system) provides the supporting framework for the human body, protects vital internal organs, and enables us to move in space through an arrangement of bones, ligaments, and articulations. The system consists of the human skeleton, made by bones attached to other bones with joints, and skeletal muscle attached to the skeleton by tendons.

Injury is damage caused to the structure or function of the body by an outside agent or force, which may be physical or chemical. Injury occurs when an acting force exceeds the elastic, plastic (hard tissues), viscoelastic (soft tissues), or endurance limits (stress, overuse) of a particular tissue (Box 1.4.1).

Box 1.4.1 Types of mechanical deformation

♦ Elastic: measure of the stiffness of a material or its ability to resist deformation. \( E = \frac{\text{stress}}{\text{strain}} \) in the elastic range of the stress–strain curve
♦ Plastic: change in length after removing the load (before the breaking point in the plastic range)
♦ Ultimate strength: maximum strength obtained by the material
♦ Breaking point: point where the material fractures
♦ Viscoelastic material: exhibits stress–strain behaviour that is time rate-dependent. The deformation depends on the load and the rate at which the load is applied
♦ Endurance limit: the stress level below which a material will withstand cyclic stress indefinitely without exhibiting fatigue failure.

In a traumatic injury, the acting internal force (e.g. a contracting hamstring muscle tearing in a sprinter) or external force (e.g. a fall from a height causing a vertebral compression fracture) exceeds the strength of a normal tissue. A pathological injury occurs when a force of ordinary magnitude damages a tissue weakened by a pathological process (e.g. tumour /bone cyst).

A stress or overuse injury occurs after ordinary forces act repeatedly on normal tissues. Microinjuries are produced which do not have sufficient time to heal prior to the next submaximal event. The tissue fails after its endurance limit has been exceeded. In an overuse injury, the repeated impact produces a chronic inflammatory response (e.g. a tenosynovitis) which may prevent ultimate tissue failure by temporarily limiting the further use of an extremity.

Traumatic injuries

Mechanical trauma is the commonest cause of injury to the musculoskeletal system. These events are governed by Newton’s second law of motion. This states that the force acting on a body is proportional to the product of the mass of the body and its acceleration (or deceleration).

Energy transmitted to the body is absorbed and dissipated through the bone and soft tissue envelope. Kinetic energy (KE) equals mass \( m \) × velocity \( v \) squared divided by two: \( KE = \frac{mv^2}{2} \). Hence doubling the mass of a moving body will double its traumatizing kinetic energy, while doubling its velocity will quadruple the resulting traumatic impact. The kinetic energy imparted to an object can deform the object temporarily (elastic deformation) or permanently (plastic deformation), or cause its complete disruption (by exceeding the ultimate failure limit). A small part of the transmitted impact can be converted to thermal energy. If the impacting force exceeds the failure limit of the bone, it breaks.

Variables such as age and the rate at which loads are applied (strain rate) affect the resulting injury patterns. An example of how the relative strength of musculoskeletal tissues changes with age can be seen when a lateral force is applied to the knee joint in a child. This will most likely lead to a fracture through the epiphyseal plate or possibly a fracture of the adjacent tibial shaft. The same mechanism will tear the medial-collateral ligament in a young adult and cause a tibial plateau fracture in an older person.
With higher loading rates, a bone appears stronger thus requiring more energy to fail. This also explains why a slowly applied load to a joint will probably lead to a bony avulsion, while at a faster loading rate an in-substance tear of the ligament is more common.

**Injuries caused by firearms**

Firearms can be divided into handguns, shotguns, and rifles. The barrels of most firearms have helical grooves imparting a spin to the bullet, which increases stability in flight and accuracy.

**Velocity and kinetic energy**

Velocity (distance divided by time) refers to the speed of a missile on exit. The muzzle velocity is the maximal velocity. Bullets with muzzle velocities below 1000 feet/s (305m/s) are considered ‘low velocity’. This includes most rifles and shotguns. Bullets with muzzle velocities more than 1000 feet/s are considered ‘high-velocity’ firearms. Velocity on impact is important since tissue damage is proportional to a missile’s KE. Because of its geometric progression, velocity is of greater importance than mass.

Ballistics is the science of the movement of a projectile through a firearm, the air, and into or through a target. The tissue destruction is determined by the dissipation of the energy upon impact ($\Delta KE$). If the bullet or its fragments have remained within the target, the exit velocity is zero and complete energy transfer has occurred.

**Maximizing tissue destruction**

Secondary missiles are created when the KE is imparted to dense tissues (e.g. a tooth) which themselves become missiles. Cavitation is caused by the rapid expansion and elastic recoil of tissues impacted by a missile (Box 1.4.2). Cavitation is proportional to the density of the tissue, the velocity of the projectile, and KE on impact. The temporal cavity may exceed the missile diameter by a factor of five to ten, which may produce tissue destruction many centimetres beyond the missile path. One of the more harmful effects of cavitation is the resulting vacuum which sucks foreign bodies and organisms into the projectile’s tract, an ideal situation for infection.

**Box 1.4.2 Side effects of cavitation**

- Injuries to tissue remote from missile track
- Foreign bodies may be sucked into the wound
- Thorough and repeated debridement is vital.

**Clinical issues**

When managing firearms injuries, ballistic information should be available (Box 1.4.3). A thorough physical evaluation with special focus on the neurovascular status must follow. Bullets may fragment and even change course in the body (for example, bouncing off the spine) so the search for injuries needs to be comprehensive. All firearm injuries involving vital structures and/or by high-velocity missiles must undergo evaluation and formal debridement in the operating room. This is frequently repeated at 24–48h.

**Box 1.4.3 Relevant ballistic information**

- Weapon type: calibre
- Distance: path of the bullet in the victim
- Presence, intensity, and location of powder burns (Figure 1.4.1)
- Number of bullets involved.
**M16 gunshot wound to the side of the chest of a soldier. The entrance wound is larger than the exit wound, and is identified by powder burns.**

**Musculoskeletal tissues: basic repair mechanisms**

*Tissues respond to injury*

Most musculoskeletal tissues heal using three common phases: inflammation, repair, and remodelling. However, some structures (e.g. tendons) can heal using tissue-specific healing mechanisms. In contrast, some tissues (e.g. meniscus with in situ tears in the white zone) are incapable of repair.

**The standard healing model: inflammation–repair–remodelling**

Soft tissue injury can initiate a complex pathway of physical and biochemical changes. Healing progresses typically in four stages: haematoma, to inflammation, to proliferation, and finally remodelling (Box 1.4.4) Healing is most effective in well-vascularized tissues, and usually initiated from the tissues surrounding the injury site.

**Box 1.4.4 The standard healing model**

- Haematoma: following injury, bleeding occurs in the zone of injury, followed by the formation of a primary platelet plug
- Inflammation: the dead tissue is phagocytosed by macrophages with the first week. The tissue is then replaced by granulation tissue
- Repair: granulation tissue replaced by tissue-specific matrix
- Remodelling: shape and structure optimized in response to stress. This continues for up to 18 months via realignment and cross linking of collagen fibres.

During haemostasis a primary platelet plug usually forms shortly after the injury. Secondary clotting occurs using fibrin and the coagulation cascade. Platelets release mediators that stimulate the next phase of healing.

During inflammation, the non-viable tissue is phagocytosed by macrophages within the first week. The end result is the formation of granulation tissue. Prostaglandins are actively involved in mediating this stage. Activation of the coagulation system and cytokines released by injured tissues attract polymorphonuclear leucocytes, monocytes, and T lymphocytes which remove necrotic material. They also release vasoactive mediators and activate growth factors and cytokines such as fibroblast growth factor, platelet-derived growth factor, and transforming growth factor-β (TGFβ). These attract cell migration, proliferation, and matrix differentiation.

**Repair**

The granulation tissue is replaced by a tissue-specific matrix which facilitates the ingrowth of undifferentiated pluripotent mesenchymal cells from surrounding muscle, periosteum, and marrow. These differentiate into tissue-specific cells such as osteoblasts, chondroblasts, myoblasts, and fibroblasts which fill the injury site with material closely resembling the original tissue.

**Remodelling**

In this phase, the disorganized repair tissue is optimized over several months under the guidance of local mechanical stresses. The result is tissue approaching the pre-injury status both structurally and functionally. However, scar tissue filling large defects
contracts and this can be cosmetically unattractive or limit the movement of a limb.

Fracture mechanics and new bone formation

Structure and mechanical properties of bone

Normal bone is lamellar and is divided into cortical and cancellous bone. The mechanical properties of bone and its failure mechanisms directly derive from its composition and three-dimensional structure (Figure 1.4.2). Bone is a viscoelastic material and fractures are subsequently related to the magnitude of the force applied and its rate of application. This force is stored until breaking point and subsequently dissipated resulting in soft tissue damage.

Cortical bone has a slow turnover rate, a relatively high Young’s modulus, and a higher resistance to torsion and bending than cancellous bone. Cortical bone is weakest in shear, weak in tension, and strongest in compression. Trabecular bone is less dense and undergoes increased remodelling related to the lines of stress (Wolff’s law). It has a higher turnover rate, a lower Young’s modulus, and a greater elasticity than cortical bone. Trabecular bone, with a much greater ability to deform plastically, is about four to 50 times weaker than cortical bone. By the fifth decade, progressive reduction in bone mass with changes in material properties reduces bone strength and modulus resulting in a greater susceptibility to fracture. This tendency is less severe in men because increased endosteal resorption is partially compensated by a concomitant subperiosteal expansion. The loss in bone material with increasing age is partially counteracted by improved structural properties (increased polar moment of inertia).

Fracture mechanics

A fracture involves a breech in the continuity of bone. Injuries may be from indirect forces such as a twist. These are termed low-velocity injuries. With high-velocity injuries, the fractures may be highly fragmented and damage to the surrounding soft tissues much greater, compromising blood supply. The forces that bone has to withstand include compression, bending, and twisting. Bone is strongest in compression and weakest in tension. Compressive forces lead to fractures predominantly in cancellous bone (metaphysis). Transverse, oblique, and spiral fracture patterns primarily occur in diaphyseal bone. Failure commences with the formation of a small crack on the tension side. As this crack progresses to the neutral axis, and then to the convex side, a transverse fracture results (Figure 1.4.3).

Transverse fractures occur following a bending force and may be associated with a small extrusion wedge on the compression side. If the wedge is less than 10% of the circumference of the bone, the fracture is defined as simple transverse fracture. With larger extrusion fragments, the fracture is termed a wedge fracture. Oblique fractures are secondary to a bending force. The extrusion wedge remains attached to one of the main fragments. Spiral fractures result from indirect twisting injuries and may occur with a spiral wedge fragment.

Mechanisms of bone regeneration: overview

Fracture healing involves a complex series of events leading to restoration of bone to its pre-injury condition. Fracture repair is influenced by factors such as the mechanical and biological environment of the fracture site, motion at the fracture site, and stability.

Fracture healing and regeneration of new bone can principally occur by primary or secondary bone healing or distraction osteogenesis. The prerequisites for the type of fracture healing include the fracture gap size and the degree of motion between the two bone fragments.

Fracture healing

Fracture healing is a continuous process progressing from the initial fracture haematoma to, ultimately, bone remodelling. The most important factor is adequate blood supply.

Inflammation—formation of granulation tissue

Bleeding from the fracture site and disruption of surrounding tissues (periosteum, blood vessels, and muscles) results in a haematoma which may expand into the surrounding tissues. Soon after fracture, the blood vessels constrict, stopping any further bleeding. The haematoma provides a source of haematopoietic cells capable of secreting growth factors. The fibrillar network of the haematoma serves as a scaffold for invading fibroblasts which become part of a composite matrix called granulation tissue (Figure 1.4.4). In the fracture thrombus, platelet-derived growth factor (PDGF) is released. Necrotic material releases cytokines which attract macrophages. Osteoclasts (derived from circulating monocytes) and their marrow precursors resorb bony debris and avascular bone ends. Cytokines also encourage vascular buds to form and begin to invade the fracture site. Examples of cytokines involved include fibroblast growth factor (FGF) which stimulates angiogenesis and TGFβ which initiates chondroblast and osteoblast formation. The fibroblasts replicate and form a loose aggregate of cells, interspersed with small blood vessels, known as granulation tissue. This is the perfused, fibrous connective tissue that replaces a fibrin clot.

Repair—formation of the fracture callus

During the repair phase, the fracture haematoma is replaced by soft callus consisting of fibroblasts, chondroblasts, and osteoblasts. A few days following the fracture, cells from the periosteum are recruited, replicated, and transformed into specific cells. The periosteal cells proximal to the fracture gap develop into chondroblasts and form hyaline cartilage. The periosteal cells distal to the fracture gap develop into osteoblasts and form woven (immature) bone. The fibroblasts within the granulation tissue also develop into chondroblasts and form hyaline cartilage. This process forms the fracture callus. Eventually, the fracture gap is bridged by the hyaline cartilage and woven bone, restoring some of its original strength and stability. The callus strength and stiffness appears to be prerequisites for mineralization of the fibrocartilage and subsequent transformation to woven bone. Mineralization appears to be a two-step process. The glycosaminoglycans (inhibit mineralization) are counteracted by neutral proteoglycanases secreted by the chondrocytes. Calcium phosphate complexes released by chondrocytes and osteoblasts initiate callus mineralization.

The next phase is the replacement of the hyaline cartilage and woven bone with lamellar bone thereby restoring much, if not all, of...
the bone's original strength. The replacement process is known as endochondral ossification with respect to the hyaline cartilage and 'bony substitution' with respect to the woven bone. The lamellar bone begins forming soon after the collagen matrix of either tissue becomes mineralized. Vascular channels and osteoblasts penetrate the mineralized matrix. The osteoblasts form new lamellar bone upon the surface of the mineralized matrix. This new lamellar bone is in the form of trabecular bone.

The fibrinous to osseous callus transformation closely resembles enchondral ossification and typically occurs in the central healing zone. More peripherally, the cambium layer of the elevated periosteum generates woven bone using intramembranous ossification (Figure 1.4.5). This develops a circumferential bone sleeve, hard callus, conveying early and progressive stability to the fracture site.

Remodelling phase

This process begins during the middle of the repair phase and continues long after the fracture has clinically healed (up to 7 years). The remodelling process substitutes the trabecular bone with compact bone and allows the bone to assume its normal configuration and shape based on the stresses to which it is exposed (Wolff's law). The trabecular bone is first resorbed by osteoclasts, creating a shallow resorption pit known as a 'Howship's lacuna'. Then osteoblasts deposit compact bone within the resorption pit. Eventually, the fracture callus is remodelled into a new shape which closely duplicates the bone's original shape and strength.

Box 1.4.5 Repair phase of bone healing

- Fibroblasts, chondroblasts, and osteoblasts invade granulation tissue
- Fibrous tissue is replaced by cartilage then bone to produce callus
- Bone healing from bone ends resembles endochondral ossification
- Bone healing from periosteum resembles intramembranous ossification.

Type of bone formation

Bone is formed via endochondral, intramembranous, and appositional ossification. With endochondral ossification, bone replaces the cartilage model. With intramembranous ossification, a cartilage precursor is not present. Undifferentiated mesenchymal cells differentiate into osteoblasts and deposit an organic matrix that mineralizes to form bone. Finally, with appositional ossification, osteoblasts align on the bone surface and lay down new bone.

Primary cortical healing occurs with rigid immobilization and anatomic reduction. With closed treatment of the fracture, endochondral ossification with periosteal bridging callus occurs. With rigidly fixed fractures (compression plate), direct osteonal or primary bone healing occurs without visible callus.

Primary bone healing

Primary or direct bone healing is characterized by the absence of formation of callus (which would otherwise be visible on x-ray). The prerequisites include anatomical reduction, absolute rigidity, and interfragmentary compression. Typically, primary bone healing usually occurs with a fracture gap of less than 2mm and motion at the fracture site of less than 1mm. With the development of anatomic reduction and stable fixation with metal plates and screws, the primary fracture healing was seen for the first time. The stability provided by the fixation allows early motion of adjacent joints allowing accelerated rehabilitation.

Primary bone healing is a continuous process of coupled bone resorption and bone formation (Figure 1.4.6). Bone remodelling units form parallel channels to the longitudinal axis of the bone and contain cutting cones lined by multinuclear osteoclasts. Behind the
cutting cone, the walls of the osteon are lined by osteoblasts which circumferentially appose new osteoid at the rate of about 1µm per day. Completion of a new osteon will take approximately 3–4 months.

The fracture site regains immediate stability with plate fixation, but fracture union usually occurs at a slower rate than would be seen under conditions of secondary bone healing. When comparing two identical fractures, one healing by primary and the other by secondary bone healing, the fracture that heals by secondary bone healing will initially be 66% stronger and 100% more rigid.

Gap healing

Gap healing typically occurs with gap sizes less than or equal to 1mm. The process requires micromotion at the fracture site and occurs in three stages. In stage one, there is rapid filling of the gap with woven bone. Stage two involves Haversian remodelling of the avascular areas at the margins of the fracture edge. In stage three, remodelling of the woven bone to lamellar bone occurs and bridges the gap.

Plate effects

Plating of a fracture provides stability but does not guarantee a particular type of fracture healing. Tightly applied plates may lead to bone necrosis and/or stress shielding.

The bone necrosis directly underneath the implant is caused by the interruption of the periosteal blood supply and the plastic deformation distorting or obliterating the small intraosseous vessels. Plates remaining in place for prolonged periods alter the load-bearing requirements. The resulting stress-shielding effect is dependent on the rigidity of the construct and may lead to permanent reduction of bone cross-sectional area. For this reason, removal of a plate from a large bone should be managed by a period of partial weight bearing (Figure 1.4.7).

Bone necrosis and remodelling after plate application. A) Application of a plate causes regional avascular necrosis under the implant. B) Within 3 months, bone metabolizing units advancing from the intact surrounding bone will remove the necrotic bone (initial porosis) and replace it with new lamellar osteons. Reproduced from Müller, M., Allgöwer, M., Schneider, R., et al. (1991).
Neutralization plates protect the primary lag screw from bending, shear, and rotational forces.

A plate applied to the tension side of a bone achieves stability by axial compression, but also, because of its location on the tension side, bending forces are generated under load. This leads to increased axial compression. Such a plate is referred to as a tension band plate.

Secondary bone healing

Secondary bone healing is often seen with fractures managed with traction or cast. Secondary bone healing progresses through an inflammatory phase followed, within a few days, by a repair phase (several weeks to a few months), and finally a remodelling phase which may continue for several years.

Distraction osteogenesis

Ilizarov invented the technique of distraction osteogenesis in the 1950s. The procedure describes a process of new bone formation after the creation of an osteotomy using controlled gradual distraction of the bone ends. Optimally, intramembranous bone develops. If the process is disturbed (e.g. lack of stability), cartilaginous tissue or fibrous tissue forms and non-union may develop. In addition to bone formation, there are effects on the muscles, vessel walls, and associated tendons. There are several prerequisites for successful distraction osteogenesis (Box 1.4.6).

Box 1.4.6 Prerequisites for distraction osteogenesis

- Fixator strong enough to provide stable fixation and eliminate torsion, shear, and bending
- Blood supply to osteotomy must be preserved—minimal soft tissue stripping/preserve periosteum
- Low energy corticotomy
- Distract at 1mm per day in steps of 0.25mm every 8h
- Osteogenic potential best where cancellous bone dominates—osteotomy through the metaphysis
- Latency period (no lengthening) of 3 days in young children and 5–10 days in adults
- Neutral fixation interval (no distraction) during consolidation
- Normal use of the extremity, including weight bearing (producing physiological loads).

The distraction period lasts until the desired length of new bone has been achieved. During the consolidation period, the newly formed bone matures. The fixators can be removed when the distraction gap has uniformly consolidated and at least three new cortices have formed (neocorticalization) as seen on orthogonal radiographs.

Histological observations

After initiation of distraction, trabeculae form on both sides of the osteotomy which are oriented in line with the distraction force. The outer surfaces of the trabeculae are covered by a layer of osteoblasts. While the interzone is relatively avascular, the regions between the trabeculae contain abundant capillary blood supply. It appears that the interzone consists of undifferentiated mesenchymal cells which, under optimal conditions, directly transform into osteoblasts (intramembranous bone formation). Under less optimal conditions, chondroblasts or fibroblasts emerge. Depending on the conditions, consolidation of the regenerate may still occur, by a process similar to enchondral ossification. Alternatively, a fibrous non-union may develop.

The Ilizarov fixator is primarily used for bone lengthening and is particularly useful where deformity correction may also be required. In addition, the fixator can be used for the management of non-unions using compression (instead of distraction) and the acute management of complex fractures (e.g. tibial pilon fracture). With optimal conditions, bone formation is principally by intramembranous ossification.

Box 1.4.7 Characteristic of ligaments

Ligaments are dense, highly organized connective tissue structures connecting bone to bone (Box 1.4.7). They are composed of cells (fibroblasts) and extracellular matrix principally of type I collagen (70% of the dry weight). They function by stabilizing joints and have embedded in them mechanoreceptors and free nerve endings. The sliding of collagen fibres over each other is key for changes in ligament length (growth and contracture). Compared with tendons, ligaments have a higher elastin content (e.g. ligamentum flaveum). In contrast to tendons, they have a uniform microvascularity and receive their blood supply at the insertion site. Ligaments are arranged in progressively more complex structures from fibrils to fasciculi which have a predominantly parallel (collateral ligaments) or spiral (cruciate ligaments) organization.
Mainly type I collagen (70% dry weight)
- Static and dynamic joint stabilizers
- Innervated for pain and proprioception (recruit musculotendinous units)
- Insert into bone directly by Sharpey’s fibres or indirect (blend with periosteum)
- Mobilization stimulates healing
- Prolonged immobilization leads to reduced strength and elasticity
- Exercise results in increased ultimate force, thickness, tensile strength, and ultimate stress
- Blood supply originates at the insertion sites and runs longitudinally through the ligament.

Ligament insertion into bone represents a transition from one material to another and can be classified into two types: indirect insertion (more common) and direct insertion.

With indirect ligament insertion, superficial ligament fibres insert at acute angles into the periosteum and tend to be broader than direct insertions (e.g. tibial insertion of the medial collateral ligament of the knee). With direct insertions (e.g. femoral insertion of the medial collateral ligament of the knee), there are superficial and deep fibres. The deep fibres insert at right angles to bone and superficial fibres blend with the periosteum. The transition from ligament to bone occurs in four stages: ligament, to fibrocartilage, to mineralized fibrocartilage, to bone. Sharpey’s fibres cross all four zones.

The tensile properties of ligaments are similar to those of tendons, with an initial toe region produced by the non-linear straightening of the crimped fibres. As elongation progresses, fibres become more parallel to the load. Ligaments exhibit viscoelastic properties such as creep, hysteresis, and stress relaxation. Clinically, this becomes relevant in anterior cruciate reconstruction where stress relaxation of graft materials may be observed in the initial hours after tensioning, and preconditioning may be appropriate prior to final tensioning. Many ligaments, such as the cruciates, have multiple bands of collagen fibres attached at different points of the insertion. This allows different components of the ligament to tighten with varying joint position.

Mechanisms of injury
Ligament sprains are the most common joint injuries. Three grades of severity are usually differentiated.

- Grade I disruption implies pain with stress, but no increase in laxity
- Grade II injuries produce a slight increase in laxity, but with a solid endpoint to stress
- Grade III injuries are complete disruptions of the ligament with significant laxity and an absence of a firm endpoint to stress.

In the knee, ligament injuries can be produced by contact (medial collateral disruption from a blow to the lateral aspect of the leg) or non-contact (anterior cruciate tears from varus internal rotation or valgus external rotation). The continued application of a deforming force will stress and injure secondary restraints, producing combined ligamentous disruptions. The most common mechanism of ligament failure is rupture of sequential series of collagen fibre bundles. Ligaments do not plastically deform. Mid-substance tears are more common in adults; avulsion injuries are more common in children. Avulsion typically occurs between the un-mineralized and mineralized fibrocartilage layers.

Healing of extra-articular ligaments
Healing occurs in three phases, a pattern similar to bone, and benefits from normal stress and strain across the joint. Immobilization adversely affects the strength (elastic modulus decreases) of an intact ligament and of a ligament repair. Immediately post injury, bleeding produces a fibrin clot. Within 3 days, macrophages, platelets, and neutrophils migrate to the injury site and release chemotactic, proteolytic and angiogenic factors. Early healing produces a disorganized cellular scar consisting primarily of type III collagen and proteoglycans. The proliferative scar formation slowly produces increased type I collagen. Remodelling takes place up to a year following injury. Mature ligament repair tissue only achieves 70% of the tensile strength of normal ligament tissue. The increased cross-sectional area of the repair tissue appears to compensate for this weakness. Increased tensile stress and early mobilization in the healing phase of a transected medial collateral ligament results in increased total collagen and improved histological organization. Therefore, operative repair is not always necessary.

Healing of intra-articular ligaments
Intra-articular ligaments do not display predictable healing. A fibrin clot is not produced after an anterior cruciate ligament injury, maybe because of synovial fluid interference. Repairs of mid-substance intra-articular ligament tears have rarely been successful and as a consequence such interventions have been replaced by primary or secondary reconstructions.

Injury and repair of articular cartilage

Basic concepts
The varieties of cartilage include: growth plate (physeal), fibrocartilage at tendon and ligament insertions, elastic (e.g. trachea), fibroelastic (e.g. meniscus), and articular cartilage. Articular cartilage functions to reduce friction and distribute loads across joints. It is classically described as avascular, aneural, and alymphatic. Chondrocytes receive nutrients and oxygen from synovial fluid via diffusion through the matrix.
Composition

The tissue predominantly consists of water (65–80% of wet weight). Shifts of the retained water in and out of cartilage allow for surface deformation secondary to the stresses applied. In osteoarthritis, the water content may increase to account for 90% of weight. Increased water content results in increased permeability, reduced strength, and decreased Young's modulus of elasticity. In addition, water is involved in nutrition and lubrication. The primary mechanism responsible for lubrication during dynamic function is elastohydrodynamic lubrication. Here, deformation of articular surfaces and thin films of joint lubricates separates the surfaces. Other types of lubrication methods include: boundary, boosted, hydrodynamic, and weeping lubrication.

Collagen makes up 10–20% of the wet weight and type II collagen accounts for approximately 90–95% of the total collagen content. The cartilaginous framework which anchors the cartilage to the subchondral bone is responsible for tensile strength and shear stiffness. Cartilage consists of a limited number of chondrocytes (5% of wet weight) surrounded by extensive extracellular matrix consisting mainly of type II collagen and proteoglycans (10–15% of wet weight). Protein polysaccharides provide compressive strength. Proteoglycans are produced by chondrocytes and are composed of subunits of glycosaminoglycans (GAGs). GAGs are bound to a protein core by a sugar bond to form an aggregan molecule. Charged hydrophilic groups on the proteoglycans hold water and produce the swelling pressure resulting in the ability of cartilage to resist compressive loads. Shear and compression squeeze water to the articular surface and thus diminish friction during joint motion. Other matrix components include adhesives (fibronectin, chondronectin) and lipids.

With aging, chondrocytes increase in size and no longer reproduce leading to a relative hypocellularity. Cartilage stiffness increases. The proteoglycans decrease in mass and size. Protein content increases and water content decreases. These changes lead to a reduced elasticity. The structure and layers of articular cartilage are described in Box 1.4.8.

Box 1.4.8 Structure of articular cartilage

- Collagen network held in tension by hydrostatic pressure from proteoglycan surface
- Surface gliding layer (10–20%): tangential array of cells and collagen fibres inserted at right angles to each other. This zone has the greatest tensile strength
- Middle transitional layer (40–60%): obliquely arranged fibres
- Deep radial layer (30%): vertical fibres with increased chondrocyte volume. The collagen fibres are oriented perpendicular to the joint surface
- Tidemark: boundary between the calcified and uncalcified cartilage
- Basal zone: calcified cartilage linking to the subchondral bone (hydroxyapatite crystals anchor the cartilage to subchondral bone) forms a transitional zone of intermediate stiffness between cartilage and subchondral bone.

Cartilage injury

Vascular–inflammatory tissue response to injury occurs only once the subchondral bone is penetrated, allowing distinction between superficial cartilage injuries which do not involve the subchondral bone and deep cartilage injuries which do (Box 1.4.9, Figure 1.4.8).

Box 1.4.9 Types of cartilage injury

- Superficial: vertical fissures (wedge-shaped defects) that rarely progress beyond the tidemark and subchondral bone
- Deep: penetrates subchondral bone resulting in haematoma, fibrin clot, and activation of inflammatory response. Fissuring of the calcified cartilage and then the subchondral bone can occur with secondary progression to fibrillation of the more superficial layers.
Cartilage healing

The stages of cartilage healing are summarized in Box 1.4.10. Deep injuries may heal with fibrocartilage which is produced by undifferentiated marrow mesenchymal stem cells that differentiate into cells capable of producing fibrocartilage. Type I collagen is in abundance at 1 year post injury. For deep injuries, most of our knowledge stems from techniques such as drilling and puncturing the bed of osteochondral defects and abrasion chondroplasty. Here the calcified cartilage is penetrated or removed down to bleeding subchondral bone which is initially covered by a fibrin clot. This is followed by formation of hyaline cartilage (type II collagen) and later fibrocartilage (type I collagen). Superficial lacerations cause chondrocytes to proliferate but do not heal because cartilage is avascular.

Box 1.4.10 Cartilage healing

- Superficial: chondrocyte proliferation and matrix production insufficient to repair the defect completely
- Deep: fibrin clot replaced by hyaline cartilage (type II collagen) and then by fibrocartilage (type I collagen)

Injury and repair of tendons

Structure and anatomy

Tendons are densely arranged tissues that connect and transmit loads from muscle to bone. They are structurally organized in order to resist high tensile forces and are composed of groups of collagen bundles (fascicles—composed of fibrils), separated by endotenon with surrounding epitenon (Box 1.4.11). The predominant cell type is fibroblasts. They are arranged in parallel rows in fascicles with surrounding peritenon (areolar tissue). The spindle-shaped fibroblasts mainly produce type I collagen and synthesize the connective tissue matrix precursors including elastin, and proteoglycans. Elastin is a protein found in small quantities within tendons (less than 1% dry weight). It enables tendons to undergo large changes in length without any permanent structural change. The water-binding capacity of proteoglycans, glycoproteins, and glycosaminoglycans influences the viscoelastic properties of tendons.

Box 1.4.11 Structure of tendon

- Mainly type I collagen (85%)
- Small amounts of type III and IV collagen
- Fascicles held together by endotenon (permits longitudinal movement)
- Endotenon is continuous with peristeum—carries blood supply, lymphatics, and nerves
- Epitenon—peripheral to the endotenon
- Paratenon surrounds some tendons and functions as an elastic sheath to allow free gliding
- Peritendon—comprised of the epitenon and paratenon (Figure 1.4.10)
- Synovium surrounding some tendons is called tenosynovium (e.g. flexor tendons in hand).
Fig. 1.4.10
Structural organization of tendon.

The collagen contains a high concentration of the amino acids glycine (33%), proline (15%), and hydroxyproline (15%). All types of collagen consist of three particular chains covalently cross-linked and combined with globular and non-helical structural elements to form a rigid triple tropocollagen molecule. In the extracellular matrix, collagen molecules become aligned head-to-tail and side-by-side in a quarter-staggered array (Figure 1.4.9) leading to a highly ordered and stable unit of microfibrils and fibrils.

Fig. 1.4.9
Schematic drawing of the structural organization of collagen in the microfibril.

Tendons surrounded by paratenon are referred to as vascular tendons. Those surrounded by a tendon sheath are called avascular tendons. The avascular tendons contained within synovial sheaths have mesotenons that function as vascularized conduits called vincula. In addition, both types of tendons have additional blood supply from vessels originating in the muscle and bone attachments.

Biomechanical properties

Tendons insert into bone via four transitional tissues: tendon, fibrocartilage, mineralized fibrocartilage (Sharpey’s fibres), and finally to bone. Tendinous structures orient themselves along stress lines and possess one of the highest tensile strengths of all soft tissues. However, because of the low amount of ground substance, tendons resist shear and compressive forces poorly.

Elongation of tendons is dependent on the force magnitude and the rate and duration of the force. With repetitive loading and unloading, their stress–strain curve moves to the right as the tendon becomes less stiff or more compliant. An increase in elongation, speed, and a higher strain rate moves the curve to the left, indicating increasing stiffness. This protects tendons from rupturing under very large eccentric forces. Tendons also exhibit creep. In an isometric contraction, tendon lengthening from creep allows the muscle to shorten over time. This increases muscle performance by decreasing fatigue.

Factors affecting the properties of tendons are described in Box 1.4.12.

Box 1.4.12 Factors affecting biomechanical properties of tendons

- Exercise increases collagen fibril size and strength, ultimate tensile strength (UTS), and stiffness
- Immobilization decreases water content and proteoglycan concentration, UTS, and stiffness
Anatomical location

- Collagen content of fibril and fibril diameter reduces with age leading to reduced UTS. The collagen cross linking increases with age leading to greater stiffness.

Tendon injury

Indirect or direct trauma may lead to tendon injury. The former commonly manifests as an intrasubstance rupture or bony avulsion. The injury is influenced by anatomic location, vascular supply, skeletal maturity, and the magnitude of the applied force. Most indirect injuries are at the bone–tendon or muscle–tendon interface. This is related to tendons’ ability to withstand high tensile forces. Mid-substance tendon rupture is often secondary to pre-existing pathological conditions and may be seen in chronic overuse injuries with repetitive microtrauma and incomplete healing. Common sites of degenerative change include the Achilles, patella, rotator cuff, and biceps tendons.

Tendon healing

Tendons have extrinsic and intrinsic healing potential. The extrinsic theory hypothesises that an inflammatory response by the surrounding tissues is involved. The intrinsic theory maintains that tendons possess an intrinsic capability to heal.

Healing continues in three phases: inflammatory, reparative or collagen-producing phase, and a remodelling phase (Box 1.4.13). In the inflammatory phase, cells from the extrinsic peritendinous tissues (synovial sheath, deep fascia, and periosteum) and intrinsic tissue of the epitenon and endotenon move into the injured area (first 48–72h) and remove cellular debris and collagen remnants. Granulation tissue is produced to bridge the defect. In the inflammatory phase, tendon repair strength is almost entirely dependent on the suture strength. In the reparative stage, fibroblasts are actively involved in collagen synthesis and resorption. The remodelling phase results in increased mechanical strength. Tension on the granulation tissue results in remodelling of fibre architecture; similar to Wolff’s law for bone.

Box 1.4.13 Healing of tendons

- Inflammatory phase (to day 14): defect filled with fibrin clot, tissue debris, and fluid
- Reparative phase: collagen synthesis begins in first week (maximum at week 4)
- Collagen orientates over 4 weeks (perpendicular to the long axis of the tendon to parallel)
- The synovial sheath repairs in 3 weeks
- Remodelling (after 4 weeks): collagen production changes from type III to type I for 12 months.

Methods of improving tendon repair

The most important factor appears to be postoperative mobilization of tendon repairs. Rapid commencement of tendon gliding provides the stimulus for cellular activation of the epitenon (intrinsic response). Continued immobilization stimulates ingrowth of cells from the surrounding tissues (extrinsic response) leading to adhesions. An ideal postoperative protocol is one providing the greatest tensile stress across a repair and preventing gap formation or rupture of the repair. The ultimate goal is to restore immediate motion and stress to a tendon repair. Limiting factors include the strength of the repair, which is a factor in all locations of injury. The benefits of passive mobilization are characterized in Box 1.4.14.

Box 1.4.14 Consequences of passive mobilization of tendons

- Rapid recovery of tensile strength
- Fewer adhesions
- Improved excursion
- Better nutrition.

Following suture principles increases strength of the repair (Box 1.4.15).

Box 1.4.15 Factors affecting suture of tendons

- The larger the suture calibre the greater the strength
- Core sutures should pass perpendicular to the tendon
- Increasing the number of suture strands increases the strength of the repair
- Peripheral epitendinous suture leads to 10–50% increase in strength and reduces gapping
Place sutures in regions that do not compromise tendon blood supply (volar 50% of flexor tendons)
Repair of tendon sheath reduces adhesion formation, restores synovial fluid nutrition, and restores sheath mechanics.

Nerve injuries and repair

Peripheral nerve anatomy

The peripheral nerve is a highly organized structure made of nerve fibres, blood vessels, and connective tissue. They possess peripheral processes named axons which are covered with a fibrous tissue called endoneurium. The axons group into nerve bundles called fascicles (smallest unit of a nerve), covered by a connective tissue layer named perineurium. Schwann cells support and surround the axons. Groups of fascicles are bound together by the epineurium, which provides a gliding surface. Fascicles are vascularized segmentally by epineurial vessels and each fascicle has a longitudinally-oriented perineural and endoneurial microvascular system. Myelinated axons conduct action potentials rapidly, facilitated by nodes of Ranvier (gaps between Schwann cells).

Classification of nerve injuries

Sharp lacerations result in nerve transactions whereas the energy transfer secondary to a blast, crush, or traction injury leads to unpredictable nerve damage. Neurological studies such as electromyography (EMG) and nerve conduction studies may be useful to document injury extent. Cortical evoked potential testing is the most accurate method. Seddon (1943) first described three types of nerve injury: neurapraxia, axonotmesis, and neurotomesis. Subsequently, Sunderland (1951) defined five severity degrees with two degrees lying between axonotmesis and neurotomesis (Box 1.4.16).

Box 1.4.16 Types of nerve injury in progressive order of severity

- First degree/neuapraxia: local conduction block secondary to segmental demyelination
- Second degree/axonotmesis: Wallerian degeneration with distal degeneration, epineurium continuity
- Third degree: disruption of the endoneurial tube and axon, perineurium continuity
- Fourth degree: disruption of all structures except the epineurium
- Fifth degree/neurotomesis: disruption of entire nerve.

Healing of nerve injuries

Peripheral nerve injury results in death of the distal axons and Wallerian degeneration of myelin. Macrophages remove degraded myelin and axoplasm. Regeneration is dependent on nerve cell survival. The remaining Schwann cell tube serves as a guide for the sprouting axon. The distal nerve stumps and target organs facilitate axonal regeneration using neurotropic and adhesive factors. Within hours of injury, a regenerating axon produces multiple sprouts from the most distal intact node of Ranvier which enter the Schwann cell tubes. Eventually, only one axon is regenerated. Proximal axonal budding occurs approximately 1 month post injury and results in regeneration at a rate of about 1mm/day. Pain is the first modality to return. The final pathway to achieving nerve regeneration requires the plasticity or re-education of the central nervous system. The brain must undergo some re-education to interpret the stimulus correctly.

Nerve repair

Basic principles

Some basic principles are discussed in Box 1.4.17. Motor recovery is unlikely if there is lack of reinnervation by 18 months, and results are worse if repair is performed 6 months after the injury.

Box 1.4.17 Principles of nerve repair

- Sharp lacerations should be explored and repaired
- Open injuries with nerve deficits: explore and nerve ends repaired or tagged for later repair
- Blunt closed injuries should be observed
- If no recovery in 3 months (lack of advancing Tinel, electrical studies), explore
- Delayed repair: contamination, lack of soft tissue cover, blast injury, or head injury prevent assessment

The following key concepts underpin successful nerve repair:

1) Microsurgical techniques with adequate magnification, instrumentation, and microsuture
2) Adequate exposure of both ends followed by debridement and resection of the damaged nerve section to minimize scar
tissue formation
3) Reapportion of nerve ends tension-free with avoidance of extreme positioning of the extremity
4) Primary nerve repair should be performed whenever possible
5) Align fascicles accurately.

Accurate nerve alignment is critical for optimal outcome. The simplest method is using anatomical landmarks such as epineural blood vessels and fascicle arrangement. Electrical stimulation in the awake patient can help delineate motor and sensory fascicles in the proximal stump. Staining of the nerve ends using acetylcholinesterase (motor) and carbonic anhydrase (sensory) may be performed on sections of proximal nerve ends to identify sensory and motor fascicles of the proximal stump only.

Repair techniques

Three types of direct repair are available to the surgeon: epineural, group fascicular, and fascicular. Factors influencing results of nerve repair are summarized in Box 1.4.18.

- **Epineural repair** is used when internal topography of the nerve is unclear. Fascicles are aligned using fine monofilament suture under high-power magnification. Sutures are placed only through the epineurium to avoid bunching. Tension must be assessed after the repair and the extremity taken through a gentle range of motion.
- **Group fascicular repair** is most useful in nerves with few groups and in partial lacerations where complete fascicular groups are lacerated. The fascicle groups are exposed by splitting the epineurium longitudinally. The largest identifiable fascicle group should be repaired first. The epineurium is finally repaired to minimize tension.
- **Fascicular repair** is useful in partial lacerations and in nerves with few fascicles. The technique requires dissection of external and internal epineurium to expose the fascicles. Repair is effected using one or two sutures of 10-0 or 11-0 nylon placed in the perineurium.

**Box 1.4.18 Factors that influence success of repair**

- Age: children do best (greater cerebral plasticity adapts well to new signals). Adults may improve up to 5 years.
- Level of injury: proximal injuries have poorer results because distal muscles become fibrotic before regenerated motor axons reach their target.
- Type of nerve: mixed motor and sensory nerves have inferior recovery compared with primarily motor or sensory nerves—difficulty in alignment.

Nerve grafts

Complex crush and blast injuries are best treated with nerve grafts. When there is no recovery after approximately 3 months, exploration and repair may be indicated. The success of grafting and sources of nerve graft are documented in Box 1.4.19.

**Box 1.4.19 Successful grafting procedures and sources of nerve graft**

- Principles which provide good nerve healing:
  - Healed and supple wound
  - Well-vascularized recipient bed
  - Nerve ends must be free of scar tissue
  - Fascicular anatomy is recorded, and appropriately matched groups of fascicles connected with a nerve graft.
  - Grafts must be sutured tension-free in the correct anatomic alignment for success.
- Sources of graft:
  - Sural nerve provides 30–40 cm of graft—tightly packed fascicles and little interfascicular tissue
  - Medial antebrachial cutaneous nerves
  - Terminal branch of the posterior interosseous nerve.

Postoperative care

The site of the nerve repair, or the proximal and distal ends of a nerve grafts, are carefully documented. The extremity is immobilized in a position that relieves all suture lines which may be maintained for 4 weeks. Regeneration is monitored by physical examination and electrical studies. As sensory axons may regenerate to sensory end-organs, the signal the brain receives may not correspond to the actual stimulation. The patient must be re-educated to interpret the new signal. Children accomplish this much more readily than older patients. Placing the cut nerve endings into a tube (silicone, biodegradable material, or vein) has demonstrated excellent results in pure sensory nerve injuries.
Proprioception

Proprioception gives us a sense of position and movement in relation to space, and initiates and coordinates the muscle functions that first stabilize a joint and then make it the fulcrum of a precise, coordinated motion. Deficits occur when afferent sensory nerve fibres are interrupted (injury or disease) and can affect entire limb function. Vision can be a substitute but is less effective in the lower than in the upper extremity. Proprioception relies on information from sensory, visual, and vestibular inputs. Based on afferent information, efferent stimuli are generated centrally. These stimuli activate agonistic and antagonistic muscle groups to reposition joints and extremity segments.

Sensory input derives from muscle spindles, Golgi tendon organs, Pacinian corpuscles, Meissner’s corpuscles, and other receptors in muscles, tendons, ligaments, joints, and skin. The cell bodies of these nerve fibres are located in the dorsal root ganglia. From here, fibres connect to neurons relaying information centrally to the cerebellum, medulla, thalamus, and the cerebral cortex (Figure 1.4.11). Isolated injuries to ligaments, joints, muscles, or other end-organs results in a focal loss of feedback.

![Central nervous system pathways mediating proprioception and stereognosis.](image)

Head injuries: presentations and outcomes

Head injury is often associated with major musculoskeletal disruptions and cerebral lesions are commonly diagnosed late or managed inadequately. Head injuries are two to three times more common in males and have a higher incidence in summer months. The commonest mechanism of injury is motor vehicle accidents. Although many head injuries present similarly, they can be differentiated by the type of pathological lesion as follows.

- **Shearing/diffuse axonal injuries** Shearing is a consequence of acceleration, deceleration, and rotational forces which damages the brain by stretching and compressing fibre tracts, and moving the brain over bony prominences. Shearing and diffuse axonal injuries are rarely picked up on initial computed tomography (CT) scans. Magnetic resonance imaging (MRI) is the gold standard in detecting these injuries.
- **Contusions** These are bruises or haematomas on or close to the brain’s surface. They commonly affect the frontal and temporal lobes. They may be asymptomatic or associated with severe neurological deficits and seizures.
- **Epidural haematoma** This refers to a collection of blood between the dura mater and the skull and occurs secondary to a tear of the middle meningeal artery. They can cause sudden compression of the brain and be fatal. Clinically, a short lucid interval is typical, followed by loss of consciousness.
- **Subdural haematoma** The bleeding occurs within the subdural space. Onset may be acute or, especially in the elderly, chronic. Chronic lesions are commonly caused by linear and rotational forces which tear the veins between the brain and the dura mater. Most subdural haematomas result in significant focal damage of the cortex and co-exist with brain contusions.
- **Subarachnoid haemorrhage** Bleeding into the subarachnoid space is often caused by trauma but may occur spontaneously after rupture of a berry aneurysm. The bleeding is usually diffuse and does not cause a space-occupying lesion.
- **Intracerebral haematomas and brain displacement** These space-occupying lesions are often accompanied by swelling of surrounding brain tissues. They may cause life-threatening brain herniation following expansion.

Classification and assessment of head injuries

The Glasgow Coma Scale provides a score (in the range 3–15) to initially assess the likelihood of a brain injury. A score of 3 indicates that the patient is unresponsive. A score less than 9 must prompt an urgent evaluation of the airway. With a score of 15,
the patient is alert, oriented, and able to follow commands. While the Glasgow Coma Scale is an excellent predictor of gross outcome, it is less reliable in predicting neurobehavioral outcomes. The most reliable predictor of neurobehavioral outcome is the duration of post-traumatic amnesia. When the patient has sustained post-traumatic amnesia of 24h or less, the head injury is classified as mild. If the post-traumatic amnesia lasts from 24h to 7 days, the head injury is considered moderate. Post-traumatic amnesia beyond 7 days indicates a severe head injury.

CT scans and MRI scans provide additional parameters to assess head injury. However, a patient with a very severe head injury may have negative initial findings on both CT and MRI scans.

In summary, the key factors that predict the severity of a head injury are as follows:

- The Glasgow Coma Scale score
- Duration of loss of consciousness or coma
- Duration of post-traumatic amnesia
- The nature and extent of the cerebral lesion as seen on CT or MRI.

Positive prognostic factors include high premorbid intelligence quotients and socioeconomic status, as well as a supportive family structure.

Clinical presentation: postconcussive syndrome

Neurobehavioral symptoms following head injuries are often missed because of inexperience or masking secondary to pain medication. Typical symptoms of postconcussive syndrome include inhibition, euphoria, emotional lability, confusion, memory disturbance, disturbance of social or occupational functions, concentration, and higher-order thought deficits.

Many head injuries have psychological sequelae such as irritability and agitation as well as exaggerated reactions to painful stimuli. Protracted malaise and depression may be the sequelae of a concomitant head injury. Diagnosis and management of many head injuries can be improved by consulting an experienced clinical neuropsychologist skilled in cognitive-behavioural techniques such as desensitization or hypnotherapy.

Acute and chronic higher cortical deficits due to head injuries

Acute deficits

Patients with significant head injuries are usually comatose or obtunded on presentation. With recovery, the level of cortical arousal becomes heightened and the mental status improves. Postcomatose patients display moderate to severe global and diffuse deficits of cognitive function.

Influence of age

Adult patients may remain in a coma for long periods and only gradually recover their mental capabilities. Children tend to improve quickly or perish. Typical symptoms resulting from traumatic brain injury in adults are either absent or short-lived in the paediatric population.

Language functions

Most adult patients sustaining injury to the temporal lobe will experience severe aphasia, difficulties in comprehension, naming, repetition, reading, and writing. If children present with aphasic symptoms, recovery is often rapid. Complete mutism, which resolves in 1 or 2 weeks, may be pronounced. Similar differences have been observed with respect to visual and visuospatial dysfunction.

Psychiatric problems

Adults may suffer a range of psychiatric conditions, from mild anxiety disorders to psychosis. Children under 10 years of age frequently suffer attention-deficit disorders without the hyperactive component. Adolescents tend to experience depression, anxiety, and explosive behaviour.

Long-term deficits

Most neurobehavioral recovery occurs 12 months after injury. Improvement up to 3 years is not uncommon. Residual deficits usually involve attention and concentration, verbal and visual memory, and higher-thought processes including planning, problem solving, and strategy formation. Resolution of these symptoms is usually much more complete in the paediatric population.

Further reading

Summary points

♦ Haemoglobinopathies are commonly inherited disorders of haemoglobin synthesis
♦ Thalassaemia is commonest around the Mediterranean countries and has skeletal manifestations due to massive marrow expansion with thinning of the cortex
♦ Sickle cell crises occur in homozygotes and are a result of venous occlusion causing avascular necrosis. Infection and exposure to cold can sometimes precipitate these painful events
♦ If surgery is needed blood cross-match must be carefully performed in advance, the theatre should be kept warm, and the hydration and acid/base balance of the patient monitored carefully.

Introduction

Haemoglobinopathies are inherited disorders of haemoglobin resulting from synthesis of abnormal haemoglobin molecules. In general, these conditions are encountered in people originating from tropical or subtropical areas, and it is believed that these conditions originally developed to confer protection against malaria. Although the management of these disorders is primarily the province of the haematologist, these conditions may be accompanied by orthopaedic and other surgical complications.

Sickle cell disease

This condition is due to a single mutation in the β-globin chain of the haemoglobin molecule: valine is substituted for glutamic acid at position 136. The abnormal haemoglobin is unstable and forms precipitates within the erythrocyte due to polymerization when deoxygenated. The gene is encountered predominantly in people of Afro-Caribbean origin, among whom the gene frequency may be as high as 5%. The gene is also found with a lower frequency among people of the Mediterranean region, Middle East, and Indian subcontinent. Carriers of this condition (sickle cell trait) have a mixture of both normal and abnormal haemoglobin (Hb A/S) but have no clinical problems. The term sickle cell disease applies to Hb S/S homozygotes, who have significant problems including recurrent episodes of painful ‘crises’. These are due to intramedullary necrosis following occlusion of small vessels. Often there is no obvious precipitating cause, but it is recognized that infections, dehydration, and exposure to cold or low levels of oxygen can provoke crises. The most frequently involved areas are the knee, lumbosacral spine, elbow, and femur. Less often the ribs, sternum, clavicles, calcaneus, and facial bones are affected. Involvement of the facial bones may be associated with impressive facial swelling. Joint effusions are commonly seen when the knees or elbows are involved. The course of sickle cell disease is variable and many patients with sickle cell disease lead essentially normal lives punctuated by only occasional painful crises. However, in others the course can be much more serious with recurrent strokes such that bone marrow transplantation may be required in some cases.

Crvises in bones and joints should be treated conservatively, with bed rest, maintenance of good fluid balance, and correction of hypoxia if the lungs are affected. Crises can be extremely painful, and opiate analgesics are usually needed. Extensive sickling within the lungs can be life threatening (‘chest crisis’). This can initially present with cough, fever, and pleuritic chest pain, and a chest radiograph shows extensive infiltration of either one or both lung fields (Box 1.5.1).

Box 1.5.1 Complications of sickle cell disease

♦ Vascular occlusions in:
  • Bone marrow
  • Brain
  • Kidney
  • Lung
  • Retina
  • Spleen
♦ Aplastic crisis (parvovirus B19)
♦ Leg ulcers
♦ Gallstones
♦ Osteomyelitis
♦ Priapism.
Adults with sickle cell anaemia typically have a chronic haemolytic anaemia, with a haemoglobin level typically in the range of 7–10g/dL. The blood film is characteristic (Figure 1.5.1), with numerous irreversibly sickled cells (which are evident even in the absence of clinical problems), target cells, and normoblasts. The chronic haemolytic process results in consumption of folic acid, and oral supplementation is often required. Parvovirus infection in young children with sickle cell disease, and other haemolytic anaemias, can trigger the onset of a profound but transient drop in the haemoglobin level (‘aplastic crisis’).

![Click to view larger](image)

**Fig. 1.5.1**
Peripheral blood film from a patient with sickle cell anaemia, showing the typical hyperchromatic sickled cells as well as target cells.

Fetal haemoglobin is composed of paired α- and γ-chains, but by approximately 6 months of age production of β-chains replaces that of fetal γ-chains and this is when the first symptoms of the condition appear. Dactylitis (‘hand–foot syndrome’) is often the first manifestation of the condition: the digits of the hand or feet become painful, swollen, hot, and tender due to sickling within the bone. There are usually no radiologic changes during the acute episode, although subperiosteal bone formation may be seen a couple of weeks afterwards. Permanent shortening of the digits may occasionally result. Children born with sickle cell anaemia have a normal birth weight, but often exhibit delayed growth, reflected by delayed bone age on radiologic examination. Avascular necrosis of the hip is a not infrequent complication in adolescents as well as adults, and may be bilateral. The risk is particularly high in individuals with haemoglobin SC disease, and this is believed to reflect the fact that these patients tend to have higher haemoglobin concentrations and thus the whole blood viscosity is higher. Total hip replacement may certainly be carried out, although the revision rate is quite high in these patients as the poor quality of the bone may result in early loosening of the prostheses. Osteonecrosis may also occur in other joints, such as the shoulder.

Repeated episodes of splenic infarction lead to loss of immune function with particular susceptibility to capsulated bacteria. Patients with sickle cell anaemia are particularly vulnerable to pneumococcal infections, and vaccination against both Streptococcus pneumoniae and Haemophilus influenzae as well as continuous prophylactic penicillin are important measures. Osteomyelitis due to Salmonella is also a recognized complication of sickle cell disease, involving the bones of the leg and axial skeleton in particular. Blood cultures may yield positive results, but needle aspiration of suspicious lesions is often required. There is a significant risk of sepsis as a complication due to infection, and this is often associated with a wide range of complications including sepsis, septicemia, meningitis, and respiratory tract infections. Early treatment of injuries to the bone may prevent the development of such ulcers. Repeated infection within the hypertonic environment of the renal medulla often results in recurrent episodes of painless haematuria. Eventually, the ability to concentrate urine is impaired, and patients are thus prone to dehydration. It is thus vital that particular attention be paid to fluid balance in patients with sickle cell anaemia who are hospitalized for any reason, particularly after surgery when oral fluid intake may be restricted.

**Surgery in patients with sickle cell anaemia**

Elective surgery in patients with sickle cell disease is generally safe, but it must be appreciated that despite optimal care there is a significant risk of perioperative complications such as precipitation of a sickling crisis (including acute chest syndrome or stroke), infection, or serious transfusion reactions. Patients with sickle cell disease do not tend to require regular transfusions to maintain a stable haemoglobin level. If they do require a blood transfusion for any reason, it should be borne in mind that these patients are at particular risk of developing red-cell antibodies after repeated transfusions (particularly against Kell and Duffy antigens) because of their different ethnic origin from the general donor population, and screening for such antibodies is thus particularly important before surgery to ensure that compatible blood can be made available in case of necessity. Certain measures can be taken in the setting of surgery to minimize the risk of provoking a sickle crisis:

- Keep operating theatre warm (at least 25°C)
- Ventilate with 100% oxygen before and after intubation or extubation
- Keep the patient warm in the recovery room
- Ensure adequate hydration at all times
- Monitor acid–base balance
- Pay particular attention to splints to ensure that peripheral circulation is not restricted.

A tourniquet can be applied in the case of procedures that require a bloodless field. The repeated postoperative use of a spirometer...
appears to reduce the risk of pulmonary complications, such as atelectasis or infection, presumably by promoting aeration throughout the lungs.

**Thalassaemia**

The thalassaemias are actually a group of haematological disorders in which a defect in the synthesis of one or more of the globin polypeptide chains is present, resulting in the formation of unstable aggregates of globin chains within erythrocyte precursors which are prematurely destroyed. A full classification of the thalassaemias is beyond the scope of this chapter, but the principal division is that between disorders involving the α-chain and the β-chain of the haemoglobin molecule. The prevalence of the genes for thalassaemia is particularly high in Mediterranean countries (especially Greece, Italy, Cyprus, and North Africa), the Middle East, the Indian subcontinent, and South East Asia. Carriers of βthalassaemia, the commonest form in European countries, have no clinical problems, apart from a mild and persistent microcytic anaemia with a haemoglobin typically in the range from 10–12g/dL.

**Clinical and laboratory features**

Severe anaemia becomes apparent at 3–6 months of age in β-thalassaemia major, and this is accompanied by massive enlargement of the liver and spleen due to excessive red cell destruction and extramedullary erythropoiesis. Examination of the blood film shows severe hypochromic, microcytic anaemia with reticulocytosis. Haemoglobin electrophoresis is required for definitive diagnosis; the hallmark of β-thalassaemia major is the absence of normal haemoglobin A, which is replaced by fetal haemoglobin (Hb F) together with some Hb A₂.

**Skeletal changes in thalassaemia**

In the absence of treatment with regular blood transfusions, there is marked expansion of the bone marrow to compensate for the ineffective erythropoiesis. This is associated with both osteoporosis and thinning of the cortex in the bones, which can result in pathological fractures. Striking features in untreated children include prominence of the parietal and frontal bones and protrusion of the maxillary bones, leading to malocclusion of teeth and orthodontic problems (Figure 1.5.2). Radiographs of the skull show a characteristic ‘hair-on-end’ appearance, due to widening of the diploë (Figure 1.5.3). Premature fusion of the epiphyses of the long bones, particularly the epiphysis of the proximal humerus, can result in shortening of the arms. Very occasionally, expansion of the haemopoietic tissue within spinal vertebrae leads to extrusion of marrow into the paravertebral area which can result in spinal cord compression. Decompressive laminectomy and even radiotherapy have been used in such cases to prevent permanent paralysis. Compression fractures of the vertebrae may also be seen (Box 1.5.2).
Fig. 1.5.3  
Skull radiograph of a patient with severe thalassaemia. The typical ‘hair-on-end’ appearance is due to widening of the diploë.

Box 1.5.2 Thalassaemia: summary of key points

- Thalassaemia trait: chronic microcytic anaemia but no other significant problems
- Thalassaemia major: profound anaemia requiring regular blood transfusion
- Iron overload can result in:
  - Diabetes mellitus
  - Cardiac failure and arrhythmias
  - Cirrhosis
- Iron chelation therapy (e.g. with desferrioxamine) can delay onset of iron overload
- Many patients from developing world exposed to hepatitis and HIV after repeated blood transfusions
- Musculoskeletal complications can include:
  - Prominence of maxillary and frontal bones of skull, with dental malocclusion
  - Frontal bossing and ‘hair-on-end’ appearance on skull x-ray
  - Premature fusion of epiphyses
  - Spinal cord compression due to extrusion of hypertrophic bone marrow
  - Pathological fracture due to cortical thinning and osteoporosis.

Medical complications

Somewhat paradoxically, many of the serious medical complications seen in thalassaemia actually result from treatment of the condition. In contrast to sickle cell disease, people with β-thalassaemia major require regular blood transfusions. A programme of regular transfusions to maintain a haemoglobin level of 10g/dL will lead to regression of hepatosplenomegaly and skeletal changes. The skeletal changes described earlier are therefore unlikely to be seen by orthopaedic surgeons working in developed countries, where children are adequately treated from an early age. Splenectomy may occasionally be needed to reduce the requirement for blood transfusions, but this should be delayed until the patient is at least 6 years old because of the high risk of pneumococcal and other bacterial infections earlier in life. Pneumococcal vaccine should be given preoperatively in such cases, and prophylactic penicillin will be required after splenectomy. Patients should also be vaccinated against Haemophilus influenzae.

Regular blood transfusion eventually leads to iron overload, with deposition of iron in the tissues resulting in fibrosis. Iron overload may result in diabetes mellitus, cirrhosis, and cardiac complications such as arrhythmias or congestive cardiac failure. Subcutaneous infusions of the chelating agent desferrioxamine may postpone the onset of iron overload. Oral iron chelators such as deferasirox and deferiprone have become available in recent years. Some patients with thalassaemia (particularly those in the developing world) have also been exposed to viral infections such as hepatitis C or even HIV through blood transfusions.

Summary points

- The risk–benefit of thromboprophylaxis in orthopaedic surgery remains unclear
- Some conditions, such as major trauma, carry a much higher risk than others, such as routine knee replacement
- Some patients appear to be genetically more predisposed than others
- In trials of efficacy of thromboembolism, the use of deep vein thrombosis as a surrogate endpoint for death from a pulmonary embolus may not be completely reliable
- There is a variety of mechanical and chemical methods available, each of which has real and potential advantages as well as real and potential dangers
- Even the length of time that a patient is at risk after major surgery is unclear
- Clinicians should adhere to guidelines where possible.

Introduction

Despite a huge literature base, thromboprophylaxis in orthopaedics remains controversial. The scale of the problem is disputed and the cost–benefit, risk–benefit, and practicality of any particular protocol is uncertain.

Areas of controversy

Do we need prophylaxis at all?

Against prophylaxis

Some surgeons question the very need for prophylaxis, citing very low death rates in series without routine prophylaxis (Box 1.6.1). With changes in orthopaedic practice (quicker surgery, regional anaesthesia, earlier mobilization) the problem of venous thromboembolism (VTE) appears to be receding. The rates of symptomatic VTE without prophylaxis are probably only in the region of 4% after joint replacement without prophylaxis and so there is much being spent, and a risk of bleeding complications being taken, for relatively small gain. No study has shown a longer-term risk of chronic venous insufficiency and pulmonary hypertension in orthopaedic patients who develop postoperative deep vein thrombosis (DVT) or pulmonary embolism (PE). The cost and potential risk of prophylaxis is thereby believed to be unjustified.

Box 1.6.1 Epidemiology

- Death still occurs even without thromboprophylaxis
- There is some evidence that thromboprophylaxis may prevent death or chronic venous insufficiency; there is good evidence that it reduces morbidity from symptomatic DVT and PE
- Thromboprophylaxis may be cost-effective depending on the modalities used
- There are few data on the morbidity of thromboprophylaxis as a result of increased bleeding.

For prophylaxis

Even a low death rate, when multiplied by the very large number of procedures performed, represents a large number. Symptomatic DVT and PE are important outcomes; society will not tolerate avoidable risk and there is an estimated £68 million in litigation costs for VTE. On the balance of probability (the civil test for breach of duty), VTE can be reduced with prophylaxis. The cost of treating a symptomatic VTE is probably higher than routine thromboprophylaxis. A robust study to show, or exclude, chronic venous insufficiency after orthopaedic thrombosis has yet to be performed; until that study is available, the potential for this expensive and morbid complication should be avoided.

How strong is the evidence that prophylaxis works?

Against prophylaxis

There are no studies which show death can be reduced with prophylaxis, or that one modality is any better than another. This is because death is so rare that an adequate sample size cannot be accrued.

For prophylaxis
There is some evidence that heparins reduce death in surgery. There is compelling evidence that thromboprophylaxis substantially reduces symptomatic VTE. That is a worthwhile effect in itself; the pyramid of VTE means that a proportionate reduction in death can be logically adduced. Most fatal PEs have no warning from a symptomatic DVT; there is very strong evidence that asymptomatic DVT (the usual endpoint in clinical trials) is reduced by suitable prophylaxis.

**Is chemical prophylaxis too dangerous?**

**Against prophylaxis**

Unavoidable bleeding is unacceptable in a surgical patient—it carries a morbidity of its own and reflects on the surgeon’s skill. Any chemical carries an intrinsic risk of bleeding. If that risk is similar to the risk of symptomatic VTE that it aims to prevent, nothing has been gained yet a healthcare resource has been spent. Anecdotal experience and many studies do show a higher rate of bleeding with chemicals than placebo.

**For prophylaxis**

There is no evidence that postoperative bleeding compromises the longevity of an implant. If a patient develops VTE in the postoperative phase, the required therapeutic anticoagulation invokes an even higher risk of bleeding. Bleeding is correlated with the administration of the chemical too close to surgery; guidelines which delaying the chemical until the risk of bleeding has evaporated, covering the interim with a mechanical method, should allow safe prophylaxis.

**Is aspirin good enough?**

**For aspirin**

It is cheap, easy to administer, and is used by a fair proportion of surgeons. There are studies to show it reduces the frequency of both radiological and symptomatic VTE. It is suitable for extended duration use because it is an oral agent. The American Academy of Orthopaedic Surgeons (AAOS) has recommended aspirin.

**Against aspirin**

It is mainly an antiplatelet rather than antithrombotic agent; the risk reduction achieved is far less than that with low-molecular-weight heparin (LMWH), fondaparinux, or newer oral agents. It carries a risk of gastrointestinal complications and bleeding, particularly in the elderly. The Pulmonary Embolism Prevention (PEP) trial showed no benefit for symptomatic VTE in the subgroup of total hip replacement (THR) and total knee replacement (TKR) patients. The death rate was the same in the placebo and the aspirin group. The AAOS guidelines only addressed PE which revealed a dearth of studies to show any benefit, let alone superiority, for aspirin. The National Institute of Health and Clinical Excellence (NICE) and the American College of Chest Physicians (ACCP) specifically advise against its use.

**Are mechanical methods alone adequate?**

**For mechanical alone**

These methods are inherently safe. Foot pumps are as effective as LMWH in the short-term for THR; intermittent pneumatic compression (IPC) appears effective in THR and TKR. Meta-analysis suggests that even simple TED (thromboembolic deterrent) stockings convey a significant risk reduction.

**Against mechanical alone**

Compliance by patient and ward staff, especially as the patient becomes increasingly mobile, limits the duration of use to a period that may be shorter than the patient’s risk of thrombosis. VTE is not only promoted by venous stasis—activation of coagulation is an important aetiological factor which may persist beyond the period of venous stasis. There may be a protective effect with chemical prophylaxis from the cardiac mortality that accompanies joint replacement.

**Pathogenesis**

Major trauma and orthopaedic surgery predispose to VTE. Virchow’s triad of altered blood components, venous stasis, and endothelial damage are all represented. The soft tissue exposure, bone cutting, and reaming induce systemic hypercoagulability and fibrinolytic inhibition. Patients may be relatively immobile after surgery. During hip replacement, femoral vein blood flow is obstructed by the manoeuvres required to expose the femoral canal and acetabulum. This may not only damage endothelium, in the proximal femoral vein, but also cause venous distension and thus endothelial damage distally, particularly in valve pockets, but also allow the concentration of clotting factors. Anterior subluxation of the knee and the vibration may cause local endothelial damage during knee replacement.

**What is the risk?**

Some orthopaedic procedures, such as minor upper limb surgery, probably carry no risk of thrombosis, whilst other procedures, such as complex lower limb trauma reconstruction or revision hip surgery, carry a particularly high risk.

Individual patients each have their own risk, determined by comorbidity (venous disease, obesity) and particularly by genetic
predisposition. A previous PE or DVT is the strongest individual risk factor.

**Fatal pulmonary embolism**

With modern surgical and anaesthetic techniques, but without prophylaxis, the death rate from PE after hip replacement or knee replacement is probably around 0.2%; perhaps slightly higher after hip fracture. With 1.2 million arthroplasties per year in Europe, that equates to 2400 deaths—a huge problem. The death rate after other orthopaedic procedures is unknown, but fatal PE is occasionally seen after lower limb trauma and pelvic trauma; there are case reports after ankle fracture, knee arthroscopy, and even elbow replacement.

**Symptomatic and asymptomatic pulmonary embolism or deep vein thrombosis**

Symptomatic event rates are summarized in Table 1.6.1.

Chronic venous and pulmonary sequelae

The frequency of chronic venous insufficiency, an important longer-term outcome, is unknown. It is likely to be rare after asymptomatic thrombosis (the majority of thrombosis after orthopaedic surgery) but common after symptomatic thrombosis. Chronic pulmonary hypertension is a potential sequela for those who survive a symptomatic PE.

Outcome measures

No study could be large enough to directly show a reduction in fatal PE because it is so rare. Reduction in fatal PE is, of course, not the only purpose in thromboprophylaxis. Symptomatic DVT and PE are a cause of considerable cost (both medical and medico-legal) and are likely to cause longer-term sequelae (chronic venous insufficiency and pulmonary hypertension). Furthermore, fatal PE usually has no warning signs in the leg, so that reduction in asymptomatic DVT is itself an important goal of prophylaxis.

Until the past few years, almost all prophylaxis studies relied on radiological surrogates assuming that a reduction in DVT demonstrable by imaging would correlate with a reduction in symptomatic endpoints. There is evidence to support this. A reduction in symptomatic DVT of 66% with heparin after orthopaedic surgery has been correlated with a similar reduction in fatal PE; a reduction in radiological DVT correlates with a reduction in symptomatic VTE when given for a prolonged time after hip replacement and hip fracture. This correlation is self-evident, given that thromboembolism represents a pyramid of the same disease (Figure 1.6.1).
Most studies refer to hip and knee arthroplasty patients; there are far fewer data on other orthopaedic procedures.

General prophylactic measures (Box 1.6.2)

| ♦ Early mobilization. No evidence in practice
| ♦ Neuraxial anaesthesia reduces VTE by 50% but precludes some types of chemical prophylaxis
| ♦ Gentle surgical technique. No evidence in practice
| ♦ Tourniquet—not thought to have any effect.

Secondary prophylaxis

This means that no prophylaxis is given around the time of surgery; an investigation (e.g. ultrasound or venogram) is performed some time after surgery and therapeutic doses of chemical are then given if the test is positive for a large clot; repeat screening for a small clot. Ultrasound is not too sensitive for small asymptomatic DVT and venography is too invasive. Thirty per cent of THR patients with a negative venogram 10 days after surgery will develop a DVT in the next 3 or 4 weeks. Major and even fatal VTE can occur within the first 10 days. Therapeutic doses of anticoagulant within the first 2 weeks of surgery invite a high complication rate. Prophylaxis is not so expensive whereas routine investigation and treatment of detected thromboses or later-emerging events is. This method of secondary prophylaxis is not recommended.

Mechanical methods (Box 1.6.3)

Advantages and disadvantages

Mechanical methods are intuitively attractive to orthopaedic surgeons, who have to balance risk and benefit in the perioperative period, as they carry no bleeding risk. The most recent meta-analysis (through the UK NHS Health Technology Assessment process) reviewed 17 Graduate compression stocking (GCS) trials, 22 Intermittent pneumatic compression (IPC) trials, and three foot pump trials. Of these, 14 trials were in hip and knee surgery. The review concluded a 72% odds reduction for mechanical methods alone. All mechanical methods have the disadvantages of expense and compliance. Furthermore, they are not practical for, nor is there evidence for, extended duration prophylaxis.

Graduated compression stockings

These are commonly used. To work, they must be properly woven, well-fitted, and remain in place. The evidence is sparse for efficacy after orthopaedic surgery, but a meta-analysis of other surgical studies suggests a modest benefit. There is no clear benefit for above-knee rather than below-knee stockings.

Compression stockings
Intermittent compression devices

These devices enhance venous flow and also have a fibrinolytic effect due to release of factors from the endothelium from compression. The peak venous flow varies with different devices: frequency of contraction; number of compartments; above- or below-knee design; inflation pressure. The ideal parameters have not been established; however, in general these devices are effective, with an overall risk reduction of about 26%.

Foot pumps

These devices empty the venous plexus in the sole of the foot rhythmically, so flushing out the deep leg veins. The foot should be level or slightly dependent so that the plexus can fill (pre-load) prior to it being emptied by the impulse. Stockings probably do not enhance flow. The efficacy will also depend on factors such as the pressure and frequency and the impulses. The risk reduction is probably similar to LMWHs in hip arthroplasty but the evidence for knee arthroplasty is less secure.

Inferior vena cava filters

These devices (‘umbrellas’) are inserted percutaneously through the femoral vein and are lodged in the inferior vena cava. They cannot prevent thrombosis in the leg, nor do they prevent embolism; they merely catch an embolus and prevents it from reaching the lungs. They are associated with a complication rate which includes death from proximal embolism and venous distension. Their role should be confined to the occasional case where anticoagulation is contraindicated yet the risk of embolism is high. The typical example would be a pelvic fracture transferred from one centre to another who has already developed a leg DVT yet needs a major surgical reconstruction.

Chemical methods (Box 1.6.4)

Advantages and disadvantages

Chemical methods such as LMWH, pentasaccharide, warfarin, direct thrombin inhibitors, and factor Xa inhibitors are effective in reducing the risk of VTE. They are generally easy to administer (tablet or injection) and can be used for an extended duration. Relative to the overall cost of surgery, they are fairly inexpensive.

These drugs all carry an inherent risk of bleeding—a risk which properly concerns orthopaedic surgeons.

Box 1.6.4 Secondary prophylactic measures (chemical)

- Aspirin: cheap but weak
- LMWH: definitely reduce symptomatic DVT. Safe if used carefully
- Warfarin: less good than LMWH and has side effects
- Pentasaccharides: at least equal effect as LMWH but not reversible. Bleeding concerns
- Anti-Xa inhibitors: as effective as LMWH but more practical as oral so can be used for a prolonged period. Not reversible.

Aspirin

Aspirin is familiar, cheap, available, and easy to use. However, it only has a weak antithrombotic effect (since it is an antiplatelet agent rather than an anticoagulant). The PEP trial (2000) showed a reduction of about a quarter for symptomatic VTE with aspirin compared with placebo, which is less than would be expected with LMWH (about two-thirds). It risks alternative complications (wound bleeding, transfusion, gastrointestinal bleeding). Although the AAOS recommend its use in THR and TKR, NICE and the two largest evidence-based consensus groups, ACCP and National Institute for Clinical Excellence (ICS), all specifically recommend against its use because if chosen as the sole prophylactic method, then patients are deprived of safer and more effective alternative mechanical and chemical methods. It is not even licensed for thromboprophylaxis in the United Kingdom (Table 1.6.3).
### Table 1.6.3 Drawbacks of aspirin and warfarin

#### Drawbacks of Warfarin
- Needs regular monitoring, which is expensive and time consuming;
- If started too close to surgery or at too high a dose, there will be a risk of bleeding;
- If started judiciously – later and at a lower dose – there will be an interval of several days during which the patient will be unprotected at their most thrombogenic phase;
- Interaction with many drugs and alcohol.
- Not as effective as LMWH

#### Drawbacks of Aspirin
- Only weak antithrombotic effect so limited efficacy
- Weak evidence base
- GI bleeding, wound bleeding
- Not recommended by NICE, ACCP (but is by AAOS)
- Not licensed for Thromboprophylaxis in UK

### Low-molecular-weight heparins

This class of drugs is readily bio-available and has a wide window of safety; therefore monitoring is not required. There are several different types but they are all broadly similar. The drugs are relatively cheap and easy to administer by injection once or twice daily, depending on half-life. LMWHs have been very widely studied and are at least as effective as warfarin, compression devices, and foot pumps. They are more effective than unfractionated heparin and far more effective than placebo. There is little evidence that if used safety they cause bleeding. However, particular care (dose amendment or alternative therapy) should be taken in those with reduced renal function.

#### Warfarin

Used carefully, it is effective in reducing venographic DVT; fatal PE is exceedingly rare as a reported outcome. It can be continued for as long as the patient is at risk for an extended duration. Meta-analysis shows that it is not as effective as LMWH. Although warfarin is used widely in North America, it is generally regarded as obsolete in Europe (Table 1.6.3).

#### Pentasaccharide

These synthetic antithrombotic agents precisely inhibit factor Xa. Fondaparinux (Arixtra) is the first of this class to be widely studied and commercially available. It is excreted renally rather than metabolized by the liver. Because of its long half-life (15h) it can be administered by once-daily injection. The clinical trial programme shows that fondaparinux may be more effective than LMWH but may cause more bleeding. However, these differences may be least partly explained by differences in the proximity to surgery when the trial drugs were administered. The drug is not readily reversed and must be used carefully or avoided in those with poor renal function.

#### Direct anti-Xa inhibitors and direct thrombin inhibitors

These drugs became available in 2008 and may transform thromboprophylaxis. They are given orally and have a broad therapeutic and safety window so that monitoring is not required. They offer a pragmatic solution to those who would otherwise need regular injections (LMWH, fondaparinux) or complex monitoring (warfarin). They are given after surgery and are continued for as long as the patient is at risk of VTE. The drugs are difficult to reverse. Presently, two are available: a. direct thrombin inhibitor (Dabigatran, Boehringer Ingelheim) and an anti-Xa inhibitor (Rivaroxaban, Bayer). Others are due to follow.

### Combined methods

#### When to start chemical prophylaxis

Thromboprophylaxis involves a balance of risk and benefit, like most medical interventions. If an effective dose of chemical is administered too close to surgery, bleeding will occur. If the drug is given before surgery, it provides an anticoagulant remedy to peroperative thrombogenic factors (tissue thromboplastins and venous stasis). If the drug is given too long before surgery, the serum levels will be too low for any prophylactic effect; if given too close to surgery then surgical bleeding can be expected. The alternative is to give the drug after surgery. If given too close after surgery, the soft tissues and bone will still be vulnerable to bleeding side effects; if given too late after surgery, then although the risk of surgical bleeding is diminished, the thrombogenic process will be well-established before the drug can act. The drug now has to function as a therapeutic rather than a prophylactic (Figure 1.6.2). The drug has to be given 'just in time' to be effective yet to avoid bleeding.
Stacked modalities

There is a trend for so-called ‘stacked modalities’ in which a mechanical method is used to cover the perioperative phase, with a drug then started only when the surgeon and anaesthetist feel that in that individual patient the bleeding risk has decayed.

Individualized flexible use of mechanical and chemical methods

In the late 20th century, there tended to be a conflict between chemical methods and mechanical methods. This dichotomy was inappropriate, as each has advantages and disadvantages. Furthermore, the obsession with evidence-based medicine tended to allow recommendations only if supported by a particular randomized trial or meta-analysis. However, the randomized trial is only as valid as the unitary hypothesis studied and generalizability is hampered by the exclusion criteria applied to the studied sample. Therefore, clinicians should regard randomized trials and meta-analyses as showing the general direction rather than constraining sensible practice. A pragmatic view would support a combination of mechanical and chemical methods.

Particularly high risk of thromboembolism

For these patients (e.g. with previous thrombosis, strong family history, or prolonged surgery), mechanical and chemical methods can both be used together for as long as possible.

Particularly high-risk bleeding

For these patients, a mechanical method should be used until the bleeding risk is lessened; an effective chemical can be safely started and continued for as long as there is a risk of thrombosis.

Uncertain delay to surgery

For these patients (e.g. hip fracture and major trauma), the mechanical method can be started as close to the moment of trauma as possible—in the Emergency Department—and continued until such time after surgery as the clinician feels that a drug can be safely commenced.

Lower risk of thrombosis

In these patients, the cost and risk of prophylaxis may not be justified at all. If prophylaxis is deemed necessary then a mechanical or chemical method could be used, whichever is judged safer and most cost-effective.

Duration of use

If prophylaxis is used, it should be given for an appropriate duration of time. The risk of thrombosis depends on many factors, such as the particular procedure performed, the likelihood of postoperative immobility, and the individual’s inherited propensity to thrombosis. Thromboprophylaxis in the latter part of the 20th century was usually continued only whilst the patient remained in hospital. This was for pragmatic rather than scientific reasons. However, it is now apparent that the risk of thrombosis in hip or knee arthroplasty and hip fracture persists for much longer (Figure 1.6.3). Several sources show that half of symptomatic VTE after knee replacement and two-thirds after hip replacement and hip fracture occur beyond the second week. Randomized controlled trials clearly show that the risk of later symptomatic VTE can be reduced by about two-thirds if prophylaxis is continued for longer. The precise period depends on many factors, but current evidence supports 14 days for knee replacement and 4–5 weeks for hip replacement and hip fracture (Box 1.6.5). This is likely to be a cost-effective approach. Because patients are discharged from hospital sooner and sooner, then a system must be established to continue prophylaxis after discharge. The advent of the new oral agents which do not require monitoring will allow effective and practical extended duration prophylaxis.

**Box 1.6.5 General considerations**

- Timing of start and end of thromboprophylaxis is a complex decision
- Prophylaxis should be continued for 2 weeks after knee replacement and 5 weeks after hip fracture and hip replacement surgery
- Stacking combines mechanical and chemical methods.

**Guidelines**

There are now several authoritative guidelines available, based on a systematic literature review (Table 1.6.4). Guidelines should ensure that safe and effective prophylaxis is routinely given according to a protocol that has been accepted by the surgeons and anaesthetist, yet properly funded by the health system.

</table>

The guidelines have two common threads: to provide *effective prophylaxis without causing harm* and to use *risk assessment*. There are differences. In particular the AAOS guidelines only address PE and support the use of aspirin; the other guidelines address the spectrum of VTE and reject aspirin. The International Surgical Thrombosis Forum has suggested a model for the design and interpretation of guidelines in orthopaedics (Box 1.6.6).

**Box 1.6.6 The ideal guideline: International Surgical Thrombosis Forum recommendation**

For those with a demonstrable risk of thrombosis, thromboprophylaxis should be started with an effective dose as close to the thrombogenic insult as possible, without introducing a greater or equal risk of alternative complications, and continued until the risk of thrombosis has reduced to a clinically negligible rate, with due consideration of cost and practicality. Surgeons also should consider their own threshold of comfort between thrombosis and bleeding based on their patient’s individual risk factors when deciding the safe proximity to surgery for chemical methods, i.e. before or after the trauma. Individual patients may have their own risk for thrombosis and bleeding as well as duration of risk for each. Initiation and duration of prophylaxis should therefore ideally be tailored. The ideal chemical agent should be both injectable and oral, reversible, have a wide therapeutic and safety margin, and be predictable in nearly all patients (elderly, renal impairment, liver impairment) without interaction and be monitored with simple coagulation tests in critically ill patients. The ideal mechanical method should be comfortable, quiet and cost-effective. The guideline should not constrain the surgeon or anaesthetist into a practice which is not available, practical, affordable or deliverable. All methods should have an acceptable compliance when handled by the patients themselves (e.g. self-administered pharmaceuticals, mechanical devices).

In the author’s institution, guidelines have been implemented which are consistent with existing guidelines, to provide effective prophylaxis yet avoid potential bleeding by using mechanical prophylaxis first, then switching to chemical (Table 1.6.5). It is likely that the LMWH will be replaced with an oral anti-Xa or direct thrombin inhibitor.

| Total hip replacement | Start IPC in recovery and continue for as long as tolerated  
|                        | Start oral anti-Xa/anti-thrombin on day after surgery  
|                        | Continue chemical for 5 weeks |
| Fractured neck of femur | Start IPC in Emergency Department and continue for as long as tolerated  
|                        | Start oral anti-Xa/anti thrombin on day after surgery  
|                        | Continue chemical for 5 weeks |
| Total knee replacement | Start IPC in recovery and continue for as long as tolerated  
|                        | Start oral anti-Xa/antithrombin or LMWH on day after surgery  
|                        | Continue chemical for 14 days |
| Major lower limb trauma | Start IPC in Emergency department and continue for as long as tolerated  
|                        | Start LMWH at 5pm daily once risk of bleeding from soft tissue, brain, spine, and surgery has been ruled out |
| Elective spinal surgery | Start IPC in theatre and continue until patient is fully mobile  
|                        | Read operation note to see if patient may be suitable for LMWH |
| Traumatic spines, pelvis, acetabulum | Ultrasound on arrival if transfer and no effective prophylaxis  
|                        | Start IPC if USS is negative. Discuss and document management with consultant if USS is positive  
|                        | Start LMWH minimum of 24h postoperatively and continue until mobile |
| Other surgery and trauma | Patient should be offered grade II compression stockings or IPC until mobile  
|                        | Risk assessment: give LMWH when bleeding risk has been ruled out if one or more risk factors |

IPC, intermittent pneumatic compression; LMWH, low-molecular-weight heparin; USS, ultrasound scan.

Future research

Individual risk analysis

Like so many other diseases in medicine, there is likely to be a genetic predisposition to both thrombosis and bleeding. Risk factor analysis should provide a clear understanding of those at greatest risk of thrombosis or bleeding; this would allow safe yet effective prophylaxis tailored to the individual’s critical thrombosis period.

Duration of risk for venous thromboembolism

The duration of risk for any procedure, let alone individual, is not known. Does the risk rebound when prophylaxis is stopped?

Ideal mechanical–chemical combination

A combined approach seems sensible, but needs to be validated; the most effective, yet safe and affordable, protocol must be established.

Role of new oral agents

A safe and effective oral agent will support simple protocols for extended prophylaxis in those with higher risk of VTE (e.g. day-case knee arthroscopy or plaster casts with additional risk factors).

Summary points

♦ The origin, transmission, and reception of chronic pain is not easy to understand
♦ The perception of pain is altered by mood and itself alters mood. There is, therefore, a close link between chronic pain and depression
♦ Although pain is subjective, pain scales and diaries can be used to provide reproducible measures of pain
♦ The choice of method of pain control is not simply a ladder. New stronger agents need to be added in, not substituted for weaker ones
♦ Neuropathic pain will require unconventional analgesics in combination.

Definition and classification of pain

Pain is an unpleasant sensory or emotional experience associated with actual or potential tissue damage, or described in terms of such damage. Chronic pain is pain which is still present after 3 months despite sensible treatment. Radicular pain is felt in the distribution of a nerve root, so that pain is felt in an area corresponding to one of the dermatomes down the arm or leg or round the trunk. It is typically caused by compression. Referred pain is felt superficially in the dermatome of an affected viscus or other deep structure innervated by that root. An example is pain felt in the left arm because of cardiac disease (Table 1.7.1).

The two major types of pain are nociceptive and neuropathic. Nociceptive pain is ‘normal’ pain, such as pain after an injury. Neuropathic pain is pain after nerve injury, and can be central (post-stroke pain) or peripheral (Box 1.7.1).

Box 1.7.1 Definitions in pain

♦ Chronic pain has been present longer than 3 months
♦ Radicular pain is caused by compression of a nerve
♦ Referred pain arises from a viscus but presents elsewhere
♦ Nociceptive pain is the normal pain after an injury
♦ Neuropathic pain arises from the nervous system itself.

Pain sensation and transmission

1. Nociceptive
   - Pain after injury
   - Normal pain

2. Neuropathic
   - Pain after nerve injury
   - Central (post-stroke)
   - Peripheral (radicular)

3. Visceral
   - Pain from internal organs
   - Typically not felt where it originates

Combined
   - Pain from multiple sources
   - May be nociceptive or neuropathic

Chronic pain
   - Pain present longer than 3 months

Radicular pain
   - Pain caused by compression of a nerve

Referred pain
   - Pain from one place but felt elsewhere

Nociceptive pain
   - Pain from normal causes

Neuropathic pain
   - Pain from nerve damage

Pelvic pain
   - Pain arising from the pelvis

Cancer pain
   - Pain from cancer
   - Often treated with targeted therapies

LBP with radiculopathy
   - Low back pain with nerve injury
   - Often treated with medications and physical therapy

Whiplash
   - Pain from neck or back due to sudden movement
   - Often treated with rest and physical therapy

Pelvic pain
   - Pain originating from the pelvis
   - Often treated with medications and physical therapy

Cancer pain
   - Pain from cancer
   - Often treated with targeted therapies

LBP with radiculopathy
   - Low back pain with nerve injury
   - Often treated with medications and physical therapy

Whiplash
   - Pain from neck or back due to sudden movement
   - Often treated with rest and physical therapy

Pelvic pain
   - Pain originating from the pelvis
   - Often treated with medications and physical therapy

Cancer pain
   - Pain from cancer
   - Often treated with targeted therapies

LBP with radiculopathy
   - Low back pain with nerve injury
   - Often treated with medications and physical therapy

Whiplash
   - Pain from neck or back due to sudden movement
   - Often treated with rest and physical therapy

Pelvic pain
   - Pain originating from the pelvis
   - Often treated with medications and physical therapy

Cancer pain
   - Pain from cancer
   - Often treated with targeted therapies

LBP with radiculopathy
   - Low back pain with nerve injury
   - Often treated with medications and physical therapy

Whiplash
   - Pain from neck or back due to sudden movement
   - Often treated with rest and physical therapy

Pelvic pain
   - Pain originating from the pelvis
   - Often treated with medications and physical therapy

Cancer pain
   - Pain from cancer
   - Often treated with targeted therapies

LBP with radiculopathy
   - Low back pain with nerve injury
   - Often treated with medications and physical therapy

Whiplash
   - Pain from neck or back due to sudden movement
   - Often treated with rest and physical therapy

Pelvic pain
   - Pain originating from the pelvis
   - Often treat
The easiest way to think of pain in the nervous system is the idea of pain receptors and nerve cables dedicated to the transmission of pain signals. This model is a hard-wired, line-labelled system. For most acute pain and, indeed, in chronic nociceptive pain, this simple idea works well. The concept of specific cables whose transmission can be blocked is reinforced by everyday observations, for instance the ability to perform surgery painlessly by using a local anaesthetic block. But the inadequacy of this simple explanation is exposed in chronic pain, particularly with nervous system damage. The return of pain after an initially successful cordotomy, and the phenomenon of phantom limb pain are two examples. In a hard-wired, line-labelled system the pain should not recur after the cordotomy and amputees should not feel pain in the absent foot or hand because the receptors and the cables are no longer there. The ability of the nervous system to rewire is called plasticity. It is manifest in the return of pain after destructive procedures, and the concept of ‘pain memory’ in the spinal cord and brain has to be invoked to explain the phantom pain. Such phenomena mean that the simple view of a hard-wired, line-labelled system does not explain all that we see.

Pain perception can be amplified or damped by endogenous influences such as mood or endorphins, or exogenous factors, drugs given, or the circumstances of the injury. The classic scenario where pain is damped down is the injured soldier who continues, despite a shattered leg, to get themselves out of battle. Conversely a stubbed toe when you are tired and miserable is immeasurably more painful than the same injury on a morning when you are cheerful. In chronic pain it is sometimes very hard to disentangle depression from pain. Pain makes depression worse and depression makes pain worse. This pattern is all too familiar to those who manage pain. The thinking clinician needs to deal with both the pain and the depression. In chronic pain, distress and disability may also amplify the pain, and good pain relief will not improve disability. Under these circumstances expectations need to be realistic.

Pain is necessarily subjective. It is what one human being reports to another. There may be few objective signs to judge the severity of reported pain and many patients have no obvious (visible) handicap (Box 1.7.1). The most important principle is that the patient and the doctor are best served if the doctor believes the patient’s report. Their problems may be ill-understood, even disbelieved, at work and at home. Chronic pain changes people, affecting their personal and working lives, and ultimately their personalities. Often such changes are reversible with successful treatment. Much time and energy is wasted on procedures designed to ‘catch the patient out’. Labelling patients as malingerers or the pain as psychogenic may be easier than admitting that there is no successful treatment.

Acute pain

In the peripheral nervous system most of the nociceptive signalling of thermal and mechanical stimuli comes from activation of polymodal nociceptors which are innervated by C-fibres. Tissue damage leads to the release of peptides and this inflammatory soup activates and sensitizes peripheral nerve endings, and causes vasodilatation and plasma extravasation. These fibres also respond to local chemical stimulation by becoming sensitized to chemical, thermal, and mechanical stimuli. The net result is swelling, pain, and tenderness. If the injury is repeated, the pain is amplified (Box 1.7.2).

Box 1.7.2 Patient’s perceptions of pain

- Varies between individuals
- It is best to believe the patient.

The idea that the nervous system can change led to the idea of ‘plasticity’, a concept which has had a major impact in both acute and chronic pain. At its simplest, a memory of a pain is created and stored in the nervous system. Preventing such a memory being laid down led to the idea of pre-empting postoperative pain; any pain after the operation would be easier to treat if the memory had been minimized. It was hoped that any long-term sequelae, such as the phantom pain which can occur after amputation, could also be prevented. These were attractive ideas, but had little evidence to support them. One issue of importance for treatment of chronic pain is to determine at what level of the nervous system such memories might be stored. If the memory is stored at a ‘central’ level, then attacking the pain in the leg or arm where it originated might not do any good. However, the memory might be held centrally but require continued input from the periphery to sustain it. Attacking the pain in the leg or arm would then have some logic. This plasticity is evident after amputation or plexus avulsion, when phantom sensations in the ‘absent’ limb can recur after the cordotomy and amputees should not feel pain in the absent foot or hand because the receptors and the cables are no longer there. The ability of the nervous system to rewire is called plasticity. It is manifest in the return of pain after destructive procedures, and the concept of ‘pain memory’ in the spinal cord and brain has to be invoked to explain the phantom pain. Such phenomena mean that the simple view of a hard-wired, line-labelled system does not explain all that we see.

Box 1.7.4 Problems in pain management

- Plasticity leads to return of pain after cordotomy
- The brain has ‘pain memory’
Internal factors (e.g. emotional state) affect pain perception.
External factors can also have profound effects.
Depression increases pain; pain increases depression.

Methods of measuring pain

Pain measurement is subjective, but if some simple rules are followed, pain measurement can be made to work well in research settings and, perhaps even more importantly, pain can be recorded along with vital signs as part of the normal clinical course (Box 1.7.3).

Box 1.7.3 Measuring pain

- Pain should be measured alongside other vital signs
- Patient diaries are best for chronic pain.

Research pain scales

The same pain scales tend to be used in acute and chronic pain. It is sensible in chronic pain to use pain scales in conjunction with disability and quality-of-life measures. It makes no sense to invent your own scale. It is far better to use proven tools. The IMMPACT group’s publications make recommendations about choice of scale for measuring pain in different contexts.

Pain intensity and pain relief can be measured by either word categories or visual analogue (100-mm line) scale.

Categorical and visual analogue scales

For chronic work, when patients are recording over long periods, we tend to use diaries with categories, and ask about both pain intensity and pain relief. The clinician’s global view is a notorious overestimate and should not be used.

Clinical practice pain scales

The argument for using pain charts as part of normal practice is to improve the quality of care. It is the fact of a chart rather than the form of the chart which is most important. Charting should be done together with vital signs (the fifth vital sign), and can then be used for both clinical care and for audit.

Problem areas

Two important groups of patients, children and the unconscious, present particular problems for pain measurement. With unconscious patients there is little alternative to using variations in vital signs, such as blood pressure rise, as a proxy for a report of increased pain. We do not know how well these proxies work. There are special scales for children over 3 years of age. Below 3 years of age, experienced staff interpreting crying and other behaviour is the best guide available (Box 1.7.4).

Treatment

Drugs are the mainstay of treating both normal (nociceptive) and neuropathic pain (Box 1.7.5). The menu of remedies also includes stimulation devices, from transcutaneous through to implanted stimulators, cognitive behavioural therapy (pain programmes), complementary techniques, and invasive methods from injection through to surgery designed to block transmission of the pain message (Figure 1.7.1).

Box 1.7.5 Principles of drug therapy for pain

- Start with safe first-line drugs
- Add in stronger drugs if necessary but continue first-line drugs
- Fit in with available drugs and specific patient requirements
- Be aware of local prejudices, e.g. NSAIDs in bone healing
- Consider best route of delivery.
Fig. 1.7.1
Treatment options for acute (A) and chronic (B) pain.

Treating normal (nociceptive) pain

The basic algorithm for treating nociceptive pain, acute, chronic, or acute on chronic, is shown in Figure 1.7.2, derived from the pain ‘ladder’ which is widely used in palliative care. This ladder was formulated originally in the 1980s under the aegis of the World Health Organization (WHO). In its raw form, it captured the treatment care pathway for pain by representing increasing strengths of analgesia as further steps or rungs up the ladder. At the bottom rung, or step 1, is a non-opioid analgesic, usually paracetamol (acetaminophen); at step 2 a non-steroidal anti-inflammatory drug (NSAID) or a combination of minor opioid with paracetamol; and at step 3 addition of a strong opioid, morphine, by mouth or injection. This simple pathway has had enormous global impact in palliative care, even though the drugs used may vary in different countries.

This algorithm is as useful in trauma and orthopaedics as it is in palliative care. In acute pain, perioperative or traumatic, one is working right to left as pain decreases. In chronic pain the patient needs to use the three strengths of analgesia as the pain increases or decreases, the ‘three pot’ system. The ‘basic’ algorithm is thus the same across the different pain intensities, making teaching and implementation more effective, but the choice of particular drugs will vary locally with availability.

The visual presentation of the ladder differs from the original WHO palliative care ladder in two main ways, because we wanted to convey visually the principle of ‘add rather than replace’, by which we meant that if the pain becomes more severe you add a stronger analgesic to your other analgesic(s), rather than replacing a weaker one. The inversion of the diagram compared with the original, with the basic building block (step 1) at the top of the picture is to emphasize the ‘add not replace’ concept, because putting the step 1 drugs at the bottom of the algorithm makes it more likely that they will be overlooked and omitted in the management of moderate or severe pain.

Fleshing out the detail of the drugs and the route of administration will vary for each of the drug choices, each section of the algorithm, and each of the pain intensities. The key concept is to keep as much in common as possible, while fitting in with available drug choice and clinical situation. For instance, lower starting doses might be used in older people. Some of the detail will rightly be determined by local custom and practice, and where the detail on the pathway is at variance with local belief, then there is a danger that the whole pathway loses credibility. A simple example is pain caused by a fractured bone and NSAIDs. When staff
have been told not to use NSAIDs because they are said to impair bone healing, then including NSAIDs on the pathway damages the credibility of the whole plan. While many may doubt that NSAIDs have significant clinical impact on bone healing, the detailed algorithm will need to be subject to local variation to give it the local ownership which it needs if it is to be part of everyday clinical practice.

The step 2 drugs in the algorithm are the NSAIDs and the minor opioids, such as codeine. NSAIDs are powerful analgesics. Standard oral NSAID doses provide analgesia equivalent to that from intramuscular morphine (10mg). However, the adverse effects of NSAIDs at therapeutic doses limit their utility, particularly for extended use in chronic pain. In those for whom NSAIDs are contraindicated and paracetamol (acetaminophen) is not sufficient, a minor opioid should be added to the paracetamol to improve analgesia.

The choice of strong opioid will vary according to local availability, custom, and practice. While morphine is the gold standard, orally in chronic pain or by injection in acute pain, other formulations or alternative opioids are used. For example, when swallowing or gastrointestinal function is impaired, injected, sublingual, topical, nasal, or inhaled routes of administration may be better. In perioperative care, patients self-administer strong opioid via patient-controlled analgesia systems (PCA). Pressing the button delivers an injected dose, but overdose is made unlikely because the patient will not be conscious enough to continue to press the button (Box 1.7.6).

**Box 1.7.6 Routes of administration**

- Patient-controlled analgesia gives patient control and avoids the risk of overdose
- Slow-release oral analgesics cover background chronic pain
- Quick release can then be used to control flares of pain.

In chronic pain, modified-release oral formulations are convenient for patients, allowing the greater part of the daily opioid requirement to be taken just twice a day. A normal-release formulation can then be used to deal with flares of pain. Faster acting nasal and inhaled formulations are now being developed to give improved control of these flares, or ‘breakthrough’ pains.

These drug regimens may fail to control pain in some cases. It is estimated that in cancer pain 5–10% of patients need a different approach. Perhaps the most important change in the last 30 years is the realization that destructive invasive techniques rarely produce long-term benefit because the system eventually rewires, and the pain may be more difficult to manage than before. Reversible invasive techniques such as long-term epidural infusions using local anaesthetic, opioid, and other drugs such as clonidine can provide the necessary control, and can be withdrawn if the pain improves, without making the situation worse (Box 1.7.7).

**Box 1.7.7 Chronic pain**

- Antidepressants are better than antiepileptics
- Titrate to optimal dose
- Skin patches and oral steroids may help
- Difficult to treat
- Plasticity makes cutting nerves valueless in the long term

**Treating nerve damage (neuropathic) pain**

Peripheral neuropathic pain can rarely be managed adequately over the long term with the conventional analgesics described earlier. An example in orthopaedics is complex regional pain syndrome (CRPS). The dose–response for opioids is shifted to the right in neuropathic pain compared to nociceptive pain, and response is often minimal. The reason remains a mystery.

The unconventional analgesics listed in Figure 1.7.1B are antidepressants and antiepileptics. Both classes of drugs have proved effective in a wide variety of neuropathic pain syndromes, and also in fibromyalgia and irritable bowel syndrome, which fall outside the usual lists of causes of neuropathic pain. An algorithm for drug management of neuropathic pain, using an analogous format to that for nociceptive pain, is shown in Figure 1.7.3.
Fig. 1.7.3

Summary points

♦ A knowledge of basic biomechanical principles is key to understanding and developing the practice of orthopaedic surgery
♦ Mathematical models can be used to calculate forces and strains in musculoskeletal tissues
♦ The musculoskeletal system is highly indeterminate
♦ It is important to know the mechanical properties of musculoskeletal tissues so that suitable replacements can be found
♦ Forces in the joints and muscles can be several times larger than the external loads applied to the body.

Introduction

Biomechanics is the application of the principles of mechanics and the techniques of engineering to the study of biological systems, including the human body. From an early date, one of the major areas of biomechanical study has been the musculoskeletal system or locomotor system. A knowledge of biomechanics is important not only for understanding existing orthopaedic practice, but also for designing new treatments, such as joint replacements and tissue-engineered bone or cartilage substitutes. This chapter explains how loads are transmitted by the tissues of the musculoskeletal system. Further information on a range of biomechanical applications in orthopaedics and on the basic principles of engineering mechanics can be found elsewhere.

Loads applied to the body

Ethical considerations and measurement difficulties mean that direct measurements of forces and strains in living human tissues are scarce. One alternative to direct measurement of forces is the creation and solution of a mathematical model of the system of interest. The particular body or mechanical system to be analyzed is isolated and all the forces or loads which act on it are defined clearly and as completely as possible. This isolation of the body of interest is accomplished by means of a ‘free-body diagram’, which is a diagrammatic representation of the isolated body showing all the forces applied to it both by mechanical contact and by body forces, such as those due to gravitational attraction. Only when a clear free-body diagram has been completed should mathematical relationships between the force quantities be written and solved (Box 1.8.1).

Box 1.8.1 Steps in drawing a free-body diagram

♦ Isolate and draw the body or system of interest
♦ Draw as arrows all forces applied to it
♦ Add a coordinate system and pertinent dimensions
♦ Write the equations of motion or static equilibrium.

Figure 1.8.1A shows a man carrying a briefcase climbing some stairs. The system of interest is the man, and so he is drawn separately as the first step in constructing a free-body diagram (Figure 1.8.1B). All the forces acting on the man are then drawn as arrows (called ‘vectors’); these represent the force magnitudes, directions, and points of application. A vector is usually written in boldface type (F) or with an arrow over it (F).
When the area over which the force is applied is small compared with the other dimensions of the body, the force is considered to be 'concentrated' at a point. These are the types of force acting on the man’s feet (labelled $F_L$ and $F_R$ in Figure 1.8.1B) and on the hand which he rests on the handrail (labelled $H_H$ in Figure 1.8.1B). These particular forces are a good example of Newton's third law of mechanics (sometimes known as 'action and reaction'). The man’s foot pushes against the stair with a certain force, and the stair pushes back on the foot with a force of the same magnitude and line of action, but in the opposite direction. The forces $F_L$, $F_R$, and $H_H$ all have units of newtons (N) in the SI system.

An arrow (labeled $H_H$) indicates the downward force due to the weight of the briefcase which the man carries in his right hand. The force $H_H = mR_g$, where $m_R$ is the mass of the briefcase in kilograms (kg) and $g$ is the acceleration associated with the gravitational force of attraction (9.81 m/s$^2$). Note that 1 N = 1 kg m/s$^2$. Note also that the force $H_H$ acts downward.

'Distributed' forces are applied over an area, or they may be distributed over a volume. The weight of a body or body segment is the force of gravitational attraction distributed over its volume, but this is usually taken as a concentrated force acting through the centre of gravity of the body or the relevant body segment. The weight of the man (not included in Figure 1.8.1B) is equal to the mass of the man $m_M$ (in kg) times $g$.

If, instead of the whole man, the bones, muscles, and joints of his feet were of interest, the non-uniform distributed forces (Figure 1.8.1B), rather than the concentrated forces $F_L$ and $F_R$ (Figure 1.8.1B), would have to be considered. The distributed forces act over the area of contact between the man’s feet and the stairs. The parts of these forces perpendicular to the soles of the man’s shoes can be thought of as pressures; they have units of force per unit area, namely N/m$^2$ or pascals (Pa). Instrumentation has been designed to measure plantar pressure using either shoe insole devices or floor-mounted platforms and mats.

When the area over which the force is applied is small compared with the other dimensions of the body, the force is considered to be 'concentrated' at a point. These are the types of force acting on the man’s feet (labelled $F_L$ and $F_R$ in Figure 1.8.1B) and on the hand which he rests on the handrail (labelled $H_H$ in Figure 1.8.1B). These particular forces are a good example of Newton's third law of mechanics (sometimes known as 'action and reaction'). The man’s foot pushes against the stair with a certain force, and the stair pushes back on the foot with a force of the same magnitude and line of action, but in the opposite direction. The forces $F_L$, $F_R$, and $H_H$ all have units of newtons (N) in the SI system.

An arrow (labeled $H_H$) indicates the downward force due to the weight of the briefcase which the man carries in his right hand. The force $H_H = mR_g$, where $m_R$ is the mass of the briefcase in kilograms (kg) and $g$ is the acceleration associated with the gravitational force of attraction (9.81 m/s$^2$). Note that 1 N = 1 kg m/s$^2$. Note also that the force $H_H$ acts downward.

'Distributed' forces are applied over an area, or they may be distributed over a volume. The weight of a body or body segment is the force of gravitational attraction distributed over its volume, but this is usually taken as a concentrated force acting through the centre of gravity of the body or the relevant body segment. The weight of the man (not included in Figure 1.8.1B) is equal to the mass of the man $m_M$ (in kg) times $g$.

If, instead of the whole man, the bones, muscles, and joints of his feet were of interest, the non-uniform distributed forces (Figure 1.8.1B), rather than the concentrated forces $F_L$ and $F_R$ (Figure 1.8.1B), would have to be considered. The distributed forces act over the area of contact between the man’s feet and the stairs. The parts of these forces perpendicular to the soles of the man’s shoes can be thought of as pressures; they have units of force per unit area, namely N/m$^2$ or pascals (Pa). Instrumentation has been designed to measure plantar pressure using either shoe insole devices or floor-mounted platforms and mats.

Pertinent dimensions should also be represented on the free-body diagram. In biomechanical studies, a wide variety of physical measurements are required, including not only body segment lengths and masses, centres of mass, and moments of inertia, but also locations of muscle origins and insertions, angles of pull of tendons, and lengths and cross-sectional areas of muscles. In the past, most of these measurements were made on cadavers, but now many subject-specific measurements can be made in vivo using plane radiography, computed tomography, or magnetic resonance imaging.

It is also usual to indicate a set of coordinate axes on the free-body diagram. For simplicity, only two dimensions will be considered in this example, and so in Figure 1.8.1B the axes x and y have been added. The x axis points to the right, and the y axis points upward. If a z axis were included, it would point out of the page. The origin O of this global coordinate system is fixed on the bottom stair.

Each force vector in Figure 1.8.1B could instead be drawn as the sum of two perpendicular vectors, one parallel to the x axis and one parallel to the y axis. An example is given in Figure 1.8.3A, in which $F = F_x + F_y$. The absolute values of the two perpendicular vectors ($|F_x| = F_x$ and $|F_y| = F_y$) are known as the 'components' of the vector $F$. The graphical construction in Figure 1.8.3A is an example of the 'parallelogram law of vector addition', in which the resultant of two vectors is found by drawing each vector to scale and arranging them tip to tail. The resultant then connects the tail of the first vector drawn to the tip of the last vector drawn. The vectors to be added need not necessarily be parallel, nor does it matter in which order they are drawn (Figure 1.8.3B).

External loads applied to the body can often be measured accurately using force transducers which give an electrical signal...
proportional to the applied force. The device used to measure the ground reaction force \( (F_r \text{ or } F_R \text{ in Figure 1.8.1B}) \) is called a force plate or force platform (Figure 1.8.4). When a person walks or runs across the force plate, the force measured no longer simply equals body weight but is an indication of both the mass and the inertia of the body (Figure 1.8.5A, B). Figures 1.8.6A–C show how the components of the ground reaction force change over time during the stance phase of walking. Figure 1.8.6D shows a normal pattern of ground reaction force vectors as seen in the sagittal plane; this plot is known as a Pedotti diagram or a butterfly diagram.

---

**Fig. 1.8.4**
The force plate. The ground reaction force (GRF), the free moment of rotation \( (M_z) \), and the centre of pressure \( (x_p, y_p) \) are shown. Note that the axis directions differ from those shown in Figure 1.8.1.

**Fig. 1.8.5**
A) A static measurement on the force plate. The ground reaction force (GRF) equals the man’s weight (W). B) A dynamic measurement on the force plate during normal level walking. The ground reaction force (GRF) does not equal the man’s weight (W).

**Fig. 1.8.6**
The ground reaction force during the stance phase of normal gait. A) The vertical component \( F_z \) is positive upward. B) The fore–aft horizontal component \( F_x \) is positive forward. C) In this case the mediolateral horizontal component \( F_y \) is positive laterally.
Statics versus dynamics

When a body is in equilibrium (either stationary or moving at constant velocity, according to Newton's first law of mechanics), the resultant force and resultant moment acting on it are zero ($\Sigma F = 0$, $\Sigma M = 0$). Moment is the term used to describe the tendency of a force to rotate a body about some axis. The magnitude of a moment $M$ is proportional to the magnitude of the force $F$ which causes it and to the moment arm $d$, which is the perpendicular distance from the axis about which rotation occurs to the line of action of the force, or $|M| = |F|d$, as shown in Figure 1.8.7A. The moment produced by two equal and opposite but non-collinear forces ($F$ and $-F$) a distance $d$ apart is known as a couple $C$ with magnitude $|F|d$ (Figure 1.8.7B). Notice that the sum of the two forces is zero since they are equal and opposite. There is no tendency for the forces to translate the body, but they do tend to rotate it. Moments and couples are vectors, and their directions are given by the ‘right-hand rule’ (Figure 1.8.8).

To check whether the sum of the forces acting on a body is zero, the force vectors must be summed either graphically using the parallelogram law (Figure 1.8.3) or algebraically using the force components. For the moments acting on a body in two dimensions to be in equilibrium, the clockwise moments about any point must balance the counterclockwise moments about the same point.

Dynamics is the study of the motion of bodies under the action of forces. It involves the tendency of unbalanced forces to translate a body and the tendency of unbalanced moments to rotate a body. From Newton’s second law, we know that $\Sigma F = ma$, or the acceleration of a particle (or of the centre of mass of a body) is proportional to the resultant force acting on it and is in the direction of the force. The constant of proportionality is the mass of the particle or body. Note that acceleration, like force, is a vector and has components in the $x$, $y$, and $z$ directions. For moments in two dimensions, $\Sigma M = I \alpha$ where $I$ is the moment of inertia (or tendency of the body to resist rotation) and $\alpha$ is the angular acceleration. The moment of inertia is usually referred to the centre of mass of the body or segment (Box 1.8.2).

Box 1.8.2 Mechanics equations in two dimensions

- **Statics**: $\Sigma F_x = 0$, $\Sigma F_y = 0$, $\Sigma M_z = 0$
- **Dynamics**: $\Sigma F_x = ma_x$, $\Sigma F_y = ma_y$, $\Sigma M_z = I \alpha$

Loads internal to the body

Before finding the forces acting in particular body tissues during activity, it is necessary to quantify the resultant force and moment acting along a limb or at a joint. For static situations, this is relatively easy. A free-body diagram of the body is drawn and an imaginary slice taken through it at the section of interest. This imaginary slice may be through a bone shaft (Figure 1.8.9A) or through a joint (Figure 1.8.9B). A resultant force $F$ and a resultant moment $M$ act at this section, and they balance the external
loads and segment weights. At a joint, these quantities are sometimes called the ‘resultant joint force and moment’ or the ‘intersegmental force and moment’. The calculated resultant forces and moments at the sections shown in Figure 1.8.9 do not correspond to actual forces and moments, and they cannot be measured with transducers. They are abstract quantities that are often used not as final results but as inputs to a second step—determination of the distribution of these forces and moments among the structures of the body.

![Fig. 1.8.9 Resultant force F and resultant moment M acting at a section (A) through the shank and (B) through the knee. Adapted from O’Connor (1991).](image)

In dynamic situations, the body is usually divided into segments, and the forces, moments, and accelerations of each segment are considered separately. An example of a two-dimensional link-segment model of the lower limb is shown in Figure 1.8.10. The limb is divided into three segments (thigh, shank, foot), each with its own mass $m_i$ and moment of inertia $I_i$ (Figure 1.8.10A). In this simple model, the links are connected by pins. To draw a free-body of each segment, we disconnect the link-segment model at the joints and draw the resultant force and moment at each joint (Figure 1.8.10C). On the foot segment, the resultant joint force $R_\text{f}$ at the ankle has two components, $R_x$ and $R_y$. The resultant joint moment is $M$. On the free-body diagram of the shank segment, $M$ and the components of $R$ are opposite in direction to those drawn on the foot segment. The same is true for the joint reaction force and moment at the knee, as shown on the free-body diagrams of the shank and thigh segments.

![Fig. 1.8.10 A, B) A sagittal-plane link-segment model of the lower limb. Each link has a mass $m_i$ and a moment of inertia $I_i$. (C) Free-body diagrams of the three links, each showing the segment weight and the intersegmental forces $F$ and moment $M_i$. Adapted from Winter (1990).](image)

In link-segment models of the lower limb, the most distal segment is considered first, followed by the next adjacent segment, moving proximally. Figure 1.8.11A is a free-body diagram of the foot segment showing all the forces acting on it: the known ground reaction force (GRF), the known segment weight ($mg$), and the unknown joint (ankle) reaction force ($R_\text{f}$) and moment ($M_\text{f}$). Figure 1.8.11B is a ‘kinetic diagram’ showing the ‘inertial forces’ $ma$ and $I\alpha$ on the foot. We know from the previous section that, for dynamics in two-dimensions, $\Sigma F = ma$ and $\Sigma M = I\alpha$, so that the diagrams in Figures 1.8.11A and 1.8.11B must be equivalent. When the linear acceleration $a$ of the centre of mass and the angular acceleration $\alpha$ of the foot are known, equations can be written to calculate the unknown joint reaction force components ($R_{\text{f}x}$ and $R_{\text{f}y}$) and the joint reaction moment ($M_\text{f}$). Once these are found, the equilibrium of the shank can be considered and, after that, the thigh.
The usual method for finding the accelerations needed for a dynamic analysis of a link-segment model is to measure the sequential positions of each segment and then to differentiate the position data with respect to time, once to obtain segment velocity and twice to obtain segment acceleration. Because measurement errors are magnified in the differentiation process, the position data must first be filtered to remove unwanted noise. Optoelectronic motion analysis systems (Figure 1.8.12) are commonly used to collect three-dimensional position data. A minimum of three markers is fixed to each body segment of interest, and the changing positions of the markers are recorded by at least two cameras. Some systems use reflective markers, while others use markers containing light-emitting diodes which flash on and off in sequence. A more detailed discussion of motion analysis systems can be found in books on gait analysis.

The problem of indeterminacy

In mechanics, a system is called ‘determinate’ if the number of equations describing it is the same as the number of unknown quantities (force, position, etc.) When there are more unknown quantities than there are equations, the system is called ‘indeterminate’ or ‘redundant’. The musculoskeletal system is highly indeterminate. Figure 1.8.13 shows as an example a sketch of the knee with its known joint force \( F \) and joint moment \( M \). Also shown on the drawing are all the unknown forces at the knee: muscle forces \( f \), ligament forces \( f \), and forces \( f \) in the articular cartilage which result from contact between the tibia and the femur. With six equations of equilibrium in three dimensions, it is possible to solve for six unknown quantities. The problem is that there are far more than six unknown forces in Figure 1.8.13—the forces cannot be found using the equations of equilibrium alone. Methods to solve this ‘problem of indeterminacy’ involve either increasing the number of equations or decreasing the number of unknowns (Box 1.8.3).
Box 1.8.3 Calculating loads internal to the body

- Resultant forces and moments in the body are found using free-body diagrams and link-segment models
- Accelerations, if needed, can be calculated from motion analysis data
- To find the forces in muscles, bones, and soft tissues, it may be necessary to solve an indeterminate problem.

Structures which carry load

Bone, muscle, tendon, ligament, and articular cartilage are the load-bearing tissues of the musculoskeletal system. Muscles produce force and are therefore thought of as ‘active’ tissues. Bones, tendons, ligaments, and articular cartilage are ‘passive’ structures, since they take up load only as needed to balance the external, inertial, and muscle forces and moments.

Muscle

As an ‘active’ tissue, a muscle generates force as a result of neural stimulation. It is possible to tell when a muscle is active by detecting the electrical signal or electromyogram (EMG) associated with its contraction. In most cases in orthopaedic biomechanics, electrodes placed on the skin (surface electrodes) are used for this measurement. The raw EMG signal varies in amplitude in a seemingly random way above and below a zero level (Figure 1.8.14). Unfortunately there is no simple relationship between the amplitude of the EMG signal and the force produced by a muscle.

In simulations in which muscle forces are prescribed, the simplest and most common model of muscle contraction dynamics is the Hill-type model (Figure 1.8.15). The force produced by the contractile process is attributed to the ‘contractile element’ and depends on the muscle length, the velocity of contraction, and the muscle activation. Hill’s equation is often modified and used to...
relate these parameters to muscle force. The passive resistance of the muscle to being stretched is represented by a spring, the ‘parallel elastic element’. Total muscle force is then the sum of the active and passive elements. Some models include a series elastic element (not shown in Figure 1.8.15) next to the contractile element. The elasticity of the muscle tendon can be included in series with the muscle model (Figure 1.8.15). Storage of energy in the elastic elements is thought to be important in activities such as running and jumping.

**Bone**

The mechanical functions of the bones of the skeleton are to support and protect the tissues of the body and to function as a lever system on which the muscles can act. As a result of external forces and muscle forces, bones are subjected to all kinds of loading: tension, compression, bending, shear, torsion, and combinations of these (Figure 1.8.16). The idea that bone perceives and adapts to the forces applied to it is known as ‘Wolff’s law’.

Bone is difficult to model using the basic techniques of classical mechanics due to its complex geometrical and mechanical properties. For instance, the cortical and trabecular parts of bone are each made up of different proportions and arrangements of organic and inorganic material. As a result, the ability of bone to resist deformation varies throughout its substance.

Since the early 1970s, an advanced computer technique of structural stress analysis called finite-element analysis (FEA) has been used in biomechanics to model bone. In FEA, the geometry of the model is defined first. The model is then divided into a number of sections called ‘elements’, all of which are connected together at points called ‘nodes’ (Figure 1.8.17). Forces must be applied at the nodes, and a sufficient number of nodes must be fixed to prevent rigid-body motion. After the material behaviour or stiffness of every element in every direction is defined, the FEA program solves a large number of equations governing force equilibrium at the nodes to find the nodal displacements within the model. From these displacements, strains and stresses can be calculated.
FEA has been used to study the stresses in bones (Figure 1.8.18), fracture fixation, prosthesis design, and bone-implant interaction. The method is particularly useful for identifying areas of ‘stress concentration’ (high and sometimes unexpected increases in stress occurring near notches, sharp changes in geometry, or cracks) and ‘stress shielding’ (in which the load distribution between two materials with very different stiffnesses leads to one of them ‘shielding’ the other from stress). An example of the latter situation is the insertion of a metal joint replacement causing lower-than-normal stresses in the surrounding bone. This could lead to bone resorption in accordance with Wolff’s law. Some FEA models now incorporate simulations of bone growth, repair, and remodelling. Although FEA is cheap compared with clinical, animal, or laboratory testing methods, the combination of FEA with experimental analyses is many times more powerful than the sum of their individual applications.

Articular cartilage

The articulating surfaces of the bones in a synovial joint are covered with a thin layer of connective tissue known as articular cartilage. The mechanical functions of articular cartilage are to transmit compressive forces across the joint, to distribute the compressive contact force between the bones (by deforming and making the contact area larger), and to allow joint motion with minimal friction and wear. Biomechanical models of cartilage often allow for the occurrence of tension, compression, and shear (see Figure 1.8.18) within the depths of the cartilage layer. Many models take into account the fact that fluid flow is intrinsically linked to articular cartilage deformation and to its time-dependent responses to loads. Simple single-phase linear viscoelastic models (see later) can be used to take the time-dependency into account, but for a full representation of fluid flow, cartilage must be modelled as at least a biphasic material, with the solid matrix and the interstitial fluid as the two phases.

Ligaments and tendons

Ligaments and tendons are approximately parallel-fibre collagenous tissues that transmit tensile forces across the joints. A ligament connects one bone to another and functions to guide and limit joint movement. A tendon connects a muscle to a bone across a joint, thereby causing joint motion when the muscle contracts. Tendons also store elastic energy. In models of the
Musculoskeletal system, ligaments and tendons are often modelled by a small number of tension-only springs. Like articular cartilage, ligaments and tendons contain a high proportion of water and so also exhibit time- and history-dependent behaviour under load.

**Mechanical properties**

Much information about the mechanical properties of tissues comes from tension and compression tests performed using a tensile-testing machine (Figure 1.8.19). The ends of the tissue specimen are held in special clamps, one attached to the rigid base of the testing machine and the other to a moving actuator (in a hydraulically-driven machine) or crosshead (in a screw-driven machine). The movement of the actuator/crosshead up or down is usually controlled electronically, and the load applied to the specimen is measured with a load cell attached to the testing machine. Deformation of the specimen can be measured by tracking the movement of the actuator/crosshead or by attaching an extensometer or strain gage directly to the specimen. In many cases, however, these methods are not accurate enough, and a non-contact optical method must be used. This typically involves recording on high-speed video the positions of reference marks placed on the specimen before the start of the test.

![Fig. 1.8.19 Schematic diagram of a tensile-testing machine.](image)

The output from any tension or compression test is typically a plot of applied load $P$ versus specimen elongation $\Delta l$. Figure 1.8.20 shows a plot for a tensile test on a ligament. The ‘structural properties’ of the entire ligament can be found from such a graph. These include the stiffness (slope of the linear part of the curve), energy absorbed (area under the curve), and ultimate (maximum) load and elongation. These values depend, amongst other things, on the geometry of the tissue, such as its cross-sectional area and length, and on the properties of the tissue substance.

![Click to view larger](image)

**Fig. 1.8.20**

To study the ‘mechanical properties’ of the ligament tissue alone, it is necessary to calculate and plot a graph of stress versus strain. Stress $\sigma$ is defined as the load $P$ divided by the cross-sectional area $A$ perpendicular to the load: $\sigma = P/A$. Strain $\varepsilon$ is defined as the change in specimen length $\Delta l$ divided by the original length $l$: $\varepsilon = \Delta l/l$. Mechanical properties such as the elastic modulus (slope of the linear part of the curve), strain energy density (area under the curve), and ultimate (maximum) stress and strain can be found from a graph of $\sigma$ versus $\varepsilon$ (Figure 1.8.21).

![Click to view larger](image)

**Fig. 1.8.21**
To study the ‘mechanical properties’ of the ligament tissue alone, it is necessary to calculate and plot a graph of stress versus strain. Stress $\sigma$ is defined as the load $P$ divided by the cross-sectional area $A$ perpendicular to the load: $\sigma = P/A$. Strain $\varepsilon$ is defined as the change in specimen length $\Delta l$ divided by the original length $l$: $\varepsilon = \Delta l/l$. Mechanical properties such as the elastic modulus (slope of the linear part of the curve), strain energy density (area under the curve), and ultimate (maximum) stress and strain can be found from a graph of $\sigma$ versus $\varepsilon$. (Figure 1.8.21).
It is important to recognize that mechanical measurements on tissues are affected by experimental, biological, and external factors. Experimental factors include specimen orientation, strain rate, temperature, and tissue hydration. Biological factors are tissue maturation, age, immobilization, and exercise. Storage by freezing and sterilization are external factors.

Viscoelasticity

Almost all polymers (plastics) and all biological materials exhibit time-dependent or viscoelastic properties. Viscoelasticity is a mechanical behaviour involving both fluid-like (viscous) and solid-like (elastic) characteristics. The viscoelastic properties of soft tissues, in particular articular cartilage, have received much attention. The main features of viscoelasticity are shown in Figure 1.8.22. Stress relaxation (Figure 1.8.22A) is a decrease in stress in a material subjected to prolonged constant strain. Creep (Figure 1.8.22B) is an increase in deformation or strain that occurs when a constant load is applied. Hysteresis (Figure 1.8.22C) is a characteristic behaviour related to energy dissipation in which a material property plot follows a closed loop, i.e. the loading and unloading curves are not coincident. These features of the behaviour of biological materials are rarely taken into account in models of joints and limbs because the duration of the activity being studied is relatively short, the viscoelastic effects are secondary, or inclusion of such effects would make the models too difficult to solve.

Load transmission across joints

Here we use a simple, well-known example to illustrate some important points about the loads across joints. Consider the situation shown in Figure 1.8.23A in which a weight is held in the hand with the elbow joint held fixed at 90° flexion and the forearm parallel to the ground. To find the forces transmitted by the anatomic structures at the elbow joint during this activity, it is necessary first to draw a free-body diagram of the forearm (Figure 1.8.23B) and to calculate the intersegmental force \( \mathbf{F} \) and moment \( \mathbf{M} \) at the elbow.
In Figure 1.8.23b, the weight $W$ of the ball and the weight $mg$ of the forearm and hand both act downwards. In this example, it is obvious that the force $F$ balances the forces $W$ and $mg$, and so must act upwards, having a vertical component only. In addition, the moment $M$ must be counterclockwise to balance the moments of $W$ and $mg$ about the centre of the elbow joint. Assuming that the arm belongs to a person of height 170cm and body mass 60kg, anthropometric tables can be used to estimate the length and mass of the forearm and hand ($L = 43$cm, $m = 1.3$kg) and the distance of their centre of mass from the centre of the elbow joint ($a = 29$cm). The position of the centre of mass of the ball from the fingertips is estimated to be $c = 9$cm. For this example, take $w = 50$N.

**Box 1.8.4 Mechanical loading of musculoskeletal tissues**

- Although loaded primarily in tension and compression, the tissues of the musculoskeletal system can also undergo shear, bending, and torsion
- Due to their complicated shapes and non-uniform properties, it may be necessary to use FEA to model these tissues
- A tensile-testing machine can be used to measure both quasi-static and time-dependent mechanical properties of tissues.

---

Solving the equations for static force and moment equilibrium in two dimensions gives $F = 62.75$N upwards and $M = 20.70$Nm counterclockwise. To distribute $F$ and $M$ amongst the anatomic structures of the joint, a model of the elbow joint is needed. Figure 1.8.23C shows a simple model in which it is assumed that the biceps is the only muscle acting. For the elbow position in Figure 1.8.23A, it is assumed that the line of pull of the biceps is parallel to the humerus and that its insertion is $b = 4$cm from the centre of the elbow joint. It is also assumed that the elbow is a hinge (has a fixed axis of rotation) and that the articular contact force $R$ acts vertically at this flexion angle. Using static equilibrium of force and moment in two dimensions (two equations, two unknowns) gives the biceps force $B = 517$N upwards and the joint reaction force $R = 454$N downwards.

It is important to note that the magnitudes of both $B$ and $R$ are larger than the magnitude of the external load $W$. The biceps force $B$ is larger because its moment arm $b$ is smaller than the moment arm of the external load ($L - c$). The joint reaction force $R$ is larger than $W$ because it must balance both $B$ and $W$. That the muscle and joint reaction forces are larger than the external loads is true for most joints. Indeed, the joint reaction forces at the hip and knee can be several times body weight.

One further important point to note is that the moment arm of a muscle about a joint may change as the joint flexes. This obviously influences the force that it is necessary for a muscle to provide to balance the moment due to an external load. The changing moment arm of the biceps about the centre of the elbow joint is illustrated in Figure 1.8.24. (Box 1.8.5).
Fig. 1.8.24
The biceps (B) at various elbow flexion angles. Note the variations in the moment arm $l$ of biceps. Reproduced from Leveau (1992).

**Box 1.8.5 Muscle forces and joint contact forces**

- Due to their smaller moment arms about the joints, muscle forces are typically much larger than external loads.
- Joint contact forces can also be rather large, since they must balance both external forces and muscle forces.
- Moment arms of muscles may change as the joints they cross flex and extend.

**Conclusions**

Much of the progress in the field of biomechanics that has been made over the past half-century has been due to collaborations between scientists, engineers, and clinicians. The scientists and engineers have had to delve into the anatomy and physiology textbooks and the medical literature, while the orthopaedic clinicians have had to return to the mathematics and physics that they studied years before. Both sides have benefited, along with many thousands of patients. This chapter has reviewed and explained some of the fundamental concepts and techniques involved in studying the biomechanics of the musculoskeletal system. It is hoped that clinicians have found this introduction useful and that they will be encouraged to explore the subject further.

Summary points

- Gait analysis tries to obtain reliable clinically relevant information from the way in which patients walk.
- Each technique has its own specific advantages and disadvantages, but all to a greater or lesser degree ‘interfere’ with the patient’s ability to walk.
- As yet it remains mainly a research tool.

Introduction

The study of non-biological systems has been defined as ‘hard’ science and those of biological systems as ‘difficult science’. This is because biological systems fluctuate. Gait analysis is the study of walking, a process made up of a multitude of complex fluctuating parameters. Each pace that we take is slightly different from the last, and your gait is different from mine. This means that some differences that we may observe are merely the result of biological variability, while other equally subtle ones may be diagnostic of abnormality.

Many techniques for performing gait analysis have been developed in an attempt to qualify (what is the problem?) and quantify (how bad is it?). Some of the techniques available are listed in Table 1.9.1. Any useful measurement of gait will strive to achieve the following (Box 1.9.1):

- **The observer principle** The equipment used to measure gait should not be so heavy and cumbersome that it interferes with the patient’s ability to move freely, i.e. it should not in itself alter the gait.
- **Sensitivity and specificity** It should reliably detect the differences in gait needed to make a diagnosis, while ignoring differences which are merely a result of inter- and intraindividual variability.
- **Relevance** The differences that it measures should be valuable in making a diagnosis and in choosing treatment. The measurements needed to diagnose a knee with cruciate instability will be different from those needed to understand the problems of cerebral palsy.
- **Reproducible** It should give the same result consistently every time the measurement is made. If possible these results should be independent of when or where the measurements were taken.
- **Useable** It should not be too expensive and should not require a highly skilled operator to use or interpret results.

Clinical utility is the concept of addressing the question of whether the test measures things which cannot be measured in any other way, and whether these measures actually lead to new clinical decisions being made which are ‘better’ than those made using the old methodology.

So far, no system of gait analysis has come close to these basic requirements.
Equipment used for gait analysis (Table 1.9.1) can be classified into four simple groups (Box 1.9.2). Those which:

1) Measure the ‘reaction forces’ which the patient has on their environment, e.g. foot pressure plates. These rely on having a force plate in the floor so the patient has to walk onto the plate
2) Record the translational movement and acceleration of limbs and how much joints bend. These rely either on putting markers on the patient which can be visualized from at least two directions so that a three-dimensional plot of the limbs can be made. Alternatively, sensors may be fitted onto the patient which measure joints bending or limbs accelerating
3) Electrical activity of muscles (myography). Records can be obtained either from needles inserted into the muscles (specific) or skin pads. Unfortunately there is little correlation between the amount of activity recorded and the power developed by a muscle
4) Overall energy expenditure. In very simple terms the ‘better’ the gait the less energy will be used to achieve an equivalent speed.

**Box 1.9.2 Types of gait analysis system**

- Pressure plates
- Measure movement and bending of joints
- Record activity of muscles
- Measure energy expenditure.

If a combination of these techniques is used, complex calculations can be performed using computers to calculate the forces passing through the patient’s limbs and the body. From that it may even be possible to determine which muscle is contracting (or failing to relax) at each phase of the gait cycle. These calculations are complex and inevitably rely on some estimations (educated guesses). Any error in the data entered into the equations will be amplified by those calculations, so paradoxically the more complex the calculations the higher the chance of meaningless results being produced.

There are few conditions in which gait analysis is still considered as being of potential value in determining what treatment is most appropriate.

**Cerebral palsy**

Myography can be used to determine whether muscles are active continuously or only during part of the gait phase. If muscles are found to be active through all phases of gait, then division or lengthening may improve gait but transfer will not. If, however, contraction only occurs during the swing phase of gait, then transfer may provide the best result. The situation is complicated by the fact that any change in the action of one muscle (by lengthening or transfer) may change the behaviour of other muscles.

**Summary**

To date, no method of gait analysis has proved invaluable in the assessment of a patient. No trials have yet demonstrated its benefit over simple clinical assessment. This may, in part, be because the surgical treatment options remain so crude in conditions such as cerebral palsy.

Summary points

- Each modality of imaging—digital radiography, multidetector computed tomography (MDCT), magnetic resonance imaging (MRI), ultrasound, and nuclear medicine studies—has its own advantages and disadvantages.
- Conventional radiography is the best for initial evaluation of a musculoskeletal problem.
- MDCT rapid survey of multiple trauma patients is easily performed using the new high speed computed tomography scanners.
- MRI is the imaging modality of choice for internal derangement of the knee and other soft tissue injuries.
- Radionuclide bone imaging is most suitable for screening the whole skeleton for metastases.
- Positron emission tomography is useful for identification of tumour, inflammation, and infection.

Introduction

There are a number of imaging modalities currently available to the practising orthopaedic surgeon, including digital radiography (DR), multidetector computed tomography (MDCT), magnetic resonance imaging (MRI), ultrasound, nuclear medicine studies, and studies where iodinated contrast is injected into the extremity joints, such as conventional arthrography or magnetic resonance arthrography.

Radiography

The radiographic examination is the best and most available imaging study for the initial evaluation of patients with orthopaedic problems. Generally, radiography should precede any complex imaging studies such as computed tomography (CT) or MRI.

X-rays used in medical imaging are either generated in x-ray tubes or emitted from radioactive isotopes. Those generated in x-ray tubes are used in radiography, fluoroscopy, and CT. X-rays emitted from radioactive isotopes are used in nuclear medicine and are called y-rays. In the x-ray tube (Figure 1.10.1), x-rays are generated when a fast stream of electrons is suddenly stopped by the target or anode (positive terminal). The electrons originate on the negative terminal of the tube which is also known as the cathode or filament. The area of the target bombarded by electrons is known as the focal spot., which should be as small as possible, preferably 1 mm or less. The quantity of x-rays emitted from the x-ray tube is proportional to the number of electrons flowing from the filament (cathode) to the target (anode); this is measured in milliamperes (mA) and is preselected by the technologist. The quality, or penetrating properties, of the x-ray beam is determined by the energy of the electrons striking the target. This is determined by the kilovoltage setting (kVp). Modern x-ray tube casings are designed with filters to remove the low energy radiation from the x-ray beam. Filtration is an essential technique utilized to change the composition and improve the quality of the x-rays beam. High-energy x-rays generate significant scatter radiation which results in foggy images and diminished tissue contrast on radiographs. The use of a fixed or a reciprocating (motorized) grid is the most commonly applied technique for controlling scatter in medical radiography.

![Click to view larger](Fig. 1.10.1)

Diagram of x-ray tube. Rotation of the anode increases the heat capacity of the tube and allows more x-rays to be generated.
X-Ray Machine design

- The anode (focal spot) is small to optimize definition
- Filters maximize useful imaging radiation
- Grids remove radiation scattering from tissues
- Quantity (mA) and energy (kV) are optimized for imaging task
- Shuttering down field size reduces radiation & improves image quality

Limiting the field size, or restricting the size of the beam to the area of interest achieves two very important objectives: it reduces scatter and cuts radiation to the patient.

Variations in tissue composition give rise to differences in how much of the primary x-ray beam is transmitted through the patient. Structures that stop much of the primary beam have high attenuation. Bone has high beam attenuation, whereas inflated lung has low beam attenuation, and appears dark on a radiograph, while bones appear white on the radiograph. Fat attenuates x-rays more than air, while water and soft tissues attenuate it more than fat but less than bone. These variations in the ability of the different tissues to attenuate the x-ray beam form the basis for tissue contrast on radiographic images.

A major problem with film as an x-ray detector in orthopaedics is related to the wide variation in extremity thickness, which may result in underexposure in one part and overexposure in another on the same radiograph. An alternative to the conventional radiographic film is the digital image or radiograph. Images can be manipulated to improve density and contrast, they can be enlarged or minimized; images can also be transmitted from station to station. The dose to the patient is reduced because the storage phosphor is more sensitive than the screen-film system; repeat exposures due to technical errors are also eliminated because the image contrast and density can be manipulated at the workstation.

Digital imaging vs Conventional films

- Improves contrast range
- Radiation dose to patients is reduced
- Assists storage

Radiographic techniques

For most orthopaedic problems, two orthogonal radiographic views of the structure under investigation are considered a basic requirement. Depending on the anatomical region, additional views are often needed. In the trauma setting, two orthogonal views may be difficult to obtain. When a non-displaced fracture of the navicular is suspected it is advantageous to put the long axis of the navicular parallel to the film (Figure 1.10.2). Small avulsion fractures at the dorum of the triquetrum are best detected on mildly pronated lateral views of the wrist (Figure 1.10.3). The pisiform, pisitriquetral joint, and the hook of the hamate are best visualized on mildly supinated lateral views as well as carpal tunnel views (Figure 1.10.4).

Fig. 1.10.2
Scaphoid view demonstrating a subtle fracture. A) The routine PA view of the wrist was unremarkable and showed no fractures. B) The scaphoid view, obtained by placing the hand and wrist in ulnar deviation along with 15 degrees of cephalad angulation of the x-ray tube, shows a subtle non-displaced fracture (arrow).
Fig. 1.10.3
Avulsion fracture of the triquetrum demonstrated on mildly pronated lateral view of the wrist. A) PA view of the wrist shows no abnormalities of the triquetrum. B) Mildly pronated lateral view clearly demonstrates the avulsion fracture of the dorsum of the triquetrum (arrow).

Fig. 1.10.4
Mildly supinated lateral view of the wrist demonstrates a pisiform fracture which was difficult to see on routine views.

Standing AP views of the knees are recommended for patients with osteoarthritis, to demonstrate the extent of articular cartilage loss (Figure 1.10.5). Many authorities believe that radiography for ankle injuries is overutilized, and several criteria have been suggested to limit unnecessary examinations; the Ottawa criteria are probably the best known.
Standing AP view of the left knee of a 70-year-old male showing marked narrowing of the joint space medially indicating almost total loss of cartilage. Varus deformity of the knee and mild lateral subluxation of the tibia are also present.

It is not necessary for orthopaedic surgeons to know all the appropriate views that can be used. X-ray departments will arrange for appropriate views, provided that the diagnosis under consideration is clearly stated in the request form.

Neck pain can be initially evaluated with an anteroposterior (AP) and lateral views of the cervical spine. The American College of Radiology has developed appropriateness criteria for the use of imaging studies in the trauma setting. If the upper thoracic spine or lower cervical spine is obscured by the shoulders, a swimmer’s view is usually quite helpful. For the lumbar spine, AP and lateral views are typically sufficient. Occasionally, oblique views are used to look for defects in the pars interarticularis, but these oblique views add significant radiation dose to the patient, increase the cost of the examination, and should not be used routinely.

Views
- For many conditions guidelines indicate when x-Rays are needed
- Two films at right angles are the usual requirement
- Some areas and problems have special views
- Radiographers will choose the most appropriate views for each diagnosis

Radiation protection
Gonadal shielding should always be used where appropriate, and care taken to minimize exposure to other patients and staff. Appropriate personnel radiation-monitoring devices should be worn by health professionals whenever there is a possibility of exposure to radiation.

Multidetector row computed tomography (Box 1.10.1)

The introduction of helical CT and MDCT has transformed the value of CT in acquiring volumetric data sets, improving resolution and allowing very thin slices (0.3mm). It also enables reconstruction of images in any plane as well as three dimensions (Figures 1.10.6-1.10.8). Other advantages of MDCT are increased speed and increased total volume covered. This is valuable for multitrauma patients, with head, chest, spine, and abdominal injuries, as all can be scanned at the same time. The whole body from the head to below the hips can be imaged in less than 30s.

Box 1.10.1 Multidetector row computed tomography
- Allows rapid scanning of multiple areas
- High definition and low dosage
- Enables reconstruction of images in any plane
- Work stations enable rapid viewing of multiple images.
Fracture non-union. A 56-year-old male with a left distal femur fracture treated with a LISS plate and screws. Patient continued to have pain several months after the surgical fixation. A, B) AP and lateral views of the distal left femur show good apposition and alignment of the fracture fragments. No complications are noted with the hardware. C) Coronal and sagittal CT reformations of the distal left femur show absence of bony bridging across the fracture gap (arrows). The diagnosis of non-union was made.

Congenital scoliosis. A 10-year-old boy who is known to have congenital scoliosis now presenting to the paediatric orthopaedic clinic with difficulty walking and long track signs. A) Axial CT section through T11 shows a spike of bone projecting into the spinal canal (arrow). This was diagnosed as representing diastematomyelia. B) A coronal multiplanar reformation illustrates the multiple congenital vertebral anomalies in the upper thoracic spine along with severe scoliosis. The blue line illustrates the plane along which the curved planar reformation will electronically correct the scoliotic curve. C) A curved planar reformation straightens the spine and provides a better view of the diastematomyelia.

MDCT scanners currently generate hundreds or even thousands of images on each patient. It has, therefore, become impractical to print images or view studies one image at a time. Postprocessing workstations are now a necessity, and the task of interpreting CT studies from printed images has disappeared. Parallel advances in picture archiving and communication (PACS) technology have taken place, allowing real-time viewing, manipulation of large stacks of images, and distribution of images throughout the medical centre.

Magnetic resonance imaging (Box 1.10.2)

Magnetic resonance imaging (MRI) is now the primary imaging technique for internal derangement of the knee, disc disease, muscle and tendon injuries, early detection of osteonecrosis, and evaluation and staging of many soft tissue and bone neoplasms.

Box 1.10.2 MRI

- Atoms with unpaired electrons align in a magnetic field
- They also spin and precess
- A radio signal disrupts the precession
- As the molecules return to their original orientation they emit a radio signal
- The source and strength of the signals allows a three-dimensional picture to be created.
Physical principles

The basic principle of clinical MRI is that any nucleus with an unpaired proton or neutron, such as hydrogen atoms, will react to external magnetic fields. When a subject is placed in a strong magnetic field, some of the protons align with the magnetic field while spinning and precessing around the axis of the magnetic field. This is analogous to the wobble of a spinning top (Figure 1.10.9). Hydrogen atoms in different tissues (fat versus muscle) will have different constants and precess at different frequencies.

![Diagram of a hydrogen proton in an external magnetic field. Note that the nucleus has spin as well as precession around the main direction of the external magnetic field.](Click to view larger)

Fig. 1.10.9
Diagram of a hydrogen proton in an external magnetic field. Note that the nucleus has spin as well as precession around the main direction of the external magnetic field.

The equilibrium of spin alignment can be disturbed by applying a radiofrequency pulse at the frequency of precession. As the protons come back into alignment, they emit electromagnetic radiation in the radiofrequency spectrum that is collected and turned into magnetic resonance images.

Definitions

- **$T_1$ relaxation time** Also called longitudinal relaxation or spin–lattice relaxation time, $T_1$ relaxation time is a tissue-specific time constant. $T_1$ images depict anatomy well: fat is white, water is black
- **$T_2$ relaxation time** Also called transverse relaxation time or spin–spin relaxation time, this is also a tissue-specific time constant. $T_2$ images show pathology well. Fat is black, water white.

Pulse sequences

A pulse sequence is a precisely defined pattern of radiofrequency pulses and listening intervals. The most commonly used pulse sequence in the study of the musculoskeletal system is the spin–echo sequence (Figure 1.10.10).

![Spin–echo pulse sequence. It consists of a 90-degree pulse followed by a pause, after which a 180-degree pulse is applied. Then after an additional pause, the receiver coil is set to listen to a signal (echo) emitted from the tissues; after a longer pause, the cycle is repeated.](Click to view larger)

Fig. 1.10.10
Spin–echo pulse sequence. It consists of a 90-degree pulse followed by a pause, after which a 180-degree pulse is applied. Then after an additional pause, the receiver coil is set to listen to a signal (echo) emitted from the tissues; after a longer pause, the cycle is repeated.

A spin–echo sequence can be $T_1$ weighted, accentuating the $T_1$ properties of tissue, or $T_2$ weighted, accentuating the $T_2$ properties of the tissue. In general, $T_1$-weighted sequences depict anatomy better and $T_2$-weighted images show pathology to advantage.

On $T_1$-weighted images, tissues with a short $T_1$ have high signal intensity and are bright (Box 1.10.3). An example of a substance with a short $T_1$ is fat. Tissues with long $T_1$, such as cerebrospinal fluid, have low signal intensity. On $T_2$-weighted sequences, tissues with a short $T_2$ have low signal intensity. Examples include tendon and ligament. Tissues with a long $T_2$, such as cerebrospinal fluid, are bright on $T_2$-weighted sequences. Inflamed, oedematous tissue has more extracellular water than normal and will therefore be lower in signal intensity on $T_1$-weighted images and will be higher in signal on $T_2$-weighted images than...
normal tissue. Most tumours appear relatively dark on T₁-weighted images, less than fat and similar to muscle. On T₂-weighted images, most tumours show increased intensity, but not usually as bright as cerebrospinal fluid.

**Box 1.10.3 T₁ and T₂ weighted images**

- On T₁ fat is white, water black
- On T₂ cerebrospinal fluid is bright, tendons and ligaments are dark
- Tumours and inflammation are dark on T₁ and light on T₂ images.

**Fast imaging**

Conventional spin-echo images are the mainstay of MRI, but the T₂-weighted images take a long time to acquire and are susceptible to motion artefacts. Other pulse sequences have been developed that generate images in much less time; one such sequence is called fast spin-echo. Imaging times can be cut significantly because up to 32 lines of the image can be acquired in a single repetition. Besides reducing time of acquisition, fast spin-echo images have less distortion of the image when hardware or metal is present in the scanned area (Box 1.10.4). One disadvantage to fast spin-echo sequences is that oedema is harder to detect than with spin-echo images. Spin-echo T₂-weighted images have traditionally been used to detect oedema that is often present as a sign of many pathological processes. These T₂-weighted sequences are sensitive for detecting oedema because signal intensity of fat is low and signal intensity of water is high on T₂-weighted images. However, with fast spin-echo T₂-weighted images, the signal from fat is not suppressed and oedema can be masked. To overcome this limitation, methods to suppress the signal from fat are often employed.

**Box 1.10.4 MRI modifications**

- Fast imaging reduces metal artefact
- Chemical presaturation and inversion recovery suppress the fat signal
- Gadolinium concentrates in inflamed tissue and enhances signal.

**Fat suppression**

The two currently used methods of suppressing fat signal are frequency selective chemical presaturation and inversion recovery. Chemical presaturation is a technique that is applied to other sequences such as fast spin-echo, whereas inversion recovery is a pulse sequence itself, and cannot be combined with other sequences. When using chemical presaturation, the machine takes advantage of the fact that the hydrogen protons in fat have a slightly faster precessional rate than water hydrogen protons. By placing a very selective radiofrequency pulse that only deflects fat hydrogens immediately before the main pulse sequence, signals from fat can be nullified, and signals from all other tissues unaffected. This is usually used with fast spin-echo T₂-weighted sequences to increase the conspicuity of oedema or fluid. Chemical presaturation can also be used with T₁-weighted images after the administration of contrast. Increases in signal from contrast accumulation are more conspicuous when surrounding fat (bright on T₁-weighted images) is dark.

Inversion recovery sequences can effectively decrease signals from fat, but they have the disadvantage of a long repetition time, and take a relatively long time to acquire. Newer inversion recovery pulse sequences include a fast inversion recovery sequence, which still suppresses fat signal and is very sensitive for oedema, but is acquired rapidly, similar to fast spin-echo. One important point is that if fat suppression is desired for images obtained following contrast administration, chemical saturation should be used and inversion recovery avoided. Inversion recovery will suppress the signal changes caused by the contrast, whereas chemical saturation will not.

**Contrast agents**

Gadolinium is a transition element which has paramagnetic activity, shortening both the T₁ and T₂ relaxation times of nearby hydrogen nuclei. The T₁ shortening produces a higher (brighter) signal on T₁-weighted images. Enhancement of tissues is roughly proportional to blood flow to the tissue, and results in increased signal on T₁-weighted images. Therefore, following contrast administration, T₁-weighted sequences are typically obtained and compared to T₁-weighted images before contrast.

Contrast is most commonly used as an intravenous agent, but can also be instilled into joints, resulting in an MR arthrogram. This has been applied to the shoulder for improving the characterization and detection of labral abnormalities and in the knee for evaluating osteochondral fragments and postoperative menisci.

**Clinical applications (Box 1.10.5)**

**Upper extremity**

Tendon degeneration, tendinopathy, partial and full thickness tears of the rotator cuff all show-up as areas of increased signals on the T₂-weighted images. Fat suppression and magnetic resonance arthrography will increase the conspicuousness of cuff...
abnormalities (Figure 1.10.11).

**Box 1.10.5 Clinical applications of MRI**

- Rotator cuff is well visualized
- In the elbow MRI shows soft tissue and bone injury simultaneously
- MRI of the wrist requires high-resolution MRI and thin slices
- Damage to the triangular fibrocartilage is well visualized.

MR arthrography extends the capabilities of conventional MRI because contrast solution distends the joint capsule, outlines intra-articular structures, and leaks into abnormalities. By demonstrating the inferior labral–ligamentous complex, MR arthrography makes a major contribution to the evaluation of patients with suspected glenohumeral instability (Figure 1.10.12). Although MR arthrographic images have demonstrated greater than 90% accuracy in the detection of anteroinferior glenoid labral tears, diagnostic confidence may be further increased when the shoulder is imaged in abduction and external rotation (ABER). This involves flexing the elbow and placing the patient’s hand posterior to the contralateral aspect of the head or neck. An anteroinferior glenoid labral tear that is non-displaced when the shoulder is in a neutral position has a greater likelihood of being displaced from the glenoid rim and becoming more conspicuous when the shoulder is in the ABER position.

![Fig. 1.10.12](image)

Glenohumeral instability. A 15-year-old boy who had dislocated his shoulder. A) Fat-suppressed transverse T1-weighted MR arthrogram demonstrates torn labrum (arrow). B) Fat-suppressed sagittal T1-weighted image shows Bankart lesion extending from 1 o’clock to 5 o’clock position (arrowheads). C) Fat-suppressed coronal T1-weighted image reveals detachment of the labroligamentous complex (arrow) from the glenoid. D) Fat-suppressed ABER (abduction external rotation) view reveals contrast material in a gap (arrowhead) between the periosteum and scapular neck (curved arrow), at the base of the anterior glenoid labrum. Note the presence of contrast material rounding the corner of the glenoid and passing through freely floating torn anterior glenoid labrum (arrow).
The multiplanar capabilities of MRI enable the elbow joint to be imaged in true sagittal and coronal planes, facilitating more accurate diagnosis of ligamentous injuries. The superior soft tissue contrast of MRI provides simultaneous evaluation of bone and soft tissue, allowing for assessment of all the static and dynamic stabilizers.

The use of MRI to evaluate the wrist has lagged behind that of larger joints, because of technical limitations of spatial resolution. Thin and contiguous slices are needed for adequate MRI of the wrist. Therefore, high-resolution MRI is essential to evaluate normal and abnormal features of the hand and wrist.

MRI or MR arthrography can localize and characterize tears of the triangular fibrocartilage complex (Figure 1.10.13), helping to identify those patients that would benefit from surgery. MR arthrography combines the advantages of arthrographic depiction of anatomic perforation with the direct visualization of marrow, cartilage, and soft tissues allowed by MRI and can be performed with single-, double, or triple-compartment injection.

![Click to view larger](Fig. 1.10.13) Triangular fibrocartilage complex tear. A 14-year-old girl with ulnar-sided wrist pain. A) Fat-suppressed coronal intermediate weighted MR arthrogram demonstrates defect and tear of the lower lamina of the triangular ligament from the styloid process of the ulna (arrowhead), indicating peripheral tear of the triangular fibrocartilage complex. B) Fat-suppressed coronal T1-weighted MR arthrogram again shows avulsion of the ulnar attachment of the triangular fibrocartilage complex (arrowhead).

Knee (Box 1.10.6)

MRI is an effective modality for diagnosing tears of the anterior cruciate ligament, and is also accurate for detection of meniscal tears. Normal menisci have low signal intensity on all pulse sequences, and tears are seen as linear increased signal that contacts a surface of the meniscus on two consecutive images. Another sign of meniscal tears is abnormal contour of the meniscus, with truncation being a sign of a displaced fragment (Figure 1.10.14). Following partial meniscectomy, re-injuries are difficult to diagnose by MRI. Intra-articular contrast is a method to improve the characterization of the postoperative meniscus.

**Box 1.10.6 MRI and internal derangement of the knee**

- Meniscal tears show linear abnormal signal in two consecutive slices
- Postmeniscectomy re-injury is hard to diagnose with enhancement
- Anterior cruciate damage can be diagnosed by primary and secondary findings
- Any change in signal in the posterior cruciate is abnormal
- Medial collateral ligament damage is well visualized
- Bone contusion and occult fractures show up well
- The patella tendon shows a bright area following damage.

![Click to view larger](Fig. 1.10.14) Bucket-handle tear of the medial meniscus. A 17-year-old male wrestler with significant knee pain and locking. A) Fat-suppressed oblique sagittal T2-weighted sequence shows an abnormal band of low signal intensity (arrowhead) and double posterior cruciate ligament sign (arrow), representing bucket-handle tear. B) Fat-suppressed coronal T2-weighted image demonstrates a centrally displaced meniscal fragment (arrow) inferior to the posterior cruciate ligament (arrowhead). C) Fat-suppressed transverse T2-weighted image reveals a displaced fragment of the meniscus (arrow).
A tear of the anterior cruciate ligament can be shown on MRI by detecting abnormalities of the ligament itself, such as increased signal within the ligament, or by detecting secondary signs that the anterior cruciate ligament is torn (Figure 1.10.15). Primary signs include abnormal increased signal of the anterior cruciate ligament, and abnormal orientation of the ligament. Secondary signs result from laxity of the knee including anterior translation of the tibia, abnormal posterior position of the posterior horn of the lateral meniscus, and abnormal orientation of the posterior cruciate ligament such as hyperbuckling. A prior severe injury may show as bone contusions, medial collateral ligament injury, and haemarthrosis.

Any increase in signal in the posterior cruciate ligament is abnormal. Conversely, the anterior cruciate ligament often has some strands of increased signal within it, and this can be problematic for detecting subtle anterior cruciate ligament tears, and decreases the accuracy of MRI for evaluating partial anterior cruciate ligament tears. Medial collateral ligament injuries produce, abnormal signals both deep and superficial to the medial collateral ligament, and if the ligament is focally disrupted or not visualized at all, then complete tear is diagnosed.

In a patient with persistent pain following trauma in whom plain films are negative, MRI can show contusions or occult fractures. It can also be used to evaluate patients with suspected injury to the patellar ligament. In patellar tendinitis or partial tearing, the ligament may show increased signal intensity on T1-weighted, T2-weighted, and proton density images; it also shows increased AP diameter proximally and the margins of the affected ligament become indistinct, especially posterior to the thickened segment.

One artefact that commonly occurs with musculoskeletal MRI is the magic-angle phenomenon (Figure 1.10.16). Tendons can have a falsely increased signal when they are oriented approximately 55 degrees out of the main magnetic field. The supraspinatus tendon, just proximal to its insertion on the greater tuberosity, commonly shows this artifact. Other tendons that commonly show magic-angle effects are the patellar ligament, the foot flexor tendons such as flexor hallucis longus, and, occasionally, the peroneal tendons. If increased signal is seen on a short echo time (TE) sequence, it is important to confirm the abnormality on a long TE sequence.

Ankle and foot

For the Achilles tendon, axial and sagittal planes are sufficient for evaluation (Figure 1.10.17). However, the other tendons that cross the ankle joint do not run in a straight course, but curve around the ankle and hindfoot roughly parallel to the posterior facet of the subtalar joint. Therefore, in order to image these tendons in cross-section, oblique imaging planes should be used. When studying the foot flexors and extensors, sagittal sequences are followed by oblique coronal sequences that are perpendicular to the
posterior facet of the subtalar joint (Figure 1.10.18).

Fig. 1.10.17

Fig. 1.10.18
Oblique coronal plane for hindfoot imaging. A) Lateral scout view during acquisition of a hindfoot MRI study shows the orientation of slices for oblique coronal imaging. Note that the slice orientation is perpendicular to the posterior facet of the subtalar joint. B) A 60-year-old patient with hindfoot pain following a fall. Oblique axial T2-weighted image showing debris in an otherwise empty tendon sheath of posterior tibial tendon (large arrow). Scan is at the level of posterior talofibular ligament (small arrow). C) Oblique T2-weighted image distal to (B) shows distal fragmented end of tendon (arrow). D) Sagittal inversion recovery image shows proximal end of tendon curled up at the musculotendinous junction.

Spine (Box 1.10.7)
From an orthopaedic standpoint, MRI is very useful for evaluating patients with possible disc disease, metastatic disease, congenital anomalies, and trauma.

Box 1.10.7 MRI of the spine

- Degenerate discs show clearly with decreased signal on T2
- 38% of ‘normal’ patients may show disc abnormalities on MRI of the spine
- Metastases in the spine show complete marrow fat loss
- The oedema from acute fractures may mimic malignant infiltration
- Vertebral osteomyelitis shows as low signal on T1, high on T2.

MRI is very sensitive for detecting abnormal signal and morphology of intervertebral discs (Figure 1.10.19). Normally the disc is lower in signal intensity than vertebral bone marrow on T1-weighted images, and higher in signal on T2-weighted images. With disc degeneration, signal remains low on the T2-weighted images.
Disc protrusion. A 20-year-old man with low back pain. A) Sagittal T2-weighted MRI demonstrates loss of signal intensity of the L5–S1 intervertebral disc (arrow), reflecting changes caused by degenerative disc disease. B) Transverse T2-weighted MRI, obtained at the level of the L5–S1 disc, shows right paracentral focal bulge of the disc (arrow), representing disc protrusion.

While MRI is very sensitive for detecting abnormal discs, care must be taken when interpreting the study to correlate with the patient’s symptoms. In an asymptomatic population, over one-third have disc abnormalities at more than one level by MRI criteria. MRI with contrast enhancement is the best technique to study individuals with the failed back syndrome, and differentiating recurrent disc herniation from epidural scarring following surgery.

For evaluating patients with suspected metastases to the spine, MRI is also the procedure of choice. It shows the extent of bony involvement, degree of compression of the cord, and extradural extension of the tumour. It is more specific than bone scan for characterizing metastatic deposits, and the entire spine can be surveyed in the right clinical setting. Metastases replace the normal fatty bone marrow and therefore appear as focal low-signal areas on T1-weighted images. MRI is also helpful for distinguishing benign from metastatic aetologies of compression fractures. If a part of the affected vertebral body marrow is intact, then the fracture is likely to be benign. Metastatic compression fractures typically show diffuse complete replacement of the marrow signal. One caveat to this rule is in the setting of acute compressions. The oedema associated with acute compression fracture leads to diffuse replacement of the marrow signal, and resembles metastatic deposit. In this setting, the best approach is to repeat the MRI in 6 weeks if the clinical suspicion for metastatic disease is low, or to biopsy the collapsed vertebra in the setting of higher suspicion.

Patients with vertebral osteomyelitis usually present with back pain. The typical plain radiographic features of adjacent vertebral endplate destruction with loss of intervertebral disc height may lag for several weeks. Often, the white blood cell (WBC) count and erythrocyte sedimentation rates are non-specific, and no fever is present. In this setting, MRI is a very sensitive method to detect vertebral osteomyelitis and discitis. The classic findings are adjacent vertebra with abnormal replacement of marrow signal with oedema, low signal on T1-weighted and high signal on T2-weighted images. The intervertebral disc usually shows increased signal on T2-weighted images as well.

Neoplasms (Box 1.10.8)

For most tumours, there are no tissue-specific features on MRI that allow definitive diagnosis. Notable exceptions include lipoma and soft tissue haemangioma. The MRI appearance of a benign lipoma is characteristic. However, differentiating the low-grade liposarcoma from a benign lipoma with some internal septations can be quite difficult. It is generally agreed that interpretation of MRIs on patients with suspected bone tumours should not be done without the plain films at hand. Use of intravenous contrast is also controversial.

Box 1.10.8 MRI and tumours

- Low-grade lipomas can be difficult to distinguish from benign ones
- Tumour margins may be exaggerated by oedema
- Seroma in a tumour bed can mimic recurrence.

The main use of MRI in the evaluation of patients with tumours is staging and postoperative follow-up. MRI is superior to plain film for detecting the extent of disease for surgical planning. It can be difficult to separate peritumoural oedema from actual tumour. When evaluating a patient with primary bone malignancy, it is important to scan the entire extremity involved to detect any occult skip metastases. For the postoperative patient, MRI can be used to detect recurrent disease. However, haematoma or seroma in the surgical bed are often present and can make exclusion of recurrent or residual tumour difficult. Follow-up scans will typically show stable or decreasing size of seromas and haematoma whereas tumours generally increase in size.

Bone scans are most commonly done using technetium-99m labelled phosphonates (99mTc MDP, 99mTc HEDP). When 99mTc decays (half-life 6h), gamma rays are emitted, which are then detected to produce an image. 99mTc-labelled phosphonates accumulate preferentially in the mineral phase of newly forming bone. Areas of increased bone remodelling, whether it is due to infection, trauma, or tumour, will appear ‘hot’ on the bone scan compared to normal bones. Therefore bone scan abnormalities are usually not specific for a disease process. The primary strength of bone scans is its relatively high sensitivity when trying to rule
Bone scans are routinely done 3h after injection of 99mTc-labelled phosphonates. The 3-h interval allows clearance of the radiopharmaceutical from the soft tissue to reach optimal bone to soft tissue contrast. Planar whole body scans are ideal for screening of the entire skeleton. They may not, however, show the optimal contrast for lesion detection in the spine because of uptake in the normal parts of the vertebrae anterior and posterior to the lesion. Spinal lesions are significantly better detected with tomographic imaging (single photon emission computerized tomography, SPECT) because of the better spatial resolution. Exact localization of the abnormality in the vertebra on SPECT imaging also helps with differentiation of benign versus malignant lesions. To evaluate the blood flow and vascularity of a lesion, a three-phase bone scan is performed, which includes immediate flow and blood pool images followed by bone scan at 3h.

**Tumour imaging (Box 1.10.9)**

Although many bone metastases are lytic on x-rays, they stimulate osteoblastic activity and new bone formation. This accounts for the increased uptake of bone tracers in osseous metastases. The typical pattern is the presence of multiple focal areas of increased uptake predominantly in the axial skeleton.

**Box 1.10.9 Bone scans for bone tumours and metastases**

- More sensitive than plain x-rays in detecting metastatic disease
- The extent of an Ewing’s sarcoma is exaggerated on bone scan
- Neoadjuvant chemotherapy also produces an abnormal scan
- Bone scans do not reliably distinguish benign and malignant tumours.

Bone scans are more sensitive than x-rays in detection of metastatic bone disease, and are used for assessment of treatment response to chemotherapy and hormonal therapy. Primary malignant bone tumours generally demonstrate intense uptake of bone tracers. Osteosarcomas typically appear as areas of markedly increased uptake on the bone scan. Bone scan cannot be used to assess the extent of the Ewing sarcoma because the area of increased uptake is usually larger than the extent of the tumour. Bone scans in osteosarcoma and Ewing sarcoma are used to evaluate metastatic disease at initial staging and follow-up (Figure 1.10.20). Bone scans are of limited value in assessing response to neoadjuvant chemotherapy because of persistent increased uptake related to bone remodelling.

**Trauma and sports injuries (Box 1.10.10)**

Bone scans are highly sensitive for diagnosis of occult fractures in patients with pain and a negative x-ray. Bone scans are done most frequently to evaluate fractures in the wrist, hips, and spine, but become positive within 24h after any fracture in 90–95% of patients. In elderly patients, bone scans may only become positive after some time and repeat imaging at 72h is suggested if the initial bone scan is negative. Bone scans may remain positive for up to 3 years after a fracture.
Box 1.10.10 Bone scans in trauma and sports injuries

- Bone scans may not become positive for up to 72h after trauma
- Shin splints and stress fractures are easily distinguished by bone scan
- Complex regional pain syndrome shows uptake especially around joints
- Heterotopic bone is ‘hot’ until it is mature
- Tomographic bone scan should be used for suspected spondylolysis.

Bone scans can be also helpful to evaluate post-traumatic complex regional pain syndrome, type 1 (CRPS-1; reflex sympathetic dystrophy). The typical pattern of CRPS-1 is diffuse increased bone tracer uptake of the involved extremity, most prominent in periarticular regions. The flow and vascularity may be increased in the initial phase of disease, but may be negative in the late phase of the disease after 60 weeks of onset of symptoms. Bone scans are also used in the management of heterotopic ossification. There is intense soft tissue uptake of the radiopharmaceutical during formation of heterotopic ossification, but this normalizes or shows only mild uptake in mature heterotopic ossification.

Early stress fractures are not usually visible on plain radiographs. A negative bone scan excludes stress fracture lesions even in clinically suspected cases. The typical finding of a stress fracture on bone scan is focal fusiform increased uptake at the site of injury (Figure 1.10.21). Bone scintigraphy is also helpful to differentiate stress fractures from shin splints. The typical presentation of shin splints on the bone scan is a linear uptake along the posteromedial aspect of the middle third of the involved tibia (Figure 1.10.21).

![Click to view larger](image)

**Fig. 1.10.21**
A) Stress fracture with focal uptake in the mid tibia on bone scan. B) Shin splints with linear cortical uptake at the posterior aspect of both tibiae.

A positive bone scan in the pars region indicates spondylolysis as the cause of low back pain and correlates with good outcome after fusion surgery. Tomographic images of bone scintigraphy (SPECT) of the lumbar spine need to be obtained as more than 50% of active spondylolysis may not be detected with routine planar bone scans (Figure 1.10.22).

![Click to view larger](image)

**Fig. 1.10.22**
Spondylolysis. Focal uptake consistent with right pars fracture at L5 on bone SPECT including transaxial, sagittal, and coronal tomographic images.
Infection imaging

A three-phase bone scan is the initial test of choice for diagnosis of osteomyelitis after a negative/inconclusive x-ray. Increased bone tracer uptake reflecting bone remodelling may, however, also be seen after fracture, surgery and hardware placement. In these cases labelled WBC scans are used to complement bone scans.

Labelled WBCs, which can be labelled with $^{111}$In or $^{99m}$Tc, do not accumulate in fractures or sites of orthopaedic surgery in the absence of infection (Figure 1.10.23). Labelled WBCs, however, accumulate in normal bone marrow. If bone marrow distribution has changed secondary to surgery or prosthesis or if there is active marrow proliferation, such as seen in patients with diabetic arthropathy, the labelled WBC scan may show increased/asymmetric uptake in the absence of infection. Therefore labelled WBC imaging should be done in conjunction with a bone marrow scan to differentiate infection from changes in bone marrow.

**Fig. 1.10.23**
Infected nonunion of the right distal tibia. A) Bone scan shows intense uptake which may be secondary to prior fracture or osteomyelitis. B) Simultaneous In-111 WBC scan demonstrates multiple foci of abnormal accumulation of labeled WBCs in the distal tibia, consistent with osteomyelitis.

Positron emission tomography (Box 1.10.11)

The most commonly used radiopharmaceutical in clinical positron emission tomography (PET) imaging is the glucose analogue 2-[18F] fluoro-2-deoxy-D-glucose (F-18 FDG). FDG uptake is enhanced in the malignant cells because of the enhanced transport of glucose (increased number of glucose transporter proteins on cancer cells) and because of the inefficient use of glucose for energy generation in malignant cells. After FDG enters the cells it is phosphorylated in the same way as glucose but does not enter further metabolic pathways and therefore accumulates inside the cell. FDG uptake is not specific for tumours and can be also seen with infections and inflammation.

**Box 1.10.11 Positron emission tomography**

- FDG uptake is enhanced in malignant cells
- PET can give false positives in some benign lesions.

F-18 FDG decays by positron emission. The emitted positron has a very short range and readily captures an electron when it comes to rest, releasing two photons.

FDG PET has been used for diagnosis and grading of soft tissue sarcomas. FDG PET is also positive in most bone sarcomas. False positive PET is seen in a number of benign bone lesions including giant cell tumours, fibrous dysplasia, eosinophilic granuloma, chondroblastoma, aneurysmatic bone cysts, non-ossifying fibroma, and osteomyelitis.

Complex regional pain syndrome

Summary points

- Complex regional pain syndrome (CRPS) is a disabling chronic pain condition of unknown aetiology.
- Traditionally it was thought to be rare; however, prospective studies demonstrate it to be common following both trauma and operative procedures involving the upper and lower limbs.
- The condition is usually self-limiting over a maximum period of 2 years, although minor abnormalities may remain.
- In a minority of cases it does not resolve and is responsible for severe chronic disability.
- Treatment is aimed at functional restoration of limb function supported by pharmacological intervention.

Introduction

Complex regional pain syndrome (CRPS), previously termed reflex sympathetic dystrophy (RSD), consists of abnormal pain, swelling, vasomotor instability, contracture, and osteoporosis (Box 1.11.1). It used to be considered a rare, devastating complication of injury, caused by abnormalities in the sympathetic nervous system and seen mainly in psychologically abnormal patients. Modern research is altering this view radically.

Box 1.11.1 Features of CRPS

- Abnormal pain
- Swelling
- Vasomotor instability
- Contracture
- Osteoporosis.

Terminology

The International Association for the Study of Pain (IASP) has replaced the condition's many synonyms with CRPS, which avoids suggesting aetiology or site. The IASP have produced diagnostic criteria which have not been universally adopted and we have proposed a different approach which is more relevant for the orthopaedic surgeon (Box 1.11.2). These two sets of criteria are identical for diagnostic purposes within an orthopaedic context.

Box 1.11.2 Suggested criteria for the diagnosis of CRPS within an orthopaedic setting

The diagnosis is made clinically by the finding of the following abnormalities:

- Neuropathic pain: non-dermatomal, without cause, burning, with associated allodynia and hyperpathia
- Vasomotor instability and abnormalities of sweating: warm, red, and dry; cool, blue, and clammy; or an increase in temperature sensitivity. Associated with an abnormal temperature difference between the limbs
- Swelling
- Loss of joint mobility
- Joint and soft tissue contracture.

These clinical findings are backed up by:

- Radiographic evidence of osteoporosis after 3 months
- Increased uptake on delayed bone scintigraphy early in CRPS.

CRPS is subdivided into type 2, where there is a causative major nerve injury (the original causalgia described by Mitchell in American Civil War casualties), and type 1, where there is not (previously reflex sympathetic dystrophy or algodystrophy). This distinction is clinically important since in type 2 CRPS, treatment can be directed directly at the damaged nerve.
Clinical features
CRPS is a biphasic condition with early swelling and vasomotor instability giving way to late contracture and joint stiffness. The hand and foot are most frequently involved, although the knee is increasingly recognized. The elbow is rarely affected, whereas shoulder disease is common and the hip is affected in transient osteoporosis of pregnancy.

CRPS usually begins up to a month after the precipitating trauma. As the effects of injury subside, a new diffuse, unpleasant, neuropathic pain arises. Neuropathic pain occurs without a noxious stimulus and spontaneous or burning pain (causalgia), hyperalgesia (increased sensitivity to a noxious stimulus), allodynia (pain provoked by innocuous stimuli, such as gentle touch), and hyperpathia (temporal and spatial summation of allodynia) are common. Pain is unremitting, worsening, and radiating with time (Box 1.11.3).

Box 1.11.3 Timeline of CRPS
- Begins within 1 month
- Neuropathic pain replaces injury pain
- Early clinical features: swelling and vasomotor instability (initially hot, pink, and dry—then blue, cold, and sweaty)
- Late clinical features: contracture, atrophy, and joint stiffness. Nails pit, hairs break. Tendons trigger.

Early phase
Vasomotor instability (VMI) and oedema dominate the early phase (Figure 1.11.1), although this is less marked with more proximal CRPS. Classically, initially the limb is dry, hot, and pink, later becoming blue, cold, and sweaty. In most cases there is merely an increase in temperature sensitivity. Oedema is marked and loss of joint mobility is due to swelling and pain.

Late phase
Passing into the late phase, VMI recedes, oedema resolves, and atrophy of every tissue occurs (Figure 1.11.2). The skin is thinned and joint creases and subcutaneous fat disappear. Hairs become fragile, uneven, and curled while nails are pitted, ridged, brittle, and discoloured brown. Palmar and plantar fascias thicken and contract simulating Dupuytren's disease. Tendon sheaths become constricted causing triggering and muscle contracture combined with tendon adherence leads to reduced tendon excursion. Joint capsules and collateral ligaments shorten and adhere, causing contracture.
Bone changes

Bone involvement is universal with increased uptake on bone scanning in early CRPS (Figure 1.11.3). This is not periarticular, suggesting arthralgia but generalized and may not occur in children. Later, the bone scan returns to normal and there are radiographic features of rapid bone loss: visible demineralization with patchy, subchondral or subperiosteal osteoporosis, metaphyseal banding, and profound bone loss (Figure 1.11.4).
Fig. 1.11.4
Radiographic features of CRPS. A) Oblique radiograph of a patient with CRPS type 1 of the foot. There is patchy osteoporosis with accentuation of the osteoporosis beneath the joints. B) Profound osteoporosis in a patient with late severe CRPS type 1 affecting the hand.

**Incidence**
Severe, chronic CRPS is uncommon and the prevalence is less than 2% in retrospective series. In contrast, prospective studies show that mild CRPS occurs after 20–40% of every fracture and surgery where it has been actively sought. Although these cases resolve substantially within a year, some features—particularly stiffness—remain, suggesting that CRPS may be responsible for significant long-term morbidity even when mild.

**Aetiology**
CRPS may occur after any particular trauma while an identical stimulus in a different limb does not cause it. The incidence is not changed by treatment method and open anatomic reduction and rigid internal fixation does not abolish it. It is unclear whether injury severity or quality of fracture reduction alters the incidence. There is, however, an association with excessively tight casts and there may be a genetic predilection. The following aetiologies have been proposed (Box 1.11.4):

**Box 1.11.4 Epidemiology and pathogenesis of CRPS**

- Up to 20–40% of all fractures if looked for carefully
- Usually resolves within 1 year
- Not affected by treatment, but tight casts may predispose
- Patients are psychologically normal.

**Psychological abnormalities**
CRPS is not primarily psychological and most patients are psychologically normal. There is an association with antecedent psychological stress which probably exacerbates pain in CRPS, as in other diseases. It seems likely that the severe chronic pain of CRPS causes depression and that a ‘Sudecky’ type of patient who develops CRPS is at risk of a poor outcome because they will not mobilize in the face of pain.

**Abnormal (neuropathic) pain**
Pain is normally caused when a noxious stimulus activates high-threshold nociceptors. Neuropathic pain in CRPS occurs without appropriate stimulus and has no protective function. However, injured peripheral nerve fibres undergo cellular changes which cause usually innocuous tactile inputs to stimulate the dorsal horn cells via A-β fibres from low-threshold mechanoreceptors, causing allodynia in CRPS 2. Furthermore, axonal injury prevents nerve growth factor transport which is essential for normal nerve function. In CRPS 1, inflammatory mediators released by the initial trauma (and possibly retained due to a failure of free radical clearance), can sensitize nociceptors to respond to normally innocuous stimuli.

**Sympathetic nervous system abnormalities**
A number of features of CRPS suggest sympathetic nervous system (SNS) dysfunction (e.g. vasomotor and sudomotor...
disturbance); however, SNS activity is not usually painful. In CRPS, some pain (termed sympathetically maintained pain, SMP) is SNS dependent and is relieved by stellate ganglion blockade and worsened by noradrenaline injection. Furthermore, there is an abnormal difference in cutaneous sensory threshold between the limbs, which is reversed by local anaesthetic sympathetic chain blockade, while increasing sympathetic activity worsens pain. SMP is explained by the body’s reaction to injury. After partial nerve division, injured and uninjured somatic axons express α-adrenergic receptors and sympathetic axons come to surround sensory neurons cell bodies in dorsal root ganglia. These changes make the somatic sensory nervous system sensitive sympathetic mediators.

Abnormal inflammation

CRPS is associated with inflammatory changes including macromolecule extravasation and reduced oxygen consumption. In animals, infusion of free radical donors causes a CRPS-like state and amputated human specimens with CRPS show basement membrane thickening consistent with overexposure to free radicals. These considerations suggest that CRPS is an exaggerated local inflammatory response to injury. In other words, CRPS represents a local form of the systemic free radical disease that causes adult respiratory distress syndrome and multiple organ failure after severe trauma. This concept is supported by evidence that the free radical scavenger, vitamin C, is effective prophylaxis against post-traumatic CRPS. An alternative explanation is a primary capillary imbalance causing stasis, extravasation, and consequent local tissue anoxia.

Immobilization

Undue immobilization has been proposed as the cause of CRPS and all features of CRPS, except pain, are seen after cast immobilization. CRPS is associated with an often overlooked abnormality of motor function, varying from weakness to incoordination and tremor. The best description is that in CRPS-1, patients find it difficult to initiate or accurately direct movement. Learned pain avoidance behaviour in response to allodynia may exacerbate changes of disuse since normal tactile and proprioceptive input are necessary for correct central nerve signal processing. In some patients, there is a central sensory confusion: in response to an apparently painful non-noxious stimulus, the patient cannot determine whether it is truly painful. The consequent impairment of integration between sensory input and motor output may be the major cause of CRPS.

Investigations and differential diagnosis

CRPS is a clinical diagnosis and there is no single diagnostic test which is definitive. The classic case is obvious and direct effects of trauma, fracture, cellulitis, arthritis, and malignancy are common alternative diagnoses. The patient is systemically well with normal general clinical examination, biochemical markers, and infection indices.

X-ray appearances and bone scans have already been discussed. Sudeck’s technique of assessing bone density by radiographing two extremities on one plate remains useful. A normal bone scan without radiographic osteoporosis virtually excludes adult CRPS. Temperature difference between the limbs is greater in CRPS than other pain syndromes but this is not usually applied in an orthopaedic context. Magnetic resonance imaging shows early bone and soft tissue oedema with late atrophy and fibrosis but is not diagnostic.

Management

Proper scientifically constructed prospectively randomized blinded studies are few and uncontrolled investigations are particularly unreliable in CRPS. Most patients are sensible people, concerned at the development of inexplicable pain, but the occasional ‘Sudecky’ patient fares poorly and should be treated vigorously. Early treatment before contractures occur gives optimal results, so a high index of clinical suspicion must be maintained.

Modern CRPS treatment emphasizes functional rehabilitation of the limb to break the vicious cycle of disuse, rather than SNS manipulation. Initial treatment from the orthopaedic surgeon is by reassurance, excellent analgesia and intensive, careful physiotherapy avoiding exacerbation of pain. Non-steroidal anti-inflammatory drugs may be preferred to opiates. Immobilization and splintage are generally avoided, but if used, joints must be placed in a safe position and splintage is a temporary adjunct to mobilization. If the patient does not respond rapidly, a pain specialist should be involved and treatment continued on a shared basis. Second-line treatment is often unsuccessful and many patients are left with pain and disability. Further treatments include centrally-acting analgesic medications such as amitriptyline, gabapentin, or carbamazepine; regional anaesthesia; the use of membrane-stabilizing drugs such as mexiletine; calcitonin; sympathetic blockade and manipulation; desensitization of peripheral nerve receptors with capsaicin; transcutaneous nerve stimulation or an implanted dorsal column stimulator. A different approach including behavioural therapy may be necessary in children. Where the knee is affected, epidural anaesthesia and continuous passive motion may be appropriate (Box 1.11.5).

Box 1.11.5 Treatment of CRPS

- Vigorous physiotherapy to avoid contractures
- Good analgesia while avoiding pain
- Avoid splintage and immobilization
- Behavioural therapy may help, especially in children
- Surgery to release contractures is rarely needed and should not be rushed into.
The role of surgery is limited. Where CRPS is caused by a surgically correctable painful lesion, such as median nerve compression at the wrist, surgery should be undertaken cautiously in the presence of active disease. Surgery is rarely indicated to treat fixed contractures which usually involve all of the soft tissues. Surgical release must therefore be radical and expectations limited. Surgery for contracture should be delayed until the active phase of CRPS has completely passed and ideally there should be a gap of at least 1 year since the patient last experienced pain and swelling.

Amputation in CRPS should be approached with extreme caution because pain may continue.

Neuromuscular disorders

**Summary points**

- Neuromuscular disorders can be sensory, motor, or a combination of the two.
- Motor disorders may be flaccid or spastic, static or progressive.
- Spastics may improve function but are not proven to prevent contractures.
- Botulinum toxin and tendonomy can be used to manage spasticity.
- Osteotomies may be needed to manage rotatory abnormalities.
- Sensory nerve abnormalities may cause Charcot joints.

**Definitions and classification**

A wide variety of conditions affect the central nervous system, peripheral nerves, or muscle and are included under the term "neuromuscular disorders." A significant number of patients with these conditions may require orthopaedic treatment.

The anatomic distribution, neurological type, and severity of neuromuscular disorders also vary substantially. Neuromuscular diseases affect the central nervous system present with an anatomical distribution depending on the affected area of the brain or spinal cord. They can, therefore, present as hemiplegia, paraplegia, quadriplegia, or total body involvement (Box 1.12.1). Peripheral nerve diseases may affect the extremities only. Muscle conditions may affect proximal or distal muscle groups.

**Box 1.12.1 Types of paralysis**

- Static versus progressive
- Spastic versus flaccid
- Hemiplegia = one side
- Diplegia = both sides (typically worse in legs)
- Paraplegia = both legs, usually with sensory loss
- Quadriplegia = all limbs

The neurological patterns also vary. Disorders affecting the central nervous system may present as paralysis, spasticity, dystonia, ataxies, or a mixture of these patterns. Sensory loss may accompany some conditions. Peripheral nerve conditions usually produce muscle weakness. Conditions affecting muscle also produce weakness which can be either generalized or confined to certain muscle groups.

Paralysis may be flaccid or spastic. Understanding of this, and of the aetiology of the development of secondary musculoskeletal deformities, is important. In flaccid paralysis, deformity is due to either the unopposed activity of antagonist muscle(s) or it is a flat deformity in which limb position is mainly due to the gravity of the body. In spastic paralysis, the aetiology of deformity is due to abnormal reactivity or muscle groups. The interaction and balance between agonist and antagonist muscles are imbalanced; patterns are more complex, and the results of treatment less predictable. In mixed patterns, or in the presence of ataxia or dystonia, the results of surgical treatment are unpredictable and sometimes catastrophic.

It is important to understand whether the condition affecting the patient is static or progressive. Establishing an accurate diagnosis is the first step for this. Some conditions (e.g. acute onset of poliomyelitis) may be progressive for a short period of time and then become static later. Others (e.g. multiple sclerosis) progress periodically with long static periods in between. The result of orthopaedic treatment is more predictable in stable neurological conditions and after the patient has established a pattern and any compensations.

**Evaluation**

The majority of adult patients with neuromuscular disorders are referred to the orthopaedic surgeon after their diagnosis is established. A significant number, however, may be referred undiagnosed for an "orthopaedic" deformity which may be the result of an underlying neurological condition. A high index of suspicion should therefore be present in order to avoid missing the diagnosis in these cases.

A thorough history and a detailed clinical examination are always the cornerstones of diagnosing and evaluating the neuromuscular patient. In particular, neurological examination including muscle power, sensation, and reflexes should be included. The range of movement of joints and any contractures should be recorded. The spine should always be examined. Specific tests should be performed as required. A positive Gower's test is indicative of muscular dystrophy. Difficulty grasping and releasing objects may indicate myotonia, while the development of cavovarus foot deformity may be the first sign of a hereditary motor sensory neuropathy. When assessing or planning treatment for conditions affecting the hand, two-point discrimination and stereognostic tests should be performed.

Treatment of the patient with neuromuscular disorders should be tailored to his or her personal needs. Some general guidelines may apply to most of these conditions but the neurological patterns and the severity of the conditions vary to the degree that an effort to apply strict treatment rules would be dangerous. While assessing a patient for orthopaedic treatment it is important to get to know their personal needs and to set a specific aim and target.

The aim of orthopaedic treatment of the adult patient with neuromuscular disorder may vary. In patients with severe scoliosis or painful hip dislocation, for example, the aim is to alleviate the pain. Improving the quality of life by offering a better sitting posture or better access for hygiene may be another aim. Correcting or preventing further progression of a deformity which is painful or produces a functional impairment may be necessary. Improving function may be a relative indication for treatment. This always carries the risk of an unpredictable negative result which may further compromise the already affected function of the patient. Such treatment should, therefore, always be discussed in depth. Finally, on rare occasions, patients may request orthopaedic treatment for cosmetic reasons. Treatment decisions are facilitated by a multidisciplinary team approach.

**Treatment modalities**

The role of the orthopaedic surgeon in the management of the patient with neuromuscular disease is limited. The number of patients who are candidates for surgery is also limited and selection should be done carefully. Conservative treatment including orthoses, splints, serial casting, and physiotherapy are used extensively to prevent joint contractures or control undesired movement (Figure 1.12.1). When orthoses are used to improve function, any benefit from these is evident and can be recorded. The use of the earlier mentioned treatment modalities to prevent contractures, however, would need extensive long-term studies to be documented. In fact, splinting, casting, and physiotherapy are all used for the prevention of contractures on an empirical basis.

However, their functional use is important. The use of ankle-foot orthoses for a foot-drop or gastrocnemius spasticity, the use of walking aids, or standing frames is certainly valuable.
Orthoses in neuromuscular disorders are used to improve function and prevent deformity.

Postural management of the non-ambulatory patient, and particularly wheelchair design and type, is important to prevent pressure sores, and to maximize the patient’s potential for mobility and communication. Seating arrangements may also provide some external support for patients with lack of head control, spinal deformity, or pelvic obliquity.

Nerve blocks with phenol or alcohol injections have long been used to control spastic muscle groups.

Intramuscular injections of botulinum toxin A are extensively used to control spasticity in several neuromuscular conditions, including multiple sclerosis, dystonia, spinal cord injury, and cerebral palsy. The toxin works by blocking the motor endplate for several months. New nerve ends sprout eventually and the muscle regains power.

Systemic drugs, such as baclofen, gabapentin, dantrolene, and diazepam, have also been used to control spasticity. More recently, intrathecal administration of baclofen through a continuous infusion using an implanted pump has been used to control lower limb spasticity.

Functional electrical stimulation of weak muscles has also been used to aid ambulation in patients with conditions producing paraplegia or hemiplegia. Results of longer-term studies are now emerging and these are encouraging (Box 1.12.2).

**Box 1.12.2 Non-operative treatment of neuromuscular disease**

- Splints
- Serial casting and physiotherapy
- Postural management in wheelchairs
- Nerve blocks with phenol and alcohol
- Intramuscular injection of botulinum toxin
- Systemic muscle relaxant drugs
- Functional electrical stimulation of muscles

Surgical treatment of adult patients with neuromuscular disorders may include division or lengthening of tendons or muscles, transferring of tendons, neurectomy, bony operations including osteotomy, or joint fusion or excision. Lengthening or transferring tendons or muscles weakens the structure. This should be taken into account when planning such surgery, particularly in adults where weakness is a greater problem than in children because of the higher ratio of body weight to muscle power. Extensive procedures, such as the multilevel soft tissue releases in cerebral palsy, are well tolerated by children but are rarely performed in adults (Box 1.12.2).

**Surgical treatment of specific conditions**

The specific problems in a number of neuromuscular disorders more commonly seen in orthopaedic clinics are presented in Table 1.12.1. Some surgical procedures commonly required for these problems are also included to provide some general information although this list is by no means comprehensive. As mentioned earlier, orthopaedic surgery in neuromuscular disorders should be personalized and tailored to the needs of the specific patient. Some of the most common orthopaedic problems in adults with neuromuscular conditions are discussed in the following sections.

### Arthrogrypotic syndromes

| Variable | etiology | Multiple joint contractures | Scoliosis can be present: severity is variable | Shoulder internal rotation Humeral osteotomy Wrist flexion and volar deviation Proximal row carpectomy | Dislocation, flexion contractures | Flexion contractures or iliotibial extension Distal femoral osteotomy | Clubfoot usually rigid Talloctony Arthrodesis | 80%–90% long-term community ambulants Good social and professional adjustment |

**Central nervous system**

Cerebral palsy (Box 1.12.3)

Despite the large number of publications on the treatment of children with cerebral palsy, little is written in the orthopaedic literature on the management of adults with the condition. While most hemiplegic patients maintain good mobility throughout life, the diplegics tend to deteriorate in their adult years. Their walking distance may diminish and they may present with joint contractures and a crouch gait. They often complain of knee and, more specifically, patellofemoral pain due to the increased loading of the joint. The persistent femoral anteversion and external tibial torsion that coexist, often referred to as 'malignant malalignment', are also responsible for the abnormal loading of the patellofemoral joint. Their frequently dysplastic hips may develop degenerative changes and become painful. Progressive foot deformity, usually planovalgus in diplegia and equinovarus in hemiplegia, and joint degenerative changes are also common.

Soft tissue surgery to eliminate joint contractures is not as effective in adult cerebral palsy as it is in children. This is partly due to the long-established intrinsic bone and joint deformities which commenced during the growing years. Extensive surgery in adult cerebral palsy also carries a high risk of compromising the patient’s already limited ability to ambulate. The reason is the inevitable muscle weakness that follows any muscle or tendon lengthening and the postoperative immobilization in addition to any underlying neurological weakness.
weakness. Limited surgery to address specific problems is more desirable. Dysplastic and/or degenerative hips in ambulant patients may require reconstruction to improve coverage. Femoral varus derotation osteotomy, often combined with pelvic osteotomy or an acetabuloplasty, can be considered. Joint replacement surgery or arthrodesis has also been suggested for adult cerebral palsy. Operations which are often performed in childhood to correct stiff or crouch knee gait, such as hamstring release with or without femoral transection, have not been reported in adults. Supracondylar extension femoral osteotomies can be used to correct severe knee flexion deformities. Foot operations to correct deformity or pain certainly have a place. Lengthening the tendon(s) responsible for the deformity and correcting the deformity with a bony operation is the principle usually followed. Subtalar or triple fusion may be necessary and this depends on the level of the deformity. A recent study in Norway showed that the most common procedures performed in adults with cerebral palsy were lower-limb soft tissue releases and foot deformity corrections.

Upper-limb surgery in adult cerebral palsy patients is rarely performed. Shoulder internal rotation deformity may be corrected with derotation osteotomy. Flexion deformity of the elbow may be improved by lengthening of the biceps and brachialis, but this involves the risk of losing adequate elbow flexion power which may be more important functionally. Pronation of the forearm is usually due to spasticity of both the pronator teres and quadratus, and lengthening may be beneficial. The expected gain from these operations, however, is less in adults as the ideal age for this surgery is during the teenage years. Hand surgery requires candidates with reasonable intelligence, voluntary control, and sensation, including stereognosis, proprioception, and two-point discrimination. Dorsal transfer of flexor carpi ulnaris to the extensor digitorum communis to aid weak extensors, as well as fractional lengthening of the finger flexors to correct fixed deformities, have been described. Furthermore, operations to correct the thumb-in-palm deformity include release of the adductor and flexors, release of the first dorsal interosseous, and rerouting of the extensor pollicis longus. Joint contractures are not correctable, however, by soft tissue procedures if bone and joint deformity is present. Proximal row carpometacarpal fusion of the wrist have been suggested for stabilization for cosmetic or functional purposes.

Non-ambulatory patients are at high risk of developing the triad of scoliosis, pelvic obliquity, and hip dislocation (Figure 1.12.3). These deformities are usually already established when patients reach skeletal maturity and those who require treatment may have received it during adolescence. Painful hip dislocation, affecting seating posture and hygiene and also associated with decubitus ulcers, can be a major problem in non-ambulant patients. However, it is unclear what percentage of untreated patients develop late pain or quality of life problems and reports are only limited. Femoral head excision or resection of the proximal femur has been suggested, but failure of these operations to alleviate pain leaves no surgical options for further management. Simple valgus proximal femoral osteotomy to alleviate the pressure on the femoral head may be a more sensible option. Arthrodesis in unilateral disease or reconstruction may be another option. Incomplete transiliac osteotomy combined with femoral varus-shortening derotation osteotomy appears to offer optimal results. Interposition arthroplasty using prosthetic material may offer salvage in difficult cases.

Knee flexion contractures in non-ambulatory patients are rarely a problem since they are functional in the sitting position. Finally, severe foot deformities may be responsible for skin pressure problems, either from the foot plate of the wheelchair or from underlying bones. Extensive soft tissue releases are usually sufficient for correction of the foot into a reasonable position that does not cause pressure problems.

Head injury and stroke

Adult patients who present to orthopaedic clinics after stroke or head injury are frequently hemiplegics. Equinus or equinovarus foot deformities are the most common orthopaedic problems (Figure 1.12.4). During their recovery period, they usually require a rehabilitation programme which may include casts or orthoses and nerve blocks or botulinum toxin injections.

The recovery period lasts about 6–12 months for stroke patients and 12–18 months for head injury patients. Surgery may then be considered for patients with equinus gait and reasonable ability for gait re-education. Tendon lengthening and transfer surgery based on dynamic electromyography will eliminate spastic equinus in most patients and over half will be able to walk brace free and have improved knee and hip motion 1 year postoperatively (Figure 1.12.2). Painful toe deformities that pose problems with footwear may also require correction.
Fig. 1.12.2
Dynamic electromyography of gastrocnemius and tibialis anterior and posterior during gait is used to aid treatment decisions on tendon lengthening and transfer.

Stiff knee gait due to quadriceps spasticity and resulting in foot clearance problems may be treated with tenotomy of the rectus femoris in carefully selected patients. An increased risk of heterotopic ossification following hip surgery in stroke and head injury patients has been reported. Furthermore, stroke patients are at a higher risk of hip fracture.

Other central nervous system disorders

Patients with multiple sclerosis may present with lower-limb problems, usually as a result of spasticity. Muscle weakness and the presence of ataxia may complicate the problems further. The same principles for the management of foot problems as for stroke apply here and tendon balancing is the aim.

Adult patients with Friedreich’s ataxia may present with stiff cavovarus feet that require correction. Triple fusion is required for these deformities and lengthening of tibialis posterior, and often the Achilles tendon should be performed to prevent recurrence of the deformity. Scoliosis also occurs in all patients with Friedreich’s ataxia. Surgery while the patient is still ambulatory would compromise the ability to walk and should be postponed until they are confined to a wheelchair.

Box 1.12.3 Surgery for cerebral palsy

- Soft tissue releases work better in children
- Osteotomies in adults help manage rotatory and angular deformity
- Aim to release contractures without causing instability
- Balance muscles and joint alignment.

Patients with rapidly progressive motor neuron disease seldom require orthopaedic treatment but may present in orthopaedic clinics complaining of limb weakness, foot deformity (usually a foot-drop), or atrophy of the small muscles of the hand.

The spine

Spinal dysraphism (myelodysplasia)

Although a large number of children and adolescents with low thoracic, lumbar, or sacral myelodysplasia are ambulators, a large percentage of them lose the ability to walk later in adult life. Almost a third of patients with sacral-level spina bifida lose their ability for independent ambulation in adult life. Scoliosis, pelvic obliquity, hip dislocation, and knee contractures have been suggested as reasons for loss of ambulation. The level of the lesion, lower limb spasticity, the additional body weight, and the lack of sensation in the sole of the foot which leads to ulcers and deep infection are certainly some of the most important parameters.

Treatment of infection appears to be the most frequent orthopaedic treatment required for the adult myelodysplastic patient and toe, ray, Symes, or below-the-knee amputations are not infrequent.

Postpolio syndrome

The postpolio syndrome is the development of new neuromuscular symptoms, including fatigue or new muscle weakness, which may involve previously unaffected muscles and musculoskeletal complaints, usually muscle pain. Back injury, radiculopathy, compression neuropathy, and any other condition that could account for these symptoms should be first excluded. Patients’ specific complaints usually include general fatigue, difficulty with motor control during walking, stair climbing, and transferring (Figure 1.12.5). The syndrome affects women more often than men and more severely affected by poliomyelitis patients are at higher risk. The prevalence of the condition is 28.5% of all paralytic poliomyelitis cases and it presents with a peak at 30–34 years after the acute illness.

Paraplegia and tetraplegia

Spinal stabilization is often necessary in patients with spinal injury, even in the presence of complete paraplegia or tetraplegia.
Spinal fusion provides better stability for the rehabilitation period and prevents late development of deformity and pain at the fracture site.

Spasticity of the muscles around the hip and particularly the adductors, may lead to contractures that cause problems with sitting balance, access to the perineum for hygiene, pelvic obliquity, and decubitus ulceration. Soft tissue releases for the contractures and gluteus maximus flaps for the treatment of pressure sores have been suggested. Hip instability may occur following infection but is otherwise rare in the absence of dysplasia. Hip dislocation due to spasticity following spinal cord injury can occur in children under the age of 8 years and is very rare in adult spinal cord injury. Treatment principles are the same as in cerebral palsy and proximal femoral resection is sometimes the last resort. Functional electrical stimulation has been used in this field with some success.

If joint contractures secondary to muscle spasticity occur, surgical release may be necessary, particularly in patients who are able to stand or walk with the aid of orthoses. Lower extremity fractures are common in spinal cord injury patients because of the existing osteoporosis: their treatment remains controversial as both surgical and conservative treatment have advantages and disadvantages.

### Neuropathies

#### Hereditary motor sensory neuropathies

The most common orthopaedic problem in these conditions is foot deformity, usually cavovarus (Figure 1.12.6). Hip dysplasia may be present and may become symptomatic and require treatment if coso valga and subsalixation are present. Scoliosis is also present in 10% of patients and follows the idiopathic pattern requiring bracing or arthrodesis of progressive curves.

#### Traumatic and degenerative neuropathies (Charcot joint)

Nerve injury may be due to acute trauma or compression. This may involve nerve roots near the spinal cord, nerve stems as at the brachial plexus, and peripheral nerves. Nerve reconstruction after such injuries and tendon transfers and reconstruction after brachial plexus injuries is discussed elsewhere (see Chapters 12.36 and 6.9).

Foot-drop or loss of active dorsiflexion of the foot may be due to pathology at the peroneal nerve, sciatic nerve, or the fifth lumbar nerve root. A simple ankle-foot orthosis is recommended for early treatment in order to prevent a fixed plantar flexion deformity. If recovery of the nerve is not expected, tendon transfers may be considered. If the foot-drop is mainly due to peroneal muscle weakness while tibialis anterior maintains activity, a split lateral transfer of the tibialis posterior may be considered and dynamic electromyography during gait may be useful to assess the activity of the muscle during the swing phase of gait.

Other conditions may cause peripheral neuropathies and diabetes is the most common. Diabetic ulcers are due to neuropathy, and loss of dexterity are the main problems. Operative treatment is rarely indicated but may be performed to release contractures, or to lengthen or transfer tendons. Wise fusion for stabilization may also be considered.

#### Mypathies

Repetitive trauma to insensate joints, particularly the weight-bearing ones, can cause characteristic changes that define the neuropathic or Charcot joint. Changes include effusion, subluxation, and bone sclerosis, erosion, and destruction. Later, osteophytes, calcium deposits, osseous hypertrophy, and periarticular fractures may be present. The development of characteristic Charcot changes often follows an injury that led to fracture or dislocation. If conservative treatment fails, surgery to arthrodesis or replace the joint has been suggested but the failure rate is high because of the lack of sensation, and amputation may be necessary in some cases.
The various types of myopathies, their inheritance, and their clinical characteristics relevant to the orthopaedic surgeon are listed in Table 1.12.1. Only a few types of myopathy may require orthopaedic surgery in adulthood.

Chapter: Neuromuscular and skeletal manifestations of neurofibromatosis

Author(s): Jeremy Fairbank

DOI: 10.1093/med/9780199550647.003.0013

Summary points

♦ Neurofibromatosis type 1
♦ Single gene disorder
♦ Serious scoliosis
♦ Pseudoarthrosis of a long bone
♦ Hypertrophy of a part
♦ An unusual radiographic lesion of bone.

Introduction

Neurofibromatosis type 1 (NF-1) is one of the commonest single gene disorders (17q11.2) (1 in 3000–4000 live births). The gene product functions as an antitumour agent, a function suppressed in mutations. At least 40% of children with NF-1 have serious cosmetic or functional involvement of the musculoskeletal system. NF type 2 is particularly associated with acoustic neuromas (22q12.2), is much rarer (1 in 25,000), and has few, if any, musculoskeletal manifestations.

NF-1 presents to orthopaedic surgeons with spinal deformity; neurofibromas, and other tumours affecting the spinal cord and peripheral nerves; pseudarthrosis of long bones, especially the tibia; limb gigantism associated with plexiform neurofibromas; and pectus excavatum. Radiological manifestations of NF-1 frequently cause diagnostic difficulties, and may mimic other conditions. A rare but important association is with phaeochromocytoma, which should be considered before anaesthetizing anyone with NF-1.

Diagnosis

Consider NF when confronted by:

♦ Serious scoliosis
♦ Pseudoarthrosis of a long bone
♦ Hypertrophy of a part
♦ An unusual radiographic lesion of bone.

Check for a family history of NF-1. Look for cafe-au-lait spots. (The skeletal manifestations of the disease may precede the appearance of neurofibromas). There should be more than 6 spots with a diameter greater than 15mm in children older than 5 years. Freckles appear in the axillae and groin later in childhood. Lisch nodules in the iris are diagnostic. These can only be seen with a slit lamp. Subcutaneous and nerve-based neurofibromas are common. There is an increased risk of developing brain tumours (especially optic glioma) and leukemia. Learning disability is common. About 2% of individuals with NF-1 also develop phaeochromocytoma. This should always be suspected in patients who are hypertensive.

Management of musculoskeletal problems

Pseudoarthrosis of long bones

Pseudoarthrosis appearing in any long bone in infancy is usually, but not always, associated with NF-1 (50–90%). The tibia is by far the most frequent (1 in 250,000 live births), but pseudoarthrosis has been observed in all of the other long bones. This is a very difficult condition to manage and beyond the scope of this text. At least six different patterns have been described (Boyd classification). Surgical treatments include: osteotomy; onlay grafts; bypass grafts; pedicle grafts; intramedullary rods; vascularized bone graft; electrical stimulation; bone transport; amputation, either as a primary procedure or as salvage.

Focal gigantism

Hypertrophy of a bone, digit, or an entire limb, combined with unusual lengthening or shortening of a bone can give serious cosmetic and practical problems. These require plastic and orthopaedic surgical expertise.

Spine

Spinal deformity occurs in about 5% of cases. Scoliosis may be indistinguishable from idiopathic scoliosis, or be dysplastic with short segment aggressive deformities with loss of part or all of the vertebral body that require surgical treatment. Kyphosis is commonly associated with dysplastic spines. This may present challenging problems for the surgeon, though not usually sufficient to damage the spinal cord unless there is dislocation of the spine or a large meningocoele. It is best to avoid resection of tumours associated with dysplastic curves. Other features are scalloping of the posterior margin of vertebral bodies; enlargement of the
intervertebral foramina; pedicle defects; vertebral body dysplasia; dumb-bell tumours; dural ectasia (a saccular dilatation of the dura, sometimes with extensive protrusion of the dura out of the intervertebral foramen); lateral meningocele; and, rarely, intrathoracic meningoceles. Spinal tumours, both intra- and extradural are common and include neurofibromas, gliomas, meningiomas and schwannomas.

**Plexiform neurofibromas**

These are extensive tumours involving muscle and bone especially in the pelvis and lower limbs. They are difficult or impossible to resect. Many remain stable, but may become malignant. Magnetic resonance can be used to monitor size and shape. Positron emission tomography scanning seems a good method for identifying malignant change.

**Radiographic features**

NF-1 patients have a high frequency of skeletal involvement, sphenoid dysplasia is diagnostic. Bone deformities are caused by destruction by neurofibromatous tissue, aberrations of skeletal growth, abnormal development of body parts or systems, malignant bone tumours, intervertebral foramenal enlargement, cortical bone defects, bone cyst formation, bowing of long bones, and pseudoarthrosis of long bones.

**Management**

This is focused on the management of complications. This can be complex and challenging. Resection of individual tumors should be confined to those that are symptomatic.

**Further reading**

Summary points

- Bone and soft tissue tumours are rare and should therefore be assessed and treated in specialized centres
- Clinical staging and pathological grading is used to classify the extent of a tumour
- Clinical staging uses various imaging techniques, pathological grading requires tumour biopsy following clinical staging
- The Enneking system is commonly used for surgical staging of bone and soft tissue tumours
- Surgery is the mainstay of treatment for musculoskeletal tumours
- The surgical margin describes the extent of the procedure
- Intralesional margins describe a procedure that removes the tumour alone, radical margins may require removal of entire bone
- Open incisional biopsy is the gold standard method for obtaining a representative specimen of tumour
- Careful planning and good collaboration between surgeons, radiologists, and pathologists is crucial to avoid unnecessary or dangerous biopsy procedures.

Introduction

Bone and soft tissue tumours are rare and constitute less than 1% of all malignancies. Such tumours should, when possible, be treated at specialized tertiary centres where there is a dedicated multidisciplinary team of medical, nursing, and counselling services to manage these often difficult problems.

A poorly performed biopsy at a non-specialist centre is reported to be the major cause of error and failure of limb salvage in two review articles. Although the procedure itself is not complicated, the indications for using this technique, the choice of needle, the appropriate setting, the anatomic site, the distribution of tissue, and the potential need for adjuvant treatment all must be carefully considered prior to performing the biopsy. Needle biopsies should be viewed as surgical procedures and are associated with risks and hazards.

Important issues that must be considered when performing biopsies for suspicion of tumour include:

- Understanding the indications, based on clinical and radiographic information
- Obtaining appropriate staging studies
- Choosing the best biopsy technique: excisional versus incisional; closed versus open
- Performing the biopsy through an appropriate anatomic approach
- Obtaining representative, diagnostic tissue
- Careful handling of the biopsy specimen
- Avoiding complications.

Biopsies are best performed in specialist centres under the supervision of an orthopaedic surgical oncologist who will ultimately be responsible for the definitive care of the patient and who is working in close collaboration with an expert musculoskeletal radiologist and pathologist.

Staging for musculoskeletal tumours

Accurate preoperative surgical staging of musculoskeletal tumours is currently possible because of advanced imaging techniques, providing diagnostic information and helping clinicians in choosing the most appropriate treatment option for the patient. The aims of surgical staging are to determine the surgical margins of resection and to facilitate interinstitutional and interdisciplinary communication regarding treatment data and results.

Box 2.1.1 Staging—summary

- Clinical staging defines the local and systemic extent of the disease; it relies on a variety of imaging studies
- Pathological grading categorizes tumours according to their predicted biological behaviour; it relies on biopsy of the tumour and therefore should follow clinical staging
- The Enneking system for the surgical staging of bone and soft tissue tumours is based on grade (G), site (T), and metastasis (M) and uses histological, radiological, and clinical criteria.
There are two aspects to staging musculoskeletal tumours, namely clinical staging and pathologic grading. Clinical staging defines the local and systemic extent of the disease which is required in the planning of treatment to achieve both local and distal control. Clinical staging relies on a variety of imaging studies which not only pinpoint the anatomical location of the tumour but also serve as baseline indices for post-treatment comparisons. Pathologic grading categorizes tumours according to their predicted biological behaviour which may range from indolence to widespread metastasis (determined by a combination of features including cellularity, degree of pleomorphism, mitotic activity, necrosis, and infiltrative nature). Pathologic grading relies on biopsy of the tumour and therefore should follow clinical staging.

Plain radiography is the initial imaging modality in the evaluation of bone tumours. Some benign lesions have characteristic radiographic features that make biopsy unnecessary. Examples include fibrous cortical defects, bone islands, simple bone cysts, and bone infarcts. Radiographic features can also help in distinguishing malignant from benign bone lesions in many patients. The important radiographic signs for grading bone tumours are listed as follows, in order of priority:

- Pattern of destruction: geographic or not geographic, appearance of marginal interface zone
- Penetration of the cortex by the lesion
- Absence or presence of a sclerotic rim
- Absence or presence of the expanded cortical shell, as well as its extent.

In the staging of bone tumours, computed tomography (CT) scanning has a role in the detailed evaluation of local disease and in assessing the lungs for pulmonary metastases. It can be used to assess disease in areas that are not easily visualized with plain radiographs, such as the spine and pelvis.

Magnetic resonance imaging (MRI) (with or without contrast) is the modality of choice for imaging and staging of musculoskeletal tumours. Accurate depiction of the soft tissues allows sensitive detection of soft tissue extension and medullary involvement by a tumour.

Certain lesions have appearances that are usually characteristic enough for a diagnosis to be made based on MRI findings. Examples of such lesions include lipomas, superficial and skeletal muscle haemangiomata, benign neural tumours, periarticular cysts, haematomas, and pigmented villonodular synovitis.

MRI is increasingly used to assess tumour response to preoperative chemotherapy. This assessment is achieved by evaluating changes in a tumour’s size, margins, signal intensity, and enhancement patterns. Moreover, MRI can be useful in differentiating tumour recurrence from chronic post-therapeutic changes.

Radionuclide bone scanning has a role in detecting metastases, skip lesions, lesion multiplicity, and postoperative tumour recurrence. Bone-forming, metastatic lesions in the lungs (e.g. osteosarcoma) are occasionally detected with bone scintigraphy.

Soft tissue masses and the soft tissue components of bony tumours may be visualized by using ultrasonography (US). The aim of ultrasonography in the evaluation of musculoskeletal lesions is to confirm the presence of a lesion, to determine if the lesion is cystic or solid, to assess the relationship of the mass to the surrounding structures (e.g. neurovascular bundle), to evaluate the vascularity of the mass, and to guide interventional procedures if indicated.

The role of angiography has largely been replaced by cross-sectional imaging modalities. Angiography can still have a preoperative role in decreasing tumour size by allowing embolization of feeding vessels and a postoperative role in decreasing haemorrhage, again through the embolization of tumour-supplying vessels.

Positron emission tomography (PET) scanning has been shown to have sensitivity similar to that of serial CT scanning and MRI for detecting lesions and for distinguishing postsurgical scanning from recurrent tumours. However, the specificity of PET is higher than that of serial CT scanning or MRI making it better in depicting residual/recurrent disease after treatment. The main disadvantage of PET scanning is the high cost of the equipment, therefore limiting availability.

Percutaneous needle biopsy is now standard practice. Given the increase in the use of CT and ultrasound for accurate needle placement, biopsy is now primarily a radiologist-led procedure.

### Enneking system for surgical staging of malignant bone and soft tissue tumours

The Enneking system for the surgical staging of bone and soft tissue tumours is based on grade (G), site (T), and metastasis (M) and uses histological, radiological, and clinical criteria. It is the most widely used staging system and has been adopted by the Musculoskeletal Tumour Society. This system should be used for staging mesenchymal lesions only, because their biological behaviour differs from that of non-mesenchymal tumours (e.g. Ewing sarcoma, lymphoma, and leukemia).

#### Grade

Bone tumours are graded as follows:

- G0: benign lesion
- G1: low-grade malignant lesion
- G2: high-grade malignant lesion.

Surgical grade generally follows histological grade; however, a higher surgical grade may be applied if the radiographical features and clinical behaviour of a lesion indicate an aggressiveness that is incompatible with its benign histological features.
Site

The site and local extent of bone tumours are classified as follows:

- **T0**: a benign tumour that is confined within a true capsule and the lesion's anatomical compartment of origin (i.e. a benign intracapsular, intracompartamental lesion)
- **T1**: an aggressive benign or malignant tumour that is still confined within its anatomical compartment (i.e. an intracompartamental lesion)
- **T2**: a lesion that has spread beyond its anatomical compartment of origin (i.e. an extracompartamental lesion).

Metastasis

Metastatic classification is as follows:

- **M0**: no regional or distant metastasis
- **M1**: regional or distant metastasis.

Under the Enneking system, malignant tumours are classified into stages I–III, with further subdivisions into A and B. Grade 1 and grade 2 tumours are stage I and stage II, respectively. T1 and T2 tumours are stage A and stage B, respectively. Tumours with distant metastasis are stage III (Table 2.1.1).

Enneking staging system for benign tumors

The Enneking staging system divides benign tumours into latent, active, or aggressive tumours (Table 2.1.2). Latent tumours are asymptomatic and are usually discovered incidentally. They reach a stage of non-growth after a period of slow growth. Active tumours are mildly symptomatic and may be discovered if pathologic fracture occurs or if the tumour is associated with mechanical dysfunction. Active tumours usually grow steadily. Aggressive benign lesions grow rapidly and usually are symptomatic and tender on palpation.

Surgical margins (Box 2.1.2)

Surgery is the mainstay of treatment for musculoskeletal tumours. These tumours are surrounded by a non-tumorous reactive zone containing inflammatory cells and neo-vascular tissue. This pseudocapsule contains microscopic extensions of tumour which may be continuous with, or satellites of, the main tumour mass (Figures 2.1.1 and 2.1.2).

Box 2.1.2 Surgical margins—summary

- Musculoskeletal tumours are surrounded by a non-tumorous reactive zone (pseudocapsule)
Intralesional margins imply a procedure which crosses the pseudocapsule and enters into the substance of the tumour. Often tumour tissue is removed piecemeal. Curettage is an example of intralesional surgery. Recurrence can be high with intralesional margins in incomplete curettages as macroscopic evidence of tumour remains after surgery. Intralesional margins are only used in benign tumours such as bone cysts, aneurysmal bone cysts, and giant cell tumours.

Marginal margins are those in which a tumour is removed in one piece and the plane of dissection passes through the pseudocapsule or reactive zone. Excisional biopsies or tumours which are shelled out are examples of surgery with marginal margins, and microscopic residual tumour may exist. Recurrent rates of malignant tumours are high after surgery with marginal margins if adjuvant chemotherapy is not used.

Wide margins include the entire tumour and its pseudocapsule or reactive zone and a cuff of normal tissue en bloc. During this procedure, tumour is never seen. Consensus has not been reached on the definition of what constitutes a cuff of normal tissue. In principle, the proximal or distal cut edge of normal muscle represents a wide margin if it is 5cm or more from the tumour border. Removal of bone at a similar distance beyond the tumour also constitutes a wide margin. Surgical margins which include the normal fascia surrounding the muscle of an intramuscular tumour are regarded as wide even though the absolute thickness of the muscle and fascial cuff may only be 1–2mm. Synovium or periosteum which covers the periosteal extension of a distal femoral tumour is regarded as an anatomic barrier and if excised en bloc with the tumour constitutes a wide margin even though again the thickness of the tissue may be 1–2mm.

Fig. 2.1.1
Coronal MRI of distal femoral osteosarcoma with extraosseous extension of tumour. The intralesional margin (dotted line), the marginal margin (broken line), and the wide margin (full line) are indicated. A radical margin would be a resection of the entire tumour-containing compartment which would imply a total femoral resection.

Fig. 2.1.2
Axial MRI of soft-tissue sarcoma of the thigh lying adjacent to the mid-diaphysis of the femur. The intralesional margin (dotted line), the marginal margin (broken line), and the wide margin (chain line) are all indicated. A radical margin (full line) would be a resection of the entire tumour-containing compartment, which in this case would mean a total quadriceps resection including a section of femoral diaphysis.
Radical margins are achieved when the entire tumour-bearing compartment is removed en bloc. For bone sarcomas, radical margins include the en bloc removal of the bone of origin and the entire soft tissue compartment into which the tumour has entered. For soft tissue sarcomas, this includes anatomical fascia surrounding that compartment and bony borders when present. Radical margins are associated with the lowest risk of recurrence.

With limb-sparing surgery as the preferred technique, the majority of uncomplicated bone or soft tissue resections aim at complete uncontaminated surgical margins. The use of chemotherapy has improved the rate of local control in osteosarcoma while allowing wide excisional limb-sparing surgery. Similarly, radiation therapy has had a major influence on decreasing the size of surgical margins in soft tissue sarcoma resections. Specifically, combination radiotherapy and marginal surgery has had the same results as surgery with wide margins alone, and the recurrence rates for surgery with wide margins combined with radiotherapy are similar for radical surgical margins alone. If vital neurovascular structures are adjacent to the tumour, marginal surgery may be selected and combined with adjuvant therapy. In selected tumours, such as those which are completely within a single muscle, or subcutaneous and not engaging the deep fascia, surgery with wide margins alone may be sufficient to achieve local control. Decisions regarding choice and combination of modalities need to be tailored to each case.

Biopsy techniques (Box 2.1.3)

Now that staging has been completed, the decision to perform a biopsy is considered. Plain radiographs of bone lesions are often diagnostic or can significantly narrow the differential and aid in determining whether or not a biopsy should be performed (i.e. a classic osteochondroma or osteoid osteoma needs no biopsy prior to excision).

Box 2.1.3 Biopsy techniques—summary

- Open incisional biopsy is considered to be the 'gold standard'.
- Percutaneous biopsy yield compares well with open biopsy, is more cost-effective, with less patient morbidity, and at a fraction of the cost of open surgical biopsies.
- All biopsy tracts must be resected en bloc with the tumour at the definitive surgical procedure.
- Careful planning is necessary and good collaboration between surgeons, radiologists, and pathologists is crucial to avoid unnecessary/dangerous procedures.

Open incisional biopsy is the conventional method for obtaining a representative specimen and is considered to be the 'gold standard.' In carefully selected patients, closed needle or trephine biopsies are appropriate. This is a well-established practice, with a reported accuracy of 78–97%. The site and method of approach must provide samples that are adequate for diagnosis and deliver them with the minimum amount of morbidity. Two attempts at percutaneous biopsy are justified. Percutaneous biopsy yield compares well with open biopsy and is more cost-effective. In experienced hands, percutaneous biopsy can be performed quickly, with less patient morbidity, and at a fraction of the cost of open surgical biopsies. Closed biopsies are ideal for difficult-to-access lesions in the vertebrae and pelvis and can be performed under CT or fluoroscopic guidance. Additionally, needle biopsies, when compared to open biopsies, lessen the risk of potential biopsy complications such as tumour spillage or haematoma and contamination, wound dehiscence, and infection. Finally, a needle biopsy tract is easier to excise en bloc with the final resection specimen. Different systems exist allowing percutaneous biopsy of musculoskeletal lesions:

- Fine needle aspiration (FNA) with a small, 18- to 23-gauge needle: FNA obtains a few cells for morphologic evaluation by a cytopathologist. Tissue is generally not available for further pathologic studies and is subject to sampling error. The architecture of the lesion is not preserved, making the diagnosis more difficult. FNA has been used successfully in select instances. The role of the cytopathologist in interpreting the sample is to decide whether the lesion is benign or malignant, primary, or metastatic. Thus, FNA is best employed to confirm suspected metastatic tumours, recurrent tumours at primary or metastatic sites such as lymph nodes, and, occasionally, suspected non-neoplastic conditions such as osteomyelitis.
- Core needle biopsy with a cannulated, cutting trocar system to obtain a core of tissue.
- Trephine system utilizing a stout, sharp bone cutting tool: the main advantage of core needle biopsy and trephine biopsy over FNA is the ability to preserve tissue architecture, facilitating both histological diagnosis and grading.

All biopsy tracts must be resected en bloc with the tumour at the definitive surgical procedure. Even needle biopsies can leave behind viable tumour cells that are a potential source for local recurrence, despite adjuvant treatment. Therefore, the skin puncture must be marked with India ink or a modest stitch so it can be identified later, even after weeks of neoadjuvant therapy.

CT guidance is used primarily for bone-based pathology and for deep soft tissue tumours that are beyond the focus of a standard ultrasound probe. CT also allows biopsy of smaller lesions with confidence and the final position of the needle can be reliably recorded. This is important for retrospective confirmation of needle position in non-diagnostic pathology reports. Ultrasound is suitable for superficial soft tissue lesions and for bone-based pathology such as osteosarcomas which commonly have a large extraneous "soft tissue" component at the time of presentation. The avoidance of critical anatomical structures within the biopsy field will affect the choice of guidance system and both CT and ultrasound may play a role. In certain centres, specialist biopsy-designed MRI is now available.

Needle systems

Several needle systems have been devised for biopsies of the musculoskeletal system. In our unit we routinely use two needle...
types:

**Jamshidi® needle**

This cutting needle with a tapered end (aiding tissue retention) and a disposable trocar is used for lesions that are predominantly osteoblastic and centrally sited within bone, or for predominantly lytic or mixed intraosseous lesions that have an intact surrounding rim or cortex (Figure 2.1.3). It is unsuitable for soft tissue biopsy work.

![Click to view larger](image)

Fig. 2.1.3
A Jamshidi® needle system.

**Tru-Cut® or Temno® (preloaded) needles**

These are predominantly used for extraosseous soft tissue specimens, or when cortical bone destruction allows access to the medulla (Figure 2.1.4). Hemorrhagic lesions may fail to produce a satisfactory core, but direction under ultrasound or CT guidance improves the diagnostic yield. Multiple specimens can be provided for the histopathologist.

![Click to view larger](image)

Fig. 2.1.4
A Tru-Cut® needle.

**Technique**

Full aseptic conditions are observed in all cases, and the appropriate method of anaesthesia, depending on the age of the patient, is selected.

Having chosen the radiological technique that complements the percutaneous biopsy, a small stab incision is made with a No. 15 blade at the site of entry of the needle and the selected needle type inserted. Care must be taken in cases of suspected malignant but contained lesions not to take the needle beyond the point of natural tissue hold-up. For example, with a subperiosteal osteosarcoma contamination of the medulla from the biopsy must be avoided. In tumours close to joints it is imperative that the biopsy is located in such a way that the joint cavity is not contaminated by needle placement.

With all specimens care is taken to reduce tissue crush. Specimens should ideally be delivered fresh and unfixed to the histopathology department allowing imprint preparation to be made to ensure that lesional tissue is present in a sample. In cases of potential infective diagnoses, additional samples must be sent for microbiology examination.

**Complications**
Any biopsy is a surgical procedure and is associated with potential risks and complications. A poorly executed or interpreted biopsy increases the risk of error in diagnosis, wound complication, and a potentially deleterious change in treatment course or outcome, including the need for a more complex resection or amputation, increased risk for local recurrence, or death. Because of the small sample size, needle biopsies are more subject to: 1) errors in diagnosis, particularly in grade of heterogeneous tumours; 2) anatomical misrepresentation resulting in obtaining non-diagnostic or indeterminate tissue; and 3) inability to perform research studies or special diagnostic studies such as cytogenetics or flow cytometry which may be necessary for definitive diagnosis, as is the case with small blue cell malignancies.

Therefore, when the diagnosis, based on needle biopsy, is in reasonable doubt having been reviewed by a specialist musculoskeletal pathologist, the clinician must proceed as though no biopsy had been performed. Frequently, this means repeating the biopsy, usually by the conventional open technique.

**Conclusion**

Optimizing surgical margins, and thus local control of tumour, requires accurate preoperative imaging of the tumour and surrounding anatomy. Surgical planning includes the selection of an appropriate position for the biopsy site. Improperly placed biopsy incisions may prevent the possibility of limb salvage surgery.

Needle biopsy of bone and soft tissue tumours is both safe and accurate when performed in a specialist centre. Radiologists are best placed to perform most biopsies as they have a number of imaging modalities at their disposal, enabling them to take the most appropriate tissue sample. The main disadvantage to pathologists is the small amount of tissue available.

Amputations, endoprosthetic joint replacement, massive bone replacement, other alternatives

Summary points

- The aims of the bone tumour surgeon are to improve survival and maintain optimal function of the patient; this can be achieved by amputation or limb salvage.
- Limb salvage provides no greater risk to the survival of the patient than with amputation.
- Reconstruction after removal of the tumour is commonly achieved by using endoprosthetic replacements, autografts, or massive allografts.
- Complications of limb salvage include infection and difficulties associated with soft tissue reattachment and coverage of the bone replacement.

Introduction

The aim of the bone tumour surgeon is to improve the survival and maintain optimum function for the patient. To achieve this, a segment of bone has to be removed and often surrounding soft tissues associated with the tumour are sacrificed aiming to achieve complete clearance of the tumour. The addition of adjuvant chemotherapy has greatly improved the outcome of this technique.

If limb salvage will not achieve tumour clearance then amputation should be undertaken. Survivorship and local recurrence rates in patients with osteosarcoma are similar for amputation and limb salvage.

Limb salvage may be undertaken by endoprosthetic replacement, massive bone replacement, or other alternatives which will be discussed later.

Amputation

Amputation of the affected limb is performed when limb-sparing surgery would leave inadequate resection margins to gain local control of disease and when resection would leave the limb useless due to sacrifice of the neurovascular bundle.

When comparing amputation to limb salvage the survival rates and local recurrence rates are similar and therefore limb salvage provides no greater risk to the survival of the patient than with amputation. Functional comparison between the two treatments has shown better function in the limb salvage group and less energy expenditure. If the amputation level is above the knee then limb reconstruction patients function better. Preservation of the knee joint has better results when compared to arthrodesis or rotationplasty.

Limb salvage

A number of issues need addressing when considering whether a patient is suitable for limb salvage and limb reconstruction. Patient considerations include the general health of the patient, the degree of metastatic disease and therefore the expected survivorship, and whether the patient wants to take on the risks associated with limb salvage. Surgical considerations include whether or not reconstruction to produce a functional limb is possible with regard to which muscles and neurovascular structures will be left after tumour clearance, whether the physes have fused, the age and size of the immature patient, and how much remaining bone will be left for fixation of the prosthesis/graft to the bone either with a stem, extracortical plates, or both. Limb salvage is more cost-effective when compared with amputation.

Endoprosthetic replacement

Endoprostheses in the context of limb salvage for bone tumours have been used extensively since the 1970s in bone tumour centres. Endoprosthetic replacement usually involves replacing one or more joints with an associated segment of the adjoining bone (Figures 2.2.1 and 2.2.2). In some cases a joint-sparing procedure, with replacement of the intervening segment, may be possible, such as in the case of a diaphyseal replacement. Traditionally these prostheses have been custom made and more recently modular off-the-shelf systems have been developed. Custom-made replacements are used for specific cases or if a growing prosthesis is required in an immature patient.
Survivorship of endoprosthetic replacements

Survival of massive endoprostheses is not as good as primary arthroplasty. Ten-year survival with mechanical failure as the end point is 75% and for failure for any cause is 58%. The limb salvage rate at 20 years is reported as 84%.

Infection rates are high and comparable to other methods of massive reconstruction. Patients with significantly increased risk are those with pelvic or proximal tibial reconstruction, radiation therapy, and paediatric expandable prostheses. If the prostheses remain infection free and are strong enough to avoid mechanical failure then aseptic loosening becomes the main problem. Survival rates are different, depending on the anatomical location and are related to the patient’s age and the amount of bone remaining after tumour resection.

Modes of failure and factors influencing failure

Aseptic loosening is more common in distal femoral and proximal tibial resections than the proximal femur. Another factor influencing the survival of distal femoral replacements is the amount of bone resected at the time of the operation. The removal of less bone increases the survival of the implant due to the decreased offset loading at the interface of the intramedullary stem with the bone. Taking all this into account the poorest outcomes, with regard to loosening, are in the under 20 age group, with greater than 60% resection of the femur.

Loosening secondary to osteolysis begins at the interface between the implant and the shoulder of the bone producing a reduction in the bone density and progresses towards the tip of the implant.

In order to combat this problem fixation has been augmented by collars allowing bone to integrate with the implant aiming to form a bony bridge and therefore a biological fixation. Collars have been made of sintered porous titanium beads and can be augmented with bone graft. Hydroxyapatite-coated collars (Figure 2.2.3) have been shown to provide more reliable bone integration in up to
70% of cases compared to no ingrowth recorded in non-grafted porous collars on a review of retrieval specimens at our institution. It was also shown that size of the radiolucent lines around the intermedullary cemented stem is inversely proportional to the amount of ingrowth on the collar. The risk of revision for aseptic loosening is reduced by 52% in distal femoral replacements when a rotating hinge is used compared to a fixed hinge design. In proximal tibial replacement the risk of revision at 10 years for aseptic loosening is 46% when using a fixed hinged design and reduced to 3% when using a rotating hinge.

Loosening can be reduced by the use of porous-coated uncemented intramedullary stems with additional stabilization with extramedullary plates and screws. In comparison to cemented intramedullary stems the incidence of aseptic loosening is reduced; however, other complications may arise, such as implant failure and bony resorption under the shoulder of the stem, potentially making revision more difficult. This has led to the use of partially-coated stems aiming to reduce stress protection and therefore bony resorption under the collar.

**Pelvic replacements**

Periacetabular tumour resection and reconstruction has become a viable alternative to hindquarter amputation. Often there is a long period from the onset of symptoms to diagnosis of tumours in this region and this makes extensive resections necessary. Complications related to the surgery are high (infection, dislocation) and reconstruction options include: arthrodesis, allografts, a saddle-type femoral prosthesis, or a hemipelvic reconstruction with a total hip replacement.

**Diaphyseal/joint-sparing replacements**

In some cases replacement of the diaphysis of a long bone is possible without replacement of the associated joint (Figure 2.2.4). In patients where complete excision of the bone tumour would leave an intact joint with only a very small segment of metaphyseal/diaphyseal bone, rather than sacrifice the joint some advocate the use of a joint-sparing prosthesis in selected patients. These prostheses use individualized methods of fixation of the segment close to the joint.
Growing prostheses

Large numbers of bone tumours occur in adolescents. Resection often necessitates excision of the epiphyseal growth plates particularly around the knee in the immature skeleton, causing subsequent leg length discrepancy with continuing growth. Extensible prostheses were first used in 1976.

There is an actively growing part which replaces the growth plate and a passively growing part which fixes the device on the other side of the joint to be replaced. Most designs have relied on a worm screw mechanism which is turned by a hexagonal screwdriver inserted through a small incision. Apart from aseptic loosening, infection is the major complication of this type of implant. Secondary to the multiple surgical interventions infection rates of up to 40% have been published.

The major development in recent years is that of non-invasive growing implants (Figure 2.2.5). The worm screw mechanism is replaced by a gear box and magnet which is driven by electromagnetic induction, enabling lengthening of the limb with no anaesthetic, in much smaller increments and on a more regular basis. This negates the need for multiple repeat procedures and has been shown to decrease the rate of infection. It also reduces other complications such as loss of range of motion requiring physiotherapy, associated with lengthening in larger increments.

Fig. 2.2.5
A non-invasively growing distal femoral replacement.

Revision of massive implants

Revision in this group of patients is unfortunately common and challenging when compared to primary arthroplasty. This is due to the relatively young population, for which the advent of chemotherapy has meant that a significant proportion of them can expect to outlive their implant. Functional limb salvage in these patients is therefore dependant on the longevity of the implant and the success of subsequent revision procedures. Options for revision are varied and highly tailored to the individual situation. The most common method of revision is the use of another massive prosthesis. Revision is technically challenging due to the loss of bone stock associated with the initial procedure and secondary to the mode of loosening. The implant design in this situation is crucial and may be modified from the traditional stem fixation by extracortical plates with or without stem fixation, cortical and medullary screw fixation, fluted stems, and the use of hydroxyapatite.

Rotationplasty has been advocated for failed endoprosthetic reconstruction. Other options for revision include the use of allografts, arthrodesis, and amputation.

Massive bone replacement

An alternative to endoprosthetic replacement is the use of autografts and allografts for reconstruction. These grafts are fixed in position with plates or intramedullary nails.

Autografts

Autografts can be vascularized or not and most commonly are taken from the fibula. These have been used for all types of reconstruction. En bloc resection of the bone and tumour, then irradiation with 50Gy and then re-implantation with or without a vascularized fibula graft has also been advocated.

Allografts

Massive allografts have problems associated with their use, including infection, fracture, and early-onset osteoarthritis.

Other alternatives

These include tumour excision and arthrodesis of the joint with or without a graft and excision without any bony replacement such as the Tikhoff-Lindberg procedure. Rotationplasty has been described for the management of tumours around the knee. It involves...
Excision of the tumour and the knee joint, rotation of the remaining tibia through 180 degrees, and fixation to the remaining femur, leaving the ankle joint at the level of the contralateral knee as the functional joint and enables prosthetic fitting. It has also been advocated as a revision procedure for failed limb salvage.

Distraction osteogenesis after excision of tumour has been used mainly in the tibia and around the knee, with good to excellent functional results.

Complications of limb salvage

These encompass all the complications associated with primary arthroplasty of the particular anatomical location, but at significantly increased rates. Most complications are associated with the soft tissue coverage of the implant and the musculature required to drive the prosthesis. One of the most challenging areas with regard to the soft tissues is around the knee. Commonly significant amounts of tissue have to be resected to enable tumour clearance, leaving the patient with a deficient extensor mechanism and a soft-tissue defect. The gastrocnemius rotation flap is commonly used to cover the defect around the knee and has been shown to significantly improve outcome with regards to the infection rate in proximal tibial replacement. Other solutions include myocutaneous latissimus dorsi free flaps.

Proximal tibial resection produces a deficient extensor mechanism by removing the tubercle. Current methods of reconstruction include turning down the middle third of the patella tendon with a central block of patella bone and attachment to the prosthesis by means of wires or plate and screw fixation into a hydroxyapatite-coated trough or simply a soft tissue reconstruction incorporating the patella tendon and a gastrocnemius flap. In other areas of the body tendons are reattached to the prosthesis by means of strategically placed suture holes through the prosthesis or to a prolene mesh placed around the prosthesis, such as around the shoulder girdle.

Resections around the proximal humerus produce a gross deficit in rotator cuff function and subsequently subluxation of the head of the prosthesis during movement can become a problem. To combat this, mesh reconstruction from the glenoid labrum to the shaft of the humerus can be used, or alternatively a captive glenoid component can be used. A stable construct should be the treatment goal in shoulder reconstruction, in order to enable effective function of the arm and hand.

Functional outcomes

Functional outcome is measured by three main scores to enable and standardize the assessment of function after limb salvage or ablative surgery in tumour patients. The Musculoskeletal Tumour Society (MSTS) score is filled out by the clinician and assigns values on a scale of 0–5 for pain, function, emotional acceptance, walking ability, use of supports, and gait. In the upper limb, gait, walking ability, and use of supports is replaced by hand positioning, manual dexterity, and lifting ability. The Toronto Extremity Salvage Score measures physical function and the Short Form 36 is used to represent the patient’s perception of their mental and physical health. These two are filled out by the patient.

**Summary points**

- Ganglion cyst
- Intramuscular myxoma
- Myositis ossificans
- Nodular fasciitis
- Haemangioma
- Lipoma
- Cavernous lymphangioma
- Glomus tumour
- Neurofibroma
- Desmoid tumour
- Elastofibroma
- Schwannoma
- Synovial chondromatosis.

**Ganglion cyst (Box 2.3.1)**

A ganglion cyst is a benign cystic lesion which occurs around a joint but does not communicate with the joint cavity. However, there are other types of cystic lesions, which are similar to this soft tissue condition, which occur in the subperiosteal area, intraosseous compartment, intraneural space within the nerve sheath, and around the meniscus (usually lateral) of the knee. A ganglion cyst is the result of myxoid degeneration and softening of the fibrous tissue around a joint capsule or tendon sheath, which produces a swelling of the surrounding connective tissue.

**Clinical presentation**

Clinically they present with a cystic swelling over the dorsum or volar aspect of the wrist, but they can also occur on the volar aspect of fingers, dorsum of foot, around knee and ankle. They are usually painless but their presence over the joint often causes restriction in joint movement and an aching sensation. Sometimes they are associated with a history of minor trauma or repetitive use of the wrist and fingers.

**Radiological features**

Ultrasound is the main investigation to prove that it is a cystic lesion, and magnetic resonance imaging (MRI) can show that it is not connected to the joint, although this is rarely indicated.

In the intraosseous type, radiographs can show a round, well-defined osteolytic area with a thin rim of sclerosis. The cortex may be thin or expanded. MRI will show a high signal on T2-weighted images and low signal in T1-weighted images.

**Pathological features**

Macroscopically, a ganglion cyst is characterized by a yellow viscous, mucoid, jelly-like material surrounded by a thick fibrous capsule. There is no synovial lining. Microscopically there are fibroblast-like cells producing the mucoid ground substance. Macrophages are also found within the myxoid tissue.

**Treatment and outcome**

A ganglion cyst can be left untreated if it is asymptomatic. Often it can regress spontaneously. Aspiration and excision with debridement of the soft tissue bed are the main treatment options, but recurrence rates are high in both, especially aspiration. In intraosseous ganglion cyst, curettage with or without grafting can be used in symptomatic cases with few recurrence.

**Intramuscular myxoma (Box 2.3.2)**

Intramuscular myxoma is a benign soft tissue neoplasm which occurs in skeletal muscle. It is rare and tends to be more common in females. Although it is benign, it can grow to a large size, and can be mistaken for a soft tissue sarcoma. These lesions typically present late in adulthood, mostly around the age of 40. Typical locations are the buttock, thigh, lower leg, shoulder, and forearm. They are either encased within a muscle group, or attached only to the muscle fascia. These lesions tend to be mobile.
**Box 2.3.1 Ganglion cyst**

- Benign cystic lesion occurring around a joint but not communicating with the joint cavity
- Usually a cystic swelling over the dorsum or volar aspect of the wrist
- Ultrasound to confirm cystic nature if in doubt
- Mucoid contents with no synovial lining
- Aspiration; surgical excision but high recurrence rate.

**Clinical presentation**

They tend to present as a firm painless soft tissue swelling, which usually grows slowly. Most intramuscular myxomas present as a solitary lesion, but in 'Mazabraud syndrome' multiple myxomas are associated with fibrous dysplasia.

**Radiological features**

As this is a soft tissue tumour, MRI scanning demonstrates the lesion clearly and in the majority of cases will confirm the diagnosis without the need of a biopsy. The tumour appears as a lobular mass within the skeletal muscle or muscular fascia. On T1-weighted images, a low intensity signal is seen, but on T2-weighted sequences a high intensity signal is returned (Figure 2.3.1). A recent radiological review suggested that in intramuscular myxoma, there is a peritumoural fat rim visible in T1 images on MRI, and the surrounding muscle shows increased signal intensity in T2-weighted or fluid-sensitive sequence. These can be the most reliable features to differentiate benign myxoma from other malignant sarcomas.

**Pathological features**

The myxoma usually appears like a soft translucent mass, with a thin rim of fibrous tissue around it, and lies against muscle or fascia. Histologically, myxomas consist of sparse, bland-appearing cells within a myxomatous matrix. The cells have small nuclei and no mitotic figures, and their appearance resemble fibroblasts.

**Treatment and outcome**

These lesions are usually treated with marginal excision. As they are easily separated from the muscle layer excision is usually complete and recurrence is rare.

**Myositis ossificans**

Myositis ossificans is an extraskeletal non-neoplastic growth of new bone. It occurs most commonly in the second and third decades. It is uncommon in children (fewer than 7% of cases occur in the first decade), where it needs to be differentiated from myositis ossificans progressive (see later section). The process is usually confined to muscle although involvement of tendon and subcutaneous fat has been reported. The quadriceps and brachialis muscles are the sites most commonly affected (80%). Other
sites affected include the intercostals, erector spinae, pectoralis muscles, glutei, small hand muscles, and the chest.

**Box 2.3.2 Intramuscular myxoma**

- Benign soft tissue neoplasm occurring in skeletal muscle; rare, typically presents late in adulthood, mostly over the age of 40
- Firm, painless soft tissue swelling
- MRI can demonstrate the nature of the soft tissue lesion clearly and confirm the diagnosis without the need of a biopsy
- Treated with marginal excision; recurrence is rare.

Myositis ossificans usually occurs in response to soft tissue trauma (75%). The history of trauma may be difficult to elicit. Proposed atraumatic mechanisms include non-documented trauma, repeated small mechanical injuries, extensive burns, immobilization due to coma/paraplegia, and injuries caused by ischaemia or inflammation (Box 2.3.3).

**Box 2.3.3 Myositis ossificans**

- Extraosseous non-neoplastic growth of new bone; occurring most commonly in the second and third decades
- Extraosseous bone appears most commonly in response to soft tissue trauma (75%)
- Usually presents as a rapidly enlarging mass with significant pain 1–3 weeks after injury
- Follicular calcified density is observable in soft tissues at 2–6 weeks
- Treatment is conservative; lesions gradually spontaneously reabsorb after 3–6 months; NSAIDs may be used as an adjunct; if troublesome surgical excision only if lesion mature (12–18 months from onset).

**Clinical presentation**

Myositis ossificans usually presents as a rapidly enlarging mass with significant pain 1–3 weeks after injury. The patient may have a swelling and the area may be warm. This acute phase is not generally associated with systemic symptoms, except in children who may feel unwell and tired. Blood tests may reveal an increased erythrocyte sedimentation rate and serum alkaline phosphatase. A subacute phase follows before the myositis matures, usually between 3–6 months, evolving into a painless, hard, well-demarcated mass averaging 3–6cm in greatest diameter. The condition may be asymptomatic and diagnosed incidentally from radiographs obtained for unrelated problems.

**Radiological features**

Early plain radiographs may be unremarkable. Follicular calcified density can be seen in the soft tissues from 3–6 weeks. By 6–8 weeks, calcification becomes sharply circumscribed, being seen around the periphery of the lesion (Figure 2.3.2). The periosteal reaction is that of benign lamination unlike the more aggressive appearance of osteosarcoma.

![Fig. 2.3.2](image-url)

A 10-year-old boy struck in the back of his knee with a hockey stick, presented 3 weeks later with an enlarging painful mass on the posterior aspect of his distal thigh. (A) Lateral radiograph of knee/distal thigh reveals a calcified mass, no periosteal reaction. (B) It was elected to follow and repeat the radiographs. Two weeks later, the mass is better defined, progressing to mineralization. Note the clear demarcation with underlying femoral cortex. (C) Ten years after the original injury further...
Serial radiographs show the zonal phenomenon of calcification first occurring in the periphery of the soft tissue mass and then working toward the centre, unlike osteosarcoma where calcification extends centrifugally to the periphery. Computed tomography (CT) scanning can be of enormous help as it demonstrates the mass with a central radiolucency surrounded by a dense peripheral calcified rim. MRI is a very sensitive technique in detecting small lesions at an early stage. Bone scans are most helpful in the early detection of myositis ossificans and are typically positive before bone mineralization is detected on radiographs.

**Pathological features**

Lesions may be classified by tissue site: the mass may be pedunculated (attached to the underlying bone by a stalk), in continuity with the periosteum, or intramuscular. Macroscopically, lesions have a well-circumscribed shell of bone and a soft red-brown centre.

Microscopically, there are three distinct zones, becoming apparent approximately 2 weeks following onset. These consist of a central undifferentiated zone, a surrounding zone of immature osteoid formation, and a peripheral zone with mature bone. Acutely, there is proliferation of undifferentiated mesenchymal cells. At approximately 2 weeks, osteoid production begins at the periphery and fibrous tissue begins to form around the shell. There is an irregular mass of immature proliferating fibroblasts at the lesion’s centre. Moving peripherally, fibroblasts become more mature and structured, osteoblasts and islands of disorganized osteoid appear. Further peripherally, trabeculae of lamellar and woven bone are present with islands of chondroid tissue. Importantly, the lesion does not invade surrounding tissue.

**Treatment and outcome**

During the acute phase, treatment for myositis ossificans is conservative, as lesions become painless and may spontaneously reabsorb after 3–6 months. No pharmacological treatment is necessary. Indomethacin or other non-steroidal anti-inflammatory drugs (NSAIDs) may be used as an adjunct, although their efficacy has not been clearly established. A biopsy may be required if the lesion appears suspicious or without a history of trauma. Early surgery is contraindicated. In occasional cases, surgical excision is required, although success is limited. This should be performed once the lesion has matured, 12–18 months following onset. There have been a few isolated reports of malignancy occurring close to myositis ossificans. This is an extremely rare event and should not prompt the removal of lesions.

**Myositis ossificans progressiva**

Myositis ossificans progressiva is a rare (incidence 1/100,000), autosomal dominant disorder with equal sexual predilection. The average age of onset is 5 years. It is characterized by skeletal malformation and progressive, disabling heterotopic osteogenesis, which is ultimately fatal.

The condition produces painful swellings in the soft tissues such as aponeuroses, fasciae, and tendons, leading to ossification in muscles and fibrous tissues. The swellings may decrease in a few weeks, but joints affected become stiff. The most common sites affected are the sternocleidomastoid, and paraspinal muscle groups as well as the masticatory muscles, shoulder, and pelvic girdle muscles. Muscle groups not affected are the abdominal muscles, extraocular muscles, gastrointestinal tract, and tongue muscles. Ossification progresses from proximal to distal and cranial to caudal.

**Nodular fasciitis (Box 2.3.4)**

Nodular fasciitis is a benign reactive process of the soft tissues related to fascia. It is also known as subcutaneous pseudosarcomatous fibromatosis, or proliferative fasciitis. It is frequently misdiagnosed as a sarcoma. It is most common between 20–40 years of age. Approximately 10% of lesions occur in children. It is rare in patients older than 60. The male to female ratio is equal and the cause is unknown.

**Clinical presentation**

Lesions are small (1–3cm) and solitary, and commonly arise in the upper limbs (46%), chest and back (20%), and in the head and neck (17%). Half of the lesions are located in the subcutaneous fascia, and the remainder is situated in deep fascia in relation to muscles, tendons, vessels, nerve sheaths, and periosteum. Patients may complain of pain or tenderness associated with the lesion.

**Radiological features**

There are no unique radiological features of nodular fasciitis. The higher fibrous components of the lesions make them hypoechoic relative to muscle when examined on ultrasonography. MRI findings vary depending on the histological characteristics of the lesion. Hypercellular lesions types can be seen as hyperintense lesions. Highly collagenous lesions return a hypointense signal on all MRI images.

**Pathological features**

Nodular fasciitis is characterized by a proliferation of fibroblasts in the subcutaneous tissues and is also usually associated with the deep fascia. Three subtypes may be identified on the basis of location: subcutaneous, intramuscular, or fascial. It is frequently misdiagnosed as a neoplastic lesion.

There is a wide range of histological presentations. The lesion is richly cellular and consists of plump, immature-appearing
Nodular fasciitis

Benign reactive process of the soft tissues related to fascia; frequently misdiagnosed as a sarcoma; most common between 20–40 years of age. Lesions can be rapidly growing, usually within 3 weeks; patients may report pain. No unique radiological features of nodular fasciitis. Characterized by a proliferation of fibroblasts in the subcutaneous tissues, commonly associated with the deep fascia. Diagnosis and treatment are by excisional biopsy.

Haemangioma (Box 2.3.5)

A haemangioma is an abnormal proliferation of blood vessels that may occur in any vascularized tissue and accounts for 7% of all benign soft tissue tumours. There is debate as to whether these lesions are neoplasms, hamartomas, or vascular malformations.
Plain radiographic appearance of haemangioma affecting the skull.

With osseous haemangiomas, the plain radiographic features vary according to the lesion’s anatomic location. In the skull, a lytic appearance, often with fine radiating striations, is seen. In the vertebrae, there are parallel vertical trabeculae (‘corduroy’ appearance). In long bones, the appearances are less specific. CT is of limited use and on MRI there is increases signal on T1 and T2 images. Ultrasound is an excellent technique for diagnosing haemangiomas. Carried out by an experienced radiologist the lesion can be characterized, the vessels seen, the type of flow noted, and the compressibility of the lesion confirmed. If solid components are found, these will require further investigation.

Pathological features

Haemangiomas are benign lesions with increased numbers of blood vessels. They can affect numerous tissue types (individually or in combination), including skin, subcutaneous tissue, viscera, muscle, synovium, and bone, but they do not spread to avascular tissue such as cartilage. The aetiology remains unclear, although it is thought that excessive angiogenesis mediated by cytokines, such as basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF), is responsible.

Histologically, haemangiomas are classified into capillary, cavernous, and arteriovenous, according to the calibre of the vessel involved. Capillary haemangiomas are characterized by a proliferation of capillary-sized vessels, lined by flattened endothelium forming small slit-like structures arranged in lobules. Microscopically, there is a proliferation of endothelial cells with numerous mitotic figures; mast cells are also seen, predominantly in the involuting phase haemangiomas. Cavernous haemangiomas show dilated blood-filled vessels, also lined by flattened endothelium. Adventitial fibrosis and inflammation often results in a thicker vessel wall. Calcification is often seen. Arteriovenous haemangiomas contain larger vessels in the form of arteries and veins in close association.

Treatment and outcome

Observation is the appropriate treatment for the majority of haemangiomas. Biopsy is sometimes required to differentiate a soft tissue sarcoma especially if solid components are found on ultrasound examination. This can either be open or needle, but there is often excessive bleeding. Embolization can be of use especially in high-flow lesions and can provide symptomatic relief. It is often more useful as an investigation prior to surgery.

Surgical excision can be considered for symptomatic haemangiomas. The osseous type tends not to require treatment unless associated with fracture. Steroids and radiotherapy are thought to be useful in Gorham disease. In Kasabach–Merritt syndrome, excision and adjuvant therapy with steroids, radiotherapy, interferon, and pentoxifylline have been used to control the disease.

Box 2.3.5 Haemangioma

- Abnormal proliferation of blood vessels that can occur in any vascularized tissue
- 7% of all benign soft tissue tumours
- MRI is the imaging of choice
- Capillary, cavernous, and arteriovenous, according to the calibre of the vessel involved
- Observation for the majority of lesions with surgical excision in symptomatic cases
- No risk of malignancy, but recurrence after excision is common (10–50%).

The natural history of many haemangiomas is that of gradual fatty replacement, atrophy, and involution over time. There is no risk of malignancy, but recurrence after excision is common (10–50%). The more limited the extent of the disease, the more likely it is to be controlled by surgical excision.

Lipoma (Box 2.3.6)
Lipomas are the commonest benign soft tissue tumour, occurring in 1% of the population.

**Clinical presentation**

Lipomas are relatively uncommon in childhood, and tend to present in the fourth and fifth decades. They are usually subcutaneous, and can present at any site, including organs. They can present in multiple sites. They are uncommon around the face and hands and feet.

Their usual location lies between the skin and deep fascia. They have a soft fluctuant and lobular feel, and a well-defined edge. Lipomas are usually asymptomatic. Pressure symptoms and a mass effect will herald their presence if large in size (in that case the possibility of a liposarcoma should be considered).

**Radiological features**

For most subcutaneous lipomas, no imaging studies are required. If imaging is needed, MRI is the most helpful, especially with intramuscular lipomas. The tumour usually appears as a small homogeneous mass, although it may appear as a large inhomogeneous lesion with infiltrative margins. MRI does not, however, allow for a reliable distinction between a lipoma and a well-differentiated liposarcoma. Fat suppression sequences are mandatory to confirm that the lesion fully suppresses. If there are areas within the lesion that remain bright then a biopsy of these areas will be required prior to excision.

![Click to view larger](Fig. 2.3.4)

Lipoma of the right arm T1-weighted (A) and fat suppression (B) images.

**Pathological features**

Lipomas are slow-growing, benign fatty tumours and consist of lobules of fat, with a surrounding capsule, which may becomes tethered to adjacent structures. Atypical lipomatous tumours are considered to be well-differentiated liposarcomas. They have a predilection for local recurrence but do not generally metastasize.

Macroscopically, lipomas are multilobular masses with a yellow appearance. Microscopically, they have the same appearance as mature non-neoplastic adipose tissue. There are many variants including angiolipomas (mixture of mature fat cells and numerous branching vascular channels), spindle cell lipomas (consisting of mature adipocytes, small spindle cells, and bundles of mature collagen), pleomorphic lipomas (mixture of mature adipocytes, spindle cells, collagen, and bizarre ‘fret-type’ multinucleated giant cells), myxolipomas (myxoid transformation), fibrolipomas (septae of connective tissue), chondrolipomas (chondroid metaplasia), osteolipomas (osseous metaplasia), and myolipomas (presence of smooth muscle proliferation).

**Treatment and outcome**

As most lipomas are asymptomatic, surgical excision is usually for cosmetic reasons. If symptomatic, marginal excision can be carried out; the tumour is simply ‘shelled out’ with complete removal of the capsule in an extracapsular plane.

Recurrence is uncommon, but may occur if excision is incomplete. Lipomas rarely undergo sarcomatous change. Liposarcomas are malignant tumours that arise from adipocytes (the majority do not arise from pre-existing lipomas). They may recur locally and may metastasize. Fatty tumours of the retroperitoneum or in intramuscular locations should be considered to be potential liposarcomas until proven otherwise. The size of liposarcomas may vary considerably. The majority of tumours present between 5 –15cm and extremely large retroperitoneal tumours have been reported.

**Box 2.3.6 Lipoma**

- Commonest benign soft tissue tumour (1% of population)
- If needed, MRI is imaging of choice
- Slow-growing, benign fatty tumours consisting of lobules of fat, with a surrounding capsule
- Surgical excision if symptomatic
- Rarely undergo sarcomatous change.
Cavernous lymphangioma (Box 2.3.7)

Lymphangiomas are uncommon, hamartomatous malformations of the lymphatic system that involve the skin and subcutaneous tissues. There are two main types: superficial lesions called lymphangioma circumscriptum (simple lymphangiomas) and deeper lesions which include cavernous lymphangiomas and cystic hygromas.

Clinical presentation

Cavernous lymphangiomas usually arise during infancy or early childhood with equal distribution between sexes. They are commonly found around the head and neck, and less so in the extremities. The lesions are located deep within the dermis, and usually present as painless swellings. The overlying skin is not affected. They are usually small (<1cm) but may be large enough to affect an entire limb. They tend to enlarge as the child grows, and episodic, or sometimes constant, pain is more likely.

Radiological features

Clinical assessment is usually sufficient for diagnosis. Plain radiographs may display any associated skeletal deformities. Contrast-enhanced MRI can help differentiate these lesions (no enhancement) with vascular lesions (which enhance). Imaging is also particularly helpful in respect to planning excision.

Pathological features

Cavernous lymphangiomas are often poorly demarcated between the skin and subcutaneous tissue, and do not have a distinct capsule. They may extend along fascial planes between muscle groups and may lie within muscle septae.

Microscopically, the nodules in cavernous lymphangioma are characterized by large, irregular channels in the reticular dermis and subcutaneous tissue that are lined by a single or multiple layers of endothelial cells. An incomplete layer of smooth muscle often lines the walls of these malformed channels. The surrounding stroma consists of loose or fibrotic connective tissue with a number of inflammatory cells, and is usually variable. These tumours often penetrate muscle.

Treatment and outcome

Observation may be the most appropriate treatment. If symptoms are severe, or if the diagnosis is of doubt, excision biopsy forms the mainstay of treatment. The indistinct margins make complete excision difficult. Additional treatment modalities include the use of intralesional OK432 (Picibanil®, Chugai Pharmaceutical Co.) after excision. This sclerosing agent has had mixed results.

Lymphangiomas have a strong tendency for local recurrence unless they are completely excised. As they represent hamartomatous malformations, there is no significant risk of malignant transformation.

Glomus tumour (Box 2.3.8)

The glomus body is a specialized form of arteriovenous anastomosis found in the stratum reticularis. This anastomosis is surrounded by smooth muscle and glomus cells (modified smooth muscle cells). Glomus tumours are relatively uncommon benign neoplasms, arising from the arterial portion of the glomus body, differentiating to become glomus cells. These tumours have also been observed in extracutaneous locations that are not known to contain glomus cells. One explanation for this finding is that these tumors may arise from perivascular cells that can differentiate into glomus cells.

The incidence is unknown. Presentation can be at any age, but most commonly in the fifth decade. Two variants occur; solitary or multiple. The former is more common in women and the latter in men where it is usually inherited in an autosomal-dominant fashion.

Clinical presentation

Patients usually suffer from paroxysmal pain, exacerbated by cold temperatures. Multiple lesions often cause cosmetic concerns, but are less likely to be painful. Solitary lesions are usually blue or purple, small, and located in the periphery, e.g. subungual areas of the fingers and toes. Multiple lesions are subdivided into regional or localized, disseminated, and congenital plaque-like forms.

Special tests to aid diagnosis during examination include the Hildreth sign (disappearance of pain after application of a tourniquet proximally on the arm) and the Love test (eliciting pain by applying pressure to a precise area with the tip of a pencil or needle).

Malignant glomus tumours, or glomangiosarcomas, are extremely rare and usually represent a locally infiltrative malignancy. They are usually larger than 1cm and grow rapidly.

Box 2.3.7 Cavernous lymphangioma

- Hamartomatous malformations of the lymphatic system involving skin and subcutaneous tissues
- May extend along fascial planes between muscle groups; may lie within muscle septae
- Conservative treatment but perform excision biopsy if uncertain diagnosis
High risk of local recurrence unless completely excised
No risk of malignant transformation.

Radiological features

In certain locations, plain radiographs are of use. For example, in subungual lesions, there may be bony erosion. In finger-tip lesions, there may show an increased distance between the dorsum of the phalanx and the underside of the nail.

MRI is most helpful. The tumour appears dark as a well-defined mass on T1-weighted images and as a bright contrast enhancing mass on T1 post-gadolinium fat saturation images. Ultrasound may also be helpful.

Pathological features

Glomus tumours are benign and rarely show local infiltration. They arise from the arterial portion of the glomus body, or the Sucquet–Hoyer canal, which is an arteriovenous shunt in the dermis that contributes to temperature regulation.

Macroscopically, they are small (less than 1cm), well-circumscribed masses with a fibrous capsule. Solitary and multiple glomus tumours have distinct histopathological features. Solitary lesions appear mostly as solid well-circumscribed nodules surrounded by a rim of fibrous tissue, containing endothelium-lined vascular spaces surrounded by clusters of glomus cells. Multiple lesions are usually less well circumscribed and less solid-appearing. They appear similar to a haemangioma, and contain multiple irregular, dilated, endothelium-lined vascular channels that contain red blood cells. The vascular spaces are larger than those in solitary glomus tumours. Small aggregates of glomus cells are present in the walls of these channels and in small clusters in the adjacent stroma.

Glomangiosarcomas resemble benign glomus tumours. However, glomangiosarcomas have more atypia, pleomorphism, and mitotic figures, and they have an invasive growth pattern.

Treatment and outcome

Asymptomatic glomus tumours can be observed. Malignant transformation is extremely rare. Excision is required for those that are symptomatic and simply involves shelling out the tumour from its fibrous capsule. Other treatment approaches include argon and carbon dioxide laser therapy and sclerotherapy with hypertonic saline or sodium tetradecyl sulfate. These are probably helpful in the presence of multiple lesions.

The prognosis is excellent. Excision of painful lesions most often results in cure, with a low recurrence rate for solitary lesions. Recurrences are secondary to incomplete excision. Malignant glomus tumours are extremely rare and usually locally aggressive. Their overall prognosis is good when they are treated with wide excision. However, metastases do occur and are associated with a very poor prognosis.

Box 2.3.8 Glomus tumour

- Most commonly seen in the fifth decade; solitary or multiple lesions
- MRI most helpful imaging modality
- Arise from arterial portion of the glomus body (an arteriovenous shunt in the dermis that contributes to temperature regulation)
- Surgical excision if symptomatic benign lesions; wide local excision for malignant lesions
- Low recurrence rate if complete excision.

Neurofibroma (Box 2.3.9)

Neurofibromas are benign tumours of fibrous and neural elements. They can occur in a peripheral nerve, but also in the skin or subcutaneous tissue. Lesions may be solitary or multiple. They affect both sexes equally, and tend to occur in young people (20–30 years).

Clinical presentation

Presentation is usually with a lump which may be painful, or with symptoms of a compressive neuropathy. Multiple neurofibromas are seen in von Recklinghausen's disease (neurofibromatosis-1; NF-1). This is an autosomal dominant condition, characterized by multiple skin nodules and café-au-lait patches, occurring in approximately one of 2500–3300 live births.

Three subtypes of neurofibroma exist, namely cutaneous, subcutaneous, and plexiform. Both cutaneous lesions and subcutaneous lesions are circumscribed and may be soft or firm. These nodules may be brown, pink, or skin coloured. Plexiform neurofibromas are non-circumscribed, thick, and irregular, and they can cause disfigurement by entwining important supportive structures. This subtype is specific for NF-1.

Radiological features
Plain radiography and CT are of limited use. On MRI, neurofibromas demonstrate low or intermediate signal on T1-weighted images and homogeneously bright signal on T2-weighted images. Heterogeneity on T2-weighted images is suggestive of malignant transformation.

**Pathological features**

Neurofibromas consist of pale fibrous tissue with neural elements running into and through the tumour. They are composed of Schwann cells, fibroblasts, mast cells, and vascular components. Microscopically, neurofibromas are characterized by wavy, spindle-shaped nuclei and a loose mucinous stroma. The cells are arranged in short interfacing fascicles or bundles, and the intercellular environment is loose and myxoid, with thin wavy collagen fibres and inflammatory cells such as lymphocytes and mast cells.

**Treatment and outcome**

Excision is the treatment of choice when the symptoms of pain and/or paraesthesia become intrusive, or when the tumour enlarges. It is not possible to separate the tumour from nerve fibres; therefore, en bloc excision is performed if the nerve can be sacrificed. If not, intracapsular shelling out of the tumour can be performed, accepting the increased risk of recurrence.

Solitary neurofibromas rarely undergo malignant transformation. Follow up, particularly in patients with NF-1, is recommend as the risk is higher (reported between 2–30%). Any change, growth, or pain may be a sign of malignant transformation and a biopsy should be performed.

---

**Desmoid tumour**

Desmoid tumour was first described arising from the rectus abdominis muscle in postpartum women. It is now recognized that they can arise from any mesenchymal tissue. They are locally aggressive, but do not metastasize. They are also known as aggressive fibromatosis.

**Clinical presentation**

Patients usually complain of a lump that slowly increases in size. Pain is often a late feature. There may be a history of local trauma, e.g. previous scar. Local pressure may cause other symptoms such as neurological dysfunction. The tumours are usually firm, smooth, and mobile, but may be adherent to surrounding structures. The overlying skin is usually unaffected.

**Radiological features**

CT and MRI are useful for both diagnosis and follow-up of desmoid tumours. In particular, MRI can demonstrate the extent of the tumour and also the relationship to adjacent structures. On MRI, these tumours are isointense to skeletal muscle on T1 images and hyperintense on T2 images (Figure 2.3.5). They also display septum-like internal inhomogeneity and a surrounding hypointense capsular band.
**Pathological features**

The cause of desmoid tumours is uncertain but may be related to trauma or hormonal factors. There may be a genetic association. Spontaneous regression of desmoid tumours has been observed following menopause. Desmoid tumours often appear as infiltrative, usually well-differentiated, firm overgrowths of fibrous tissue, and they are locally aggressive. Macroscopically, these tumours are firm and white in appearance. The size varies considerably. Microscopically, desmoid tumours are composed of abundant collagen surrounding poorly circumscribed bundles of spindle cells.

**Treatment and outcome**

Surgical excision with wide local margins is the treatment of choice. Marginal excision is associated with recurrence. Achieving adequate excision of recurrent disease is difficult. Alternatives to excision include radiotherapy, medication (antioestrogens and prostaglandin inhibitors) and chemotherapy (e.g. vincristine, methotrexate, or doxorubicin). These are usually reserved for those who refuse or are unfit for surgery or as an adjunct to surgery when further excision would be technically difficult.

After surgery, MRI may be useful for monitoring recurrence. Local recurrence rates are reported to be as high as 70%, although some ‘recurrences’ may actually be metachronous disease. Malignant transformation is extremely rare, but may follow radiotherapy.

**Elastofibroma (Box 2.3.11)**

Elastofibroma is a rare, benign, slow-growing connective-tissue tumour that occurs most often in the subscapular area in elderly women, and was first described in 1961. They are usually solitary, and in up to one-third of cases, there is a family history of the same tumour suggesting a genetic predisposition.

**Box 2.3.10 Desmoid tumour**

- Most commonly seen in women after childbirth
- Can arise in any skeletal muscle but seen most commonly in anterior abdominal wall and shoulder girdle
- Infiltrative, well-differentiated, firm overgrowths of fibrous tissue, that are locally aggressive
- Surgical excision with wide local margins is the treatment of choice to reduce risk of recurrence
- Malignant transformation is extremely rare.

**Clinical presentation**

Elastofibromas are usually located at the lower pole of the scapula, deep to the serratus anterior, and often attached to the periosteum of the ribs. There is normally a long history of swelling and pain. Often, they are detected incidentally during chest CT examinations. Less common sites include the deltoid muscle, ischial tuberosity, greater trochanter, olecranon, and thoracic wall.

**Radiological features**

Radiographs are usually normal, but may show a mass displacing the scapula (Figure 2.3.6). Ultrasound is helpful with an
appearance consisting of arrays of linear strands against an echogenic background. However, the appearances can be similar to
the surrounding muscle, making it difficult to detect. MRI shows a lenticular, unencapsulated, soft tissue mass with skeletal
muscle attenuation interspersed with strands of fat attenuation. Smaller lesions are better seen with gadolinium enhancement.

![Click to view larger](image)

**Fig. 2.3.6**
Radiograph of the left chest wall in a 67-year-old male showing soft tissue fullness secondary to a large elastofibroma.

**Pathological features**

The aetiology of this tumour remains unclear, although there is an increased prevalence in people who perform manual labor
involving the shoulder girdle. It is uncertain as to whether elastofibromas are a true neoplastic process or a formation of reactive
tissue in response to the local movements.

Macroscopically, the tumour is an ill-defined nodular mass with a white or grey glistening surface. Microscopically, they are dermal
unencapsulated tumours composed of branched and unbranched elastic fibres, eosinophilic collagen bundles, and scattered fatty
tissue. The elastic fibres have a degenerated, beaded appearance or are fragmented into small globules or droplets arranged in a
linear pattern. The interspersed spindle or stellate cells show a fibroblast-like appearance.

**Treatment and outcome**

Biopsy is usually required to confirm the diagnosis, although its characteristic location and radiological appearances are sometime
sufficient. Complete surgical excision is the treatment of choice in symptomatic patients.

Recurrence after surgery is unusual. Spontaneous regression without treatment has also been observed.

**Schwannoma (Box 2.3.12)**

Schwannomas are benign, encapsulated tumours of the nerve sheath. They are seen in peripheral nerves and in the spinal roots,
and are the commonest neurogenic tumour.

**Clinical presentation**

Schwannomas usually affect people aged 20–50 years. The prevalence is unknown. The lesion usually presents as a palpable
mass or pain and paraesthesia (compressive neuropathy). The masses are slow growing, and may be present for several years
before becoming symptomatic. Common locations for the tumours include the head, the flexor surfaces of the upper and lower
extremities, and the trunk. The mass is usually mobile in the transverse plane and tethered along the axis of the nerve from which
it arises. It is usually tender. Schwannomas are almost always solitary, but multiple lesions may be seen in patients with
neurofibromatosis type 1 (von Recklinghausen’s disease).

**Radiological features**

Plain radiograph are generally not helpful, except in the case of the rare intraosseous lesions. The features are of a benign-
appearing, well-circumscribed lesion. MRI is more useful. It usually shows a round or oval mass with a moderately bright signal on
T1-weighted images and a bright, heterogeneous signal on T2-weighted images. The lesion enhances uniformly with gadolinium
contrast. There is often a ‘target’ sign on T2-weighted images.

**Pathological features**

Their cells of origin are thought to be Schwann cells derived from the neural crest. These masses usually arise from the side of a
nerve (Figure 2.3.7), are well encapsulated, and have a unique histological pattern. The capsule consists of epineurium.
Microscopically, there are two distinct regions, known as Antoni A and B. The amount of each varies from lesion to lesion.
Box 2.3.11 Elastofibroma

- Rare, benign, slow-growing connective-tissue tumour occurring most often in the subscapular area of elderly women
- Usually located at the lower pole of the scapula, deep to serratus anterior
- Uncertain if they represent a true neoplastic process or a formation of reactive tissue in response to local movement
- Surgical excision for symptomatic patients.

Fig. 2.3.7
Characteristic macroscopic appearance of a schwannoma as an encapsulated eccentric growth of the associated nerve.

Treatment and outcome

These tumours are generally easily excised. The nerve is usually splayed out over the lesion. The lesion is excised marginally, and the nerve fibres are spared. Intraleisional resection is warranted when complete resection would result in permanent neurologic deficit.

The most common complication is initial neurapraxia; however, neurologic deficit can be permanent, if significant neural tissue is excised. Generally, after resection patients experience complete and rapid relief of symptoms. Recurrence is unlikely following complete resection.

Synovial chondromatosis (Box 2.3.13)

Synovial chondromatosis is a rare benign condition in which foci of cartilage develop in the synovial membrane of joints, bursae, or tendon sheaths as a result of metaplasia of the subsynovial connective tissue. These ectopic foci of cartilage can result in painful joint effusions and the generation of loose bodies and mechanical symptoms.

Clinical presentation

Most patients are middle-aged, but it can be seen in children. Typically, a patient presents with monoarticular pain (most commonly the knee), swelling, stiffness, and symptoms of locking and giving way. The presence of a large effusion is not uncommon together with a restricted range of motion. The knee is affected in 60–70% of cases, with the shoulder, elbow, and hip being the next most commonly affected.

Box 2.3.12 Schwannoma

- Benign, encapsulated tumours of the nerve sheath (commonest neurogenic tumour)
- Palpable mass or pain and paraesthesia (compressive neuropathy); multiple lesions in NF-1
- ‘Target sign’ on MRI scan
- Cells of origin are Schwann cells; mass arises from the side of a nerve and is well encapsulated
- Marginal surgical excision sparing nerve fibres.

Radiological features

If loose bodies undergo ossification, they may be visible on plain radiographs, with two views of the affected joint (Figures 2.3.8 and 2.3.9). On MRI, cartilaginous nodules have intermediate signal intensity on T1-weighted images and high signal intensity on T2-
weighted images. Intra-articular gadolinium increases the sensitivity for these lesions. This imaging is particularly helpful preoperatively, as it shows the extent of unmineralized as well as mineralized disease.

**Fig. 2.3.8**
Anteroposterior (A) and lateral (B) plain radiographs of the right hip and computed tomography scan (C) demonstrating multiple opacities consistent with synovial chondromatosis.

**Fig. 2.3.9**
Anteroposterior (A) and lateral (B) views of the right knee showing multiple opacities characteristic of synovial chondromatosis.

**Pathological features**

Synovial chondromatosis occurs as either a primary or secondary form. In primary synovial chondromatosis, there is ectopic cartilage in synovial tissue and loose bodies in the joint cavity with or without calcification (osteochondromatosis). There is no joint pathology. This is either synovial metaplasia or a true neoplasia. In secondary synovial chondromatosis, there is associated pathology, such as osteoarthritis, rheumatoid arthritis, osteonecrosis, osteochondritis dissecans, neuropathic osteoarthropathy, tuberculosis, or osteochondral fractures. Free chondral or osteochondral fragments formed by underlying disease implant into the synovium and induce metaplastic cartilage around them.

**Treatment and outcome**

Symptoms due to the acute inflammation can be treated with NSAIDs, as well as rest and thermal therapy. Patients with recurrent painful effusions, mechanical symptoms, or both, due to synovial chondromatosis refractory to conservative interventions are candidates for surgery. This can range from arthroscopic excision of loose bodies, with limited synovectomy to an open arthrotomy and total synovectomy. However, controversy exists regarding the benefit of synovectomy. In older patients with secondary disease, primary arthroplasty is an option.

The most common complications include stiffness and recurrence of mechanical symptoms due to loose-body generation. Recurrence from surgery is in up to 20% of cases. Aggressive postoperative physiotherapy is required to minimize joint stiffness. Transformation to synovial chondrosarcoma is rare.
Box 2.3.13 Synovial chondromatosis

- Foci of cartilage develop in synovial membranes as a result of metaplasia of the subsynovial connective tissue
- Present with pain ± joint mechanical symptoms
- Primary or secondary
- Consider partial/complete synovectomy in resistant cases
- Rare transformation to synovial chondrosarcoma.

Malignant tumours of soft tissues

DOI: 10.1093/med/9780199550647.003.002004

Summary points

- Malignant vascular tumours of soft tissue
- Synovial sarcoma
- Malignant peripheral nerve sheath tumours
- Rhabdomyosarcoma
- Leiomyosarcoma
- Epithelioid sarcoma
- Clear cell sarcoma
- Malignant fibrous histiocytoma
- Chordoma.

Malignant vascular tumours of soft tissue

Three major categories of vascular tumours have been identified: benign lesions such as haemangiomas; tumours of intermediate malignancy (haemangioendothelioma); and highly malignant tumours (angiosarcoma). They are all very rare tumours accounting for less than 1% of soft tissue sarcomas.

Clinical presentation

The majority of haemangioendotheliomas are solitary lesions but may occur in association with other cutaneous vascular abnormalities such as those found in Klippel–Trenaunay or Maffucci’s syndrome. The mass is usually painless.

The majority of angiosarcomas arise in skin. Associations exist with lymphoedema, trauma, and previously irradiated tissues. Lesions are often diffuse and can present late with ulceration and a nodular character.

Radiological features

Plain radiographs may demonstrate punctate calcification within the tumour, which can be encountered in any vascular lesion. Magnetic resonance imaging (MRI) may show high-flow signals of vascular structures. Angiography is useful as it may help to identify feeding vessels for preoperative embolization.

Pathological features

The vessel in which endotheliomas arise usually remains intact with the tumour developing within the lumen of the vessel.

Cutaneous angiosarcomas are usually well- or moderately-differentiated tumours that tend to form vascular-like structures infiltrating or dissecting irregularly into the dermis (unlike haemangiomas).

Treatment and outcome

Surgery with or without adjuvant radiotherapy is the mainstay of treatment. Angiosarcomas are generally more difficult to control locally because of their infiltrative nature.

The prognosis of haemangioendothelioma is comparatively good with more than 80% 5-year survival (lung and local lymph nodes being the commonest sites of dissemination).

Angiosarcomas are aggressive tumours with less than 20% 5-year survival. They commonly metastasize to the lung, liver, and spleen.

Synovial sarcoma (Box 2.4.1)

Synovial sarcoma is a rare and aggressive soft-tissue tumour, which accounts for 8–10% of all human malignant sarcomas diagnosed annually. Its peak incidence is in adults in their third to fifth decades of life, but it can also occur in children.

Clinical presentation

The most common mode of presentation is a deep-seated, painless mass. Periarticular regions in the extremities are especially affected. It is more common in the lower limb and appears to have a close association with tendon sheaths, bursae, joint capsules and in less than 10% of cases involves the articular surface. Invasion of adjacent bone is seen in 10–20% of cases, which is not as common as in other soft-tissue sarcomas. Other sites of involvement include the head and neck, trunk, lung, intestine, and...
Retroperitoneum.

**Radiological features**

Plain radiography of synovial sarcomas reveals calcifications within the lesion in 30% of cases. Computed tomography (CT) scanning demonstrates heterogeneous lobulated masses with mixed cystic and solid appearances, which can be secondary to necrosis and/or haemorrhage. Thoracic CT scans are obtained to detect pulmonary metastases, and are an important part of the staging process.

MRI is the imaging modality of choice for diagnosing synovial sarcoma. The clear contrast between the lesion and normal tissues enables accurate assessment of tumour local invasion. It also is very valuable in revealing involvement of the neurovascular bundle and lymphatics. MRI is also excellent for surveillance and monitoring of the development of local recurrence after surgical resection, or sarcomatous changes secondary to radiation treatment.

Tumours appear sharply marginated, largely cystic or multiloculated with internal septations. Because of the cystic appearance and the well-defined margins, synovial sarcomas can be misdiagnosed on MRI.

Technectium-99m (Tc) bone scans and positron emission tomography (PET) scans are obtained to screen for bony metastases. These can be either lytic or mixed in nature.

**Pathological features**

Histologically, synovial sarcomas are divided into three subtypes: biphasic, monophasic, and poorly differentiated. The biphasic type contains epithelial and spindle cell elements (Figure 2.4.1A). The monophasic contains only spindle cells (Figure 2.4.1B). The poorly differentiated type has areas of mono-biphasic morphology surrounded by poorly differentiated areas with high cellularity, pleomorphism, round cells, mitoses, and necrosis.

Ninety to 95% of synovial sarcoma cells are characterized by the presence of a translocation t(X:18). This seems specific to the disease, as it is not seen in other soft-tissue sarcomas, and this can be used as a good diagnostic tool.

**Treatment and outcome**

Complete surgical excision is the mainstay of treatment. The extent of resection has a significant bearing on the outcome. Local recurrence and metastases are common with contaminated surgical margins. Many authors have reported the use of radiotherapy as an aid to surgery to achieve local disease control, especially in cases with positive resection margins. However, its role after achieving complete excision has not been fully evaluated.

The use of chemotherapy remains a controversial issue, and its influence on survival is debatable. Some authors recommend its use for systemic disease control, especially in children, but other believe the use of multiple chemotherapy agents does not affect survival.

Overall survival for completely resected lesions ranges from 50–80% at 5 years, compared to 25–30% when there are distant metastases at the time of presentation.

**Malignant peripheral nerve sheath tumours (Box 2.4.2)**

These are a rare variety of soft-tissue sarcomas of ectomesenchymal origin. The World Health Organization (WHO) recommends the use of the term MPNST as a replacement for the terms malignant schwannoma, malignant neurilemmoma, and new ribbon...
sarcoma. They are commonly misdiagnosed because of their cellular origin and the histopathological similarities with other spindle cell sarcomas (leiomyosarcoma, rhabdomyosarcoma).

**Clinical presentation**

MPNST represent 10% of all soft-tissue sarcomas, affecting adults in their second to fifth decades of life. Patients with type 1 neurofibromatosis are, however, affected at an earlier age. The most common sites of occurrence include the sciatic nerve, brachial plexus, and sacral plexus. Other sites include the pelvis, retroperitoneum, and infratemporal fossa. They usually present as painful mass with a biologically aggressive behaviour.

**Box 2.4.1 Synovial sarcoma**

- 8–10% of all human malignant sarcomas
- Deep-seated, painless mass affecting predominantly perarticular regions
- 90–95% are characterized by the presence of a translocation t(X:18)
- Surgical excision ± adjuvant radiotherapy.

**Radiological features**

MRI of these tumours reveals inhomogeneous lesions with necrosis and haemorrhage. It is the imaging modality of choice as in all soft-tissue sarcomas, as it can reveal the nerve of origin and the relationship to adjacent structures.

**Pathological features**

Histological examination in most cases shows spindled cells with many nuclei, similar to Schwann cells. These are arranged in sweeping fascicles alternating with myxoid areas. Mitotic figures are frequent. Heterotopic islands of cartilage and bone can also be seen. Four subtypes are recognized in the literature and include: cartilagenous, epitheliod, glandular, and rhabdoid. Tumour cells in all four subtypes show positive staining for S100.

**Treatment and outcome**

Radical surgical resection is the treatment of choice. In extremity lesions, amputations should be considered when there is extensive involvement of surrounding structures, especially the neurovascular bundle, making excisions not feasible. These tumours are resistant to radiation and chemotherapy, but radiotherapy is still sometimes used in cases with contaminated surgical margins.

Local recurrence occurs in approximately 40% of MPNST cases, this being the highest local recurrence rate of any soft-tissue sarcoma. Survival at 5 years is 40–45%. Metastases occur in the lungs, bone, pleura, and retroperitoneum.

**Rhabdomyosarcoma (Box 2.4.3)**

Represents the most common soft-tissue sarcoma in children, accounting for 5–8% of all childhood cancers.

**Clinical presentation**

These are fast growing and highly malignant neoplasms, arising from rhabdomyoblasts. Lesions can arise in any part of the body except bone. The most commonly affected sites include the head and neck, extremities, genitourinary (GU) tract, trunk, orbit, and retroperitoneum. Approximately 90% of patients are younger than 18, with two age peaks (2–6 years—head and neck tumours; 14 –18 years—extremities).

**Radiological features**

Plain radiographs usually reveal calcifications in lesions. CT scans are obtained to diagnose pulmonary and liver metastases. MRI is the main diagnostic tool and it reveals a clear definition of the mass and its invasion of adjacent structures. It is also very valuable in detecting local recurrence, and bone marrow metastases. The latter cases are usually associated with normal Tc and PET scans, which are insensitive to bone marrow infiltration when the bone cortex is intact.

**Box 2.4.2 Malignant peripheral nerve sheath tumours**

- Represent 10% of soft tissue sarcomas
- Term encompasses malignant schwannoma, malignant neurilemmoma, new ribbon sarcoma
- Surgical excision; resistant to radio/chemotherapy
- High local recurrence rate (40%).
Pathological features

Histologically, rhabdomyosarcomas are divided into four different subtypes according to the cells encountered in the tumour (Figure 2.4.2). These are embryonal, alveolar, spindle cell, and undifferentiated (anaplastic, pleomorphic).

Fig. 2.4.2
A) Typical embryonal rhabdomyosarcoma featuring fascicles of elongated spindle cells with striking rhabdomyoblastic differentiation (20×; H&E stain). B) Typical features of alveolar rhabdomyosarcoma showing small round blue cells with focal rhabdomyoblastic differentiation (20×; H&E stain). C) Intertwining long fascicles of spindle cells with eosinophilic cytoplasm and prominent nucleoli characterize the spindle cell variant of rhabdomyosarcoma (10×; H&E stain). D) Pleomorphic rhabdomyosarcoma is characterized by large cells with pleomorphic nuclei and eosinophilic cytoplasm (20×; H&E stain).

The embryonal is the most common and affects children under the age of 15, occurring mainly in the head and neck. In the botryoid subtype of embryonal rhabdomyosarcoma, the cambium layer is characteristic, and contains a condensation of loose tumour cells below an epithelial surface. This usually affects the vagina and GU tract. The alveolar type is characterized by cells lining up along membranes resembling lung alveoli. This is more aggressive and affects the trunk and extremities. The spindle cell type has a fascicular, spindled, and leiomyomatous growth pattern and can demonstrate notable rhabdomyoblastic differentiation. In the undifferentiated type, no evidence of myogenesis differentiation is present.

Treatment and outcome

Treatment involves a combination of surgery, radiotherapy, and chemotherapy. Obtaining a 2-cm clear margin is recommended, and all cases are routinely given radiotherapy postoperatively. Chemotherapy is used in certain cases to shrink the tumour to aid later surgical resection. Common agents used include cyclophosphamide, adriamycin, and ifosfamide.

Patients with non-metastatic rhabdomyosarcoma have a survival rate of 70% at 5 years after combined modality therapy. In 14% of patients, metastases are present at the time of diagnosis, decreasing the survival rate to 20% at 5 years. The most common sites of distant lesions include the lungs and bone marrow.

Leiomyosarcoma (Box 2.4.4)

Leiomyosarcoma is an aggressive soft-tissue sarcoma derived from smooth muscle cells. These malignant tumours arise from mesenchymal cell lines.

Of all soft-tissue sarcomas, approximately 5–10% are leiomyosarcomas. The aetiology of this tumour is unknown. Leiomyosarcoma of soft tissue is thought to arise from the smooth muscle cells lining small blood vessels. Leiomyosarcoma can also arise directly from the viscera, including the gastrointestinal tract and uterus.

Box 2.4.3 Rhabdomyosarcoma

- Most common soft tissue sarcoma in children (5–8% of all childhood cancers)
- Fast growing and highly malignant neoplasms, arising from rhabdomyoblasts
- Neo-adjuvant chemotherapy + surgical excision + adjuvant radiotherapy
- Non-metastatic disease has 70% survival at 5 years.

Clinical presentation

There are no specific clinical features diagnostic of leiomyosarcoma of soft tissue that distinguish these tumours from other soft tissue sarcomas. Women are affected more than men (2:1), with the disease typically occurring in the fifth and sixth decades of life. This gender distribution may reflect the proliferation of smooth muscle in response to oestrogen. It is a tumour of adulthood but
it does account for about 6–7% of all childhood malignancies.

The most common site of involvement of leiomyosarcoma is the retroperitoneum, accounting for approximately 50% of occurrences. Presenting signs and symptoms for retroperitoneal tumours can include: an abdominal mass, pain, swelling, weight loss, nausea, or vomiting.

Leiomyosarcoma of somatic soft tissues, like other soft tissue sarcomas, often present as an enlarging, painless mass. However, when leiomyosarcoma arises from a major blood vessel, symptoms of vascular compromise or leg oedema may be present, as well as neurologic symptoms.

Approximately 15–30% of patients have metastatic disease at presentation. The most common metastatic site is the lung. Other common sites for metastases are the skin, bone, liver, and lymph nodes.

**Radiological features**

Initial imaging should include plain radiographs of the affected area, an MRI of the lesion, and a chest CT scan (to evaluate for the presence of metastatic disease).

MRI is the study of choice for the evaluation of the anatomic extent of the tumour, especially to adjacent structures. CT imaging is useful in evaluating the extent of retroperitoneal tumours.

**Pathological features**

While histologically similar, soft tissue leiomyosarcoma has classically been subdivided into three groups for prognostic and treatment purposes: leiomyosarcoma of somatic soft tissue; cutaneous leiomyosarcoma; and leiomyosarcoma of vascular origin.

There is little histological difference between leiomyosarcoma arising from deep, subcutaneous, or dermal sites or in association with vessels.

Leiomyosarcomas are typified by spindle cells with a centrally placed blunt-ended cigar-shaped nucleus and abundant cytoplasm, arranged in intersecting bundles (Figure 2.4.3). Greater nuclear eccentricity, hyperchromatism, atypia, and size accompany more poorly differentiated cells.

![Click to view larger](image)

**Fig. 2.4.3**

Typical microscopic features of high-grade leiomyosarcoma characterized by intersecting fascicles of eosinophilic spindle cells (10×; H&E stain).

**Treatment and outcome**

Leiomyosarcomas are aggressive tumours that are often difficult to treat. The prognosis is poor, with survival rates among the lowest of all soft tissue sarcomas.

Surgical resection remains the only potentially curative treatment option. Five-year survival rates of 80% and 67%, respectively, in stages I and II, and of 12–50% in the more advanced stages. Tumours of the extremity have a better prognosis with greater than 60% survival at 5 years.

Adjuvant radiotherapy is indicated if the tumour is larger than 10cm or situated adjacent to neurovascular structures, which, if spared, necessitate a marginal resection. Chemotherapy comes into play as the primary treatment with inoperable tumours and may be a first line of treatment of choice in the case of lung disease. The two drugs most frequently used are doxorubicin and ifosfamide.

The prognoses of infants and young children tend to be better than those of adolescents and adults with similar diagnoses.
10% of all soft tissue sarcomas
Most develop in the skin and deep soft tissues of the extremities and retroperitoneum
15–30% have metastatic disease at presentation
Surgical resection ± adjuvant radiotherapy; chemotherapy for inoperable/metastatic disease

Epithelioid sarcoma (Box 2.4.5)
The term ‘epithelioid sarcoma’ was first coined by Enzinger in 1970. He described a group of hand sarcomas often confused with a chronic inflammatory process, a necrotizing granuloma, or a squamous cell carcinoma.

Clinical presentation
These represent the most common soft tissue sarcomas occurring in the hand in young adults. They mainly arise from the subcutaneous tissue, fascia, tendon sheaths, or joint capsule. The upper extremity is more commonly affected than the lower extremity. In many cases, patients present with a small, painless, ulcerating nodule on the extensor surface of the hand or forearm.

Radiological features
MRI is the imaging modality of choice to reveal the extent of local invasion and association with surrounding structures.

Pathological features
The histological features of epithelioid sarcoma include the presence of malignant cells which are epithelioid, spindled, or mixed in appearance. An abundance of chronic inflammatory cells is commonly encountered along the margins of tumour nodules, which can obscure the diagnosis in some cases.

Treatment and outcome
Radical resection and/or amputation are the treatments of choice. The role of radiotherapy and chemotherapy as adjuvant treatments is not very clear and has not yet been fully determined. Five-year survival in the literature ranges between 50–70%. Local recurrence and metastases, especially pulmonary, are common features of the disease. Routes of spread include the tendon sheaths, the fascia, and the lymphatic system.

Clear cell sarcoma (Box 2.4.6)
Clear cell sarcoma of tendons and aponeuroses is a rare and aggressive cancer, accounting for less than 1% of all soft tissue sarcomas. They are easily mistaken for malignant melanomas because of their histochemical and structural similarities. Many authors use the term ‘malignant melanoma of the soft parts’ to refer to these tumours.

Clinical presentation
They represent a distinct entity with a predilection for occurring in the tendons and aponeuroses of young adults. Eighty to 90% of lesions develop in the lower limb, with the ankle and foot being the commonest sites. Other sites include the knee, thigh, elbow, hand, head and neck, and trunk. They all exhibit an aggressive behaviour with a high incidence of local recurrence and metastases.

Box 2.4.5 Epithelioid sarcoma
- Most common soft tissue sarcomas occurring in the hand in young adults
- Chronic inflammatory cells are commonly found in lesions making diagnosis difficult
- Radical resection is the treatment of choice
- Local recurrence and pulmonary metastases are common.

The commonest presentation is a painless, deep-seated mass, which is bound to adjacent tendons or aponeuroses.

Radiological features
Intralesional calcifications are rarely seen on plain radiography or CT scanning. MRI commonly reveals areas of necrosis and/or haemorrhage within the lesion.

Pathological features
Clear cell sarcomas are mainly made up of round or fusiform cells arranged in nests separated by fibrosclerotic bands or septa. Giant cells with more than 10–12 nuclei may also be encountered within the tumour mass. Tumour cells are mostly uniform and have vesicular nuclei containing prominent nucleoli and clear or pale staining cytoplasm. These tumours and malignant melanomas
share similar histological characteristics and features, and both are positive for the protein S100, suggesting a close relationship between both entities. The site of occurrence is, however, different. The majority of cases are associated with a chromosomal translocation t(12;22)(q13: q12).

**Treatment and outcome**

The recommended treatment is a wide/radical excision or amputation if necessary, both with local lymph node clearance. The roles of adjuvant radiotherapy and chemotherapy are debatable, but used in many centres.

The prognosis is generally poor, with a 5-year survival rate of 60–70% after radical excision ± adjuvant treatments. This falls to 30% at 10 years. Local recurrence and metastases are common features, especially with a positive surgical margin. Metastases are usually to lymph nodes and the lungs. Less common sites include the skin, bone, and liver. Overall, 70% of patients develop metastases at some stage of the disease.

**Malignant fibrous histiocytoma (Box 2.4.7)**

Malignant fibrous histiocytoma (MFH), described by O'Brien and Stout in 1964, is the most common soft tissue sarcoma of late adult life accounting for 20–24% of soft tissue sarcomas.

It is a heterogeneous tumour with respect to histology and prognosis with malignant cells of histiocytic origin. Early osseous invasion and metastases to regional lymph nodes is common. The term MFH is still in use, but is gradually being replaced by the term pleomorphic sarcoma.

**Box 2.4.6 Clear cell sarcoma**

- Rare and aggressive cancer; less than 1% of all soft tissue sarcomas
- Predilection for occurring in the tendons and aponeuroses in the lower limbs of young adults
- Painless, deep-seated mass, bound to adjacent tendons or aponeuroses
- Similar histological features to malignant melanomas
- Poor prognosis; 70% will develop metastases at some stage of the disease.

**Clinical presentation**

MFH occurs more commonly in Caucasian patients. The male to female ratio is approximately 2:1. Peak incidence is in the fifth and sixth decades. Although rare in children, the angiomatoid subtype is the most frequently occurring variety in patients younger than 20 years.

MFH occurs most commonly in the extremities (70–75%, with lower extremities accounting for 59% of cases), followed by the retroperitoneum. Tumours typically arise in deep fascia or skeletal muscle.

MFH has been associated with hematopoietic diseases such as non-Hodgkin lymphoma, Hodgkin lymphoma, multiple myeloma, and malignant histiocytosis.

The most common clinical presentation is an enlarging painless soft tissue mass in the thigh, typically 5–10cm in diameter. Two-thirds are intramuscular. Retroperitoneal MFH usually presents with constitutional symptoms, including fever, malaise, and weight loss. This can be confused with infection or abscess presentation. MFH also occurs secondary to radiation exposure and may occasionally be seen adjacent to metallic devices, including total joint prostheses.

**Radiological features**

Plain radiographs are always indicated, reflecting the invasive nature of tumour. Bony lesions will show destructive changes with cortical erosion and a poorly defined, permeative margin. Other changes such as matrix mineralization are less common. CT typically reveals a non-specific, large, lobulated, soft tissue mass of predominantly muscle density, with nodular and peripheral enhancement of solid portions.

One should keep in mind that the diagnosis of MFH is made using histopathology, not by imaging; however, MRI remains invaluable for delineating tumour extent.

**Pathological features**

Uncertain histogenesis and numerous subtypes make MFH a rather controversial entity.

The tumour contains both fibroblast-like and histiocyte-like cells in varying proportions, with spindled and rounded cells exhibiting a storiform arrangement.

Five histologic subtypes have been described:

1) Storiform/pleomorphic (most common)
2) Myxoid
3) Giant cell
4) Inflammatory (usually retroperitoneal)
5) Angiomatoid.

Treatment and outcome

Early and complete surgical removal is indicated because of the aggressive nature of the tumour. Surgical excision with irradiation to residual local disease is the treatment modality of choice. The sensitivity of MFH to radiotherapy and chemotherapy is poor, and evidence is lacking for adjuvant treatment.

Patients with low-grade, intermediate-grade, and high-grade tumours have 10-year survival rates of 90%, 60%, and 20%, respectively. Patients with tumours smaller than 5cm at presentation have survival rates of 79–82%. Patients with tumours larger than 10cm have survival rates of 41–51%.

The rate of metastasis varies with the histologic subtype from 23% (myxoid) to 50% (giant cell). Distant metastasis most commonly occurs to the lung (90%) and bone (8%). Resection with negative microscopic margins decreases the incidence of local recurrence.

The overall survival rate of patients with MFH ranges from 36–58% at 5 years; however, patients with retroperitoneal tumours have an overall 5-year survival rate of 15–20%.

Chordoma (Box 2.4.8)

Chordomas are tumours arising from remnants of the primitive notochord and are epithelial in origin. They are relatively rare (make up only 1–4% of primary malignant soft tissue tumours) slow growing, malignant neoplasms. Peak distribution is in patients aged 55–65 years. Males are affected twice as frequently as are females, with a preponderance of cases in the sacrococcygeal location.

Chordomas have a predilection for the ends of the spinal column. Approximately 50% of spinal chordomas originate in the sacrococcygeal area. Approximately 35% occur at the base of the skull near the sphenoid-occipital area, and 15% are found in the vertebral column. These lesions present clinically as destructive bony masses with extensive soft tissue involvement. They erode and impinge upon adjacent structures, giving rise to variable presentation.

In the cranial region, they can cause cranial nerve palsies, hydrocephalus, headaches, and torticollis.

Sacral chordomas are often missed at the initial presentation, with patients being symptomatic for several months or even years prior to being correctly diagnosed. Most patients have pain that is difficult to distinguish from mechanical back pain. Symptoms may include altered bowel habits, or a feeling of fullness in the rectal area. Physical examination must include a rectal examination to exclude a potential presacral mass.

Box 2.4.7 Malignant fibrous histiocytoma

- Most common soft tissue sarcoma of late adult life
- Occurs most commonly in the extremities (70–75%, with lower extremities accounting for 59% of cases), followed by the retroperitoneum
- Contains both fibroblast-like and histiocyte-like cells in varying proportions
- Surgical excision ± radiotherapy for residual disease
- Aggressive with survival rate between 36–58% at 5 years.

Chordomas are locally aggressive but metastasis is relatively uncommon.

Radiological features

Plain radiographs do not provide sufficient information concerning the diagnosis or the planning of the surgical procedure and can often be obscured by bowel gas. Chordoma lesions are seen as midline lobular lesions, with areas of osteolysis, occasionally with expansion and osteosclerotic rimming. MRI scans are essential to map out the true extent of the tumour especially sagittal views of the whole of the sacrum (Figure 2.4.4).
Pathological features

Based on light microscopic morphology, chordomas have been divided into three subtypes: conventional, chondroid, and dedifferentiated. Grossly, conventional chordomas have a soft, tan, myxoid appearance with areas of haemorrhage. Immunochemistry is extremely useful for distinguishing chordoma from other tumours, especially chondrosarcoma.

Dedifferentiation or sarcomatous transformation occurs in 2–8% of chordomas and is associated with a poor prognosis.

Treatment and outcome

Definitive resection should always wait until a final pathological diagnosis is made. The mainstay of treatment is en bloc resection of the tumour with a wide margin, leaving a cuff of normal tissue.

Aggressive initial therapy improves overall outcome. Tumours detected and diagnosed early have a favourable prognosis if treated with a complete or en bloc excision. A complete excision may involve a combined anterior-posterior operation, vertebrectomy if the spine is involved, and subsequent stabilization. A permanent colostomy may be required and the patient may need intermittent self catheterization in the long term.

The importance of a complete excision is demonstrated by the longer disease-free period compared to that following an incomplete excision. In aiming to achieve a clear resection margin, sacrificing sacral nerve roots and excision of the rectum may be required.

Surgical resection margins are reportedly the most important predictor of survival and local recurrence with sacral chordomas. The findings suggest that obtaining wide surgical margins posteriorly, by excising parts of the piriformis, gluteus maximus, and sacroiliac joints, may result in better local disease control in patients with sacral chordoma.

Adjuvant radiotherapy must be given in the case of incomplete excision. Radiation therapy may also salvage some patients with local recurrence.

The 5-year and 10-year survival rates for conventional chordoma are approximately 50% and 25–30%, respectively. Survival rates appear to be influenced more by local tumour progression than by metastasis.

All three types of chordomas can metastasize, usually later in the course of the disease (except dedifferentiated chordomas, which can metastasize early). Vertebral body chordomas have a higher incidence of metastasis than do those arising in the clivus or sacrum.

Box 2.4.8 Chordoma

- Develops from notochordal remnants
- Divided into three subtypes: conventional, chondroid, and dedifferentiated
- Locally aggressive but metastasis is relatively uncommon
- Usually present with pain and often cause neurological deficits
- Mainstay of treatment is en bloc resection of the tumour with a wide margin.

Benign bone tumours

Anthony Mcgrath, Kesavan Sri-Ram, Eric Yeung, Ben Spiegelberg, Nick Kalson, Barry Rose, Rob Pollock, and John Skinner

DOI: 10.1093/med/9780199550647.003.002005

Summary points

- Unicameral bone cyst
- Aneurysmal bone cyst
- Non-ossifying fibroma/fibrous cortical defect
- Bone island
- Fibrous dysplasia
- Osteochondroma
- Enchondroma
- Langerhans cell histiocytosis
- Chondroblastoma
- Giant cell tumour
- Osteoblastoma/osteoid osteoma
- 12. Periosteal chondroma.

Unicameral bone cyst (Box 2.5.1)

Unicameral bone cyst, (solitary bone cyst, simple bone cyst) (UBC) is a benign lesion characterized by a fluid-filled intramedullary cavity lined by a thin soft tissue membrane. It comprises between 3–5% of all primary bone tumours, with a 2:1 male predominance. Most UBCs occur in the proximal humerus and femur in young people aged 5–15 years, and in the ilium and calcaneum in older patients. The exact pathogenesis is still unclear.

Clinical presentation

Unicameral bone cysts are often asymptomatic, and discovered following an associated fracture. Other symptoms include localized tenderness, joint stiffness, swelling, and deformity or growth retardation if the cyst disrupts the epiphysis.

Radiological features

Plain radiographs are the investigation of choice for UBC (Figure 2.5.1). Typically they appear as a purely lytic lesion with a well-defined border and narrow zone of transition. They tend to occur centrally with some mild expansion of the bone but not breaching the cortex. The cortex is thinned and there is no periosteal reaction unless it is associated with a fracture. It is a unilocular lesion, but often appears multiloculated due to the prominent ridges on the cortical wall.

Fig. 2.5.1
Typical appearance of a proximal humeral unicameral bone cyst.

When a thinned cortical area fractures, the periosteum often remains intact, and the small fracture fragment can be seen within the base of the lesion (the fallen fragment sign) which is pathognomonic for a UBC with a fracture.
In young children, a UBC starts at the metaphysis adjacent to the epiphysis. As the bone grows, the lesion moves away towards the diaphysis. The lesion is classified as active when it is still within 1cm from the epiphysis, and latent when it is near the diaphysis.

Bone scan is often normal, and computed tomography (CT) shows only a fluid level. Intracystic septa can be demonstrated if radio opaque contrast is injected within the lesion. Magnetic resonance imaging (MRI) shows a bright fluid signal in T2-weighted images, and low signal in T1-weighted images.

Pathological features

Occasionally, a biopsy is taken to differentiate between UBC, aneurysmal bone cyst, and fibrous dysplasia. Grossly, the cortex is thin; the fluid is clear or yellow, with a fibrous membrane which lines the inner wall. Associated bleeding can be seen within the cavity if there is a fracture. Histological examination shows that the membrane consists of fibroblasts, with a cementum-like structure deep to it. This consists of strong eosinophilic and calcified material, surrounded by immature bone fragment, osteoclast-like giant cells, mesenchymal cells, and lymphocytes, but there would be no cellular atypia.

Treatment and outcome

Treatment is often non-operative. Small lesion in non-weight-bearing bone can be monitored regularly until skeletal maturity, but large cysts, or cysts at sites where there is high risk of fracture, should be treated. Operative management includes aspiration of the cyst followed by injection with either steroid or bone marrow, with recent studies suggesting that steroids may provide superior healing rates. Repeat injection may be required if there is no evidence of healing after 2 months. If it is not healing despite several injections, especially in the weight-bearing skeleton, curettage and bone grafting with or without internal fixation can be of benefit. Pathological fracture through the cyst often causes healing of the cyst after the fracture is united, probably due to an antiprostaglandin effect or decompression of the pressure of the cyst following the fracture.

More recently, injection of demineralized bone matrix and bone marrow had been shown to have good effect. In general, most patients will achieve an excellent outcome following any of the treatments.

Aneurysmal bone cyst (Box 2.5.2)

Aneurysmal bone cyst (ABC) is a locally destructive, expansile benign lesion. It is characterized by multiple loculations filled with blood and separated by fibrous septa. It accounts for about 2% of all primary bone tumours, and there is a slight female dominance of 3:2. It can arise as a primary lesion, or as secondary process associated with other lesions such as giant cell tumour, chondroblastoma, UBC, osteoblastoma, fibrous dysplasia, or even osteosarcoma.

ABC usually presents in the metaphysis of long bones, especially the proximal humerus, distal femur, and proximal tibia. It can also present in the ilium and in the posterior column of the vertebrae (accounts for 15–25%). Seventy-five per cent of patients present under the age of 20. It is postulated that ABCs arise from an increase of venous pressure secondary to some local circulatory compromise causing local haemorrhage.

Box 2.5.1 Unicameral bone cyst

- Proximal humerus and femur in young people aged 5–15 years, ilium and calcaneum in older patients
- Often asymptomatic, pathological fracture common presentation
- Plain radiographs most useful: purely lytic lesion, well-defined border, narrow zone of transition
- Macroscopically: cortex is thin, fluid is clear or yellow, fibrous membrane lines inner wall
- Large cysts at high-risk sites should be treated: aspiration ± steroid injection; curettage ± grafting ± internal fixation.

Clinical presentation

Most cases present with mild pain and swelling, but sometimes it can progress quite rapidly, mimicking malignancy. Spinal lesions can present with neurological symptoms. Pathological fracture, however, is not common (8–20%).

Radiological features

ABC appears as a destructive cystic lesion with bony resorption on plain radiographs (Figure 2.5.2). It is usually eccentric, with a narrow zone of transition and associated with cortical expansion. The growth plate is not normally breached, unless the ABC is secondary to a chondroblastoma or giant cell tumour.
Fig. 2.5.2
Typical appearance of an aneurysmal bone cyst of the proximal tibia. A destructive cystic lesion is evident with thinning of the cortex but no breaching of the growth plate.

Radiographic appearance is often seen in four phases:

1) Initial: small lytic lesion
2) Growth: rapid expansile growth, a ‘blow-out’ appearance
3) Stable: multiloculated cystic appearance, with thin outer cortex contained by the periosteum. Septation with fluid level can often be seen
4) Healing: ossification within the trabeculae of the lesion.

Bone scan shows a diffuse increased uptake in the periphery with a decreased central uptake. Angiography shows accumulation of contrast in the cavity, with hypervascularity in the periphery. CT and MRI can demonstrate the cavities and fluid level as well as delineating the lesion from the surrounding structures.

Pathological features

Macroscopically, ABC is a cystic lesion with septated cavities filled with blood. Microscopically, evaluation of the curetted tissue shows haemorrhagic tissue separated by cellular stroma. This stroma contains fibroblast, histiocytes, haemosiderin-packed macrophages, and osteoclast-like giant cells. There are numerous mitotic figures without atypical forms present in this stroma, and the vessels within them are quite dilated, probably contributing to the bleeding in the cavities. A ‘highly mineralized matrix with a chondral aura’ lining the vascular area can be a diagnostic characteristic for ABC.

A solid variant of ABC has also been described. It has similar clinical and radiographic features to the cystic form, but lacking the cavernous spaces. The highly proliferative stromal cells appear very similar to giant cell tumour, which gives an impression that it may be a secondary ABC.

Treatment and outcome

Spontaneous healing is rare, and treatment is usually surgical. Curettage with or without bone grafting has been the acceptable method, together with various adjuvant therapies like phenol, liquid nitrogen and high-speed burring of the cavity wall, to reduce the recurrence rate. Recurrence rate of ABC following curettage with or without grafting has been shown to be about 20–30%, and reduced to about 10% with adjuvant therapy. Selective embolization of the feeding vessels prior to surgery can help to significantly reduce blood loss and should be used in large lesions. Resection of the expanded extremity of lesion, such as fibula or metatarsal, is another option.

Newer methods of minimally invasive introduction of demineralized bone and autologous bone marrow into the cysts, with no curettage has been used with some success. Percutaneous sclerotherapy using polidocanol has also been tried with some good results. Both of these methods have the advantage of avoiding open curettage, and hence reducing the risk of surgical morbidity. However, this does not provide tissue sample for definitive diagnosis and still has the potential for further cyst progression.

Non-ossifying fibroma/fibrous cortical defect (Box 2.5.3)

Fibrous cortical defects and non-ossifying fibroma are considered as abnormal developmental proliferations of fibrous tissue and histiocytes. Non-ossifying fibroma is larger, slightly different in radiological appearance, but is histologically identical. They are often termed as ‘metaphyseal fibrous defects’. These lesions are common, and are present in over one-third of children under 14 years. Most are incidental findings. There is a slight male dominance of about 2:1.

They commonly present in the metaphysis of lower limbs, such as distal femur, proximal/distal tibia, and fibula. Occasionally they can present in the humerus, clavicle, or ilium. Most of the lesions are solitary, but rarely can be multiple. A Jaffe–Campanacci syndrome had been described with multiple lesions, mental retardation, precocious puberty, congenital blindness, and kyphoscoliosis. The aetiology of these lesions is largely unclear.
Clinical presentation

Most of these lesions are completely asymptomatic. Large lesions can present with swelling, mild pain, or pathological fracture. There is no evidence to suggest that they can undergo malignant transformation.

Radiological features

On plain radiographs, fibrous cortical defects are usually in the metaphysis or diaphysis of long bones, they appear as eccentric radiolucent areas up to 2cm with a smooth margin and a thin sclerotic rim (Figure 2.5.3). The cortex can sometimes be eroded, but no periosteal reaction develops. Non-ossifying fibroma presents with similar features, but much larger in size, reaching to about 7cm. They can cause cortical expansion, and sometimes involve the whole width of thin bones, such as the fibula. Both lesions have their long axis parallel to the axis of the long bone, and are often found near the insertion of tendons, which suggests that stress or avulsion injury may contribute to the cause. With bone growth, they migrate from metaphysis to diaphysis. But when healing occurs, the sclerosis starts from the diaphyseal end towards the metaphysis.

The diagnosis of these lesions can usually be made by plain radiographs; bone scans only show increased uptake in the active healing phase or in pathological fractures. CT and MRI are not usually indicated.

Pathological features

It is rare that any sample will reach the pathologist as no surgical treatment or biopsy is required. For those curetted samples which reach the pathology lab, the proliferative spindle cell stroma is intermixed with fibroblasts, collagen fibres, and histiocytes. Multinucleated giant cells are often present, and there is no cellular atypia. There is no reactive bone formation unless in the case of pathological fractures.

Treatment and outcome

Most of the fibrous cortical defects and non-ossifying fibromas regress and heal spontaneously, and no treatment is necessary. For those who present with pathological fracture, closed treatment is recommended to allow spontaneous union. The lesions that are at high risk of fracturing can be treated with close monitoring and modification of activity until they regress. Surgical treatment comprises curettage and bone grafting; more recently, demineralized bone matrix with bone marrow has been used with good results. Internal fixation is occasionally necessary if the pathological fracture is unstable or irreducible.
population, predominantly adults, they have no gender predilection. They are predominantly found in adults, and rarely in children. In long bones they usually present in the epiphysis or metaphysis. The size of the bone island varies between 2–20mm, but occasionally they can be as large as 10cm. Any lesion larger than 2cm is termed ‘giant bone island’.

Clinical presentation

Bone islands are asymptomatic, usually found incidentally, and should not cause pain. They can grow very slowly with time, enlarging about 30% over 20 years. Any bone island that is painful or grows more rapidly in size would suggest more aggressive disease.

Osteopoikilosis is a rare condition consisting of multiple periarticular lesions, identical to bone island, throughout the skeleton.

Box 2.5.3 Non-ossifying fibroma/fibrous cortical defect

- Mostly found in children/young adults between 2–20, commonly present in the metaphysis of the lower limbs, such as distal femur, proximal/distal tibia and fibula
- Usually asymptomatic
- Metaphysis or diaphysis of long bones; eccentric radiolucent area, smooth margin, and thin sclerotic rim; cortex can sometimes be eroded, but no periosteal reaction develops; non-ossifying fibromas are much larger in size, reaching to about 7cm
- Multinucleated giant cells are often present; there is no cellular atypia
- Most regress and heal spontaneously; for those presenting with pathological fracture, closed treatment of the fracture is recommended to allow spontaneous union.

Radiological features

Typically bone island can be diagnosed with plain radiographs, with the characteristic round or oval shape of high density within the cancellous bone (Figure 2.5.4). It is homogenous and blends into the native bone, giving a ‘brush border’-like appearance. There is no bone destruction or periosteal reaction in the surrounding area.

Bone island is usually cold on bone scanning, but occasionally it can have increased uptake in the giant form. CT can demonstrate the benign morphology if plain radiographs are not enough to make the diagnosis.

Pathological features

Bone island rarely needs biopsy, but histologically it is an area of compact, mature lamellar bone with a well-developed Haversian system. Occasionally there is some woven bone present, with some increased osteoblastic activity and blood flow, indicating a degree of remodelling.

Treatment and outcome

Repeat radiographs can be used to monitor if the lesion is growing in size. If it enlarges more than 25% in 6 months, or 50% in 12 months, especially in the large ones (greater than 2cm), then it should be biopsied to exclude more aggressive lesions. Otherwise no treatment is required.
Fibrous dysplasia is a slow-growing lesion where normal bone marrow is replaced by metaplastic woven bone and fibrous tissue. It may involve one (monostotic, 85% of the cases) or multiple bones (polyostotic 15%). They can be clustered around a single limb of the upper or lower extremity, or involve the whole skeleton. Certain syndromes, such as McCune–Albright disease and Mazabraud disease, have been associated with this lesion.

A mutation of the Gs\(^\alpha\) gene has been found to be associated with fibrous dysplasia. It was first discovered in patients with McCune–Albright syndrome, and recent studies had shown that isolated fibrous dysplasia also has the mutated Gs\(^\alpha\) gene present. This gene mutation can lead to activation of adenylate cyclase within the cell, which increases cell proliferation but inappropriate differentiation, resulting in excessive production of disorganized fibrotic bone matrix.

Clinical presentation

The majority of monostotic lesions are asymptomatic, and are found incidentally during the investigation of other problems in the same region. Bone pain, stress fractures, and pathological fractures are the usual modes of presentation, especially on weight-bearing bones such as the femur.

Fibrous dysplasia can also present with a gradual deformity of the limb. The severity of the deformity depends on the age of the patient, the extent, the site of the lesion, or whether it is monostotic or polyostotic. The classic ‘shepherd’s crook deformity’ of the proximal femur is characteristic of fibrous dysplasia. It is postulated that the deformity is secondary to the intermittent stress fractures through the dysplastic bone, and the bone then deforms with normal mechanical load. Other presenting symptoms and signs include limping, leg length discrepancy, tibial bowing, and exophthalmos associated with skull lesions.

Fibrous dysplasia is known to be associated with other conditions in certain syndromes. In McCune–Albright syndrome, polyostotic fibrous dysplasia is associated with precocious puberty and pigmented skin lesions. In Mazabraud syndrome, polyostotic lesions are associated with intramuscular myxoma. Oncogenic osteomalacia is a rare condition that is sometimes found in patients with fibrous dysplasia, symptoms of which are fatigue, joint pain, weakness, and fractures with an abnormal blood picture (hypophosphataemia, normocalcium, and increased alkaline phosphatase). Malignant transformation can occur in about 0.5%, but much higher (4%) in McCune–Albright syndrome.

Radiological features

On plain radiographs, fibrous dysplasia appears as a well-circumscribed diaphyseal lesion with a ‘ground-glass’ appearance (Figure 2.5.5). This is similar to cancellous bone, but more homogenous with no trabecular pattern. The lesions are usually in the centre of the medullary canal and are surrounded by a rim of reactive bone which fades into the surrounding cancellous bone. As the lesion replaces normal cortical and cancellous bone, the distinction becomes obscured. The bone diameter can expand as the lesion enlarges with its reactive rim of bone, and the cortex is slowly resorbed at variable rates, producing endosteal scalloping. There is, however, no periosteal reaction. As the lesion becomes quiescent after skeletal maturity, the rim of reactive bone is thicker and the lesion itself has a higher density.
Fig. 2.5.5
A) Anteroposterior and (B) lateral radiographs of the tibia and fibula in a 20-year-old female with Albright’s syndrome. Note the extensive involvement of the tibial medullary canal with mild cortical expansion. The classic ground-glass appearance is seen.

Other variations of the classical appearance of fibrous dysplasia have also been described, with a cystic form (a radiolucent area with a sclerotic rim), pagetoid form with dense trabeculae-like pattern, or intralesional calcification indicating the presence of cartilage. Of note, the polyostotic form has similar appearance and variations as the solitary form.

Radionuclide bone scintigraphy can be used to show the extent of the disease. Isotope uptake is high in active lesions in young people, but reduces as the lesions mature. CT is the best investigation to show the characteristic of fibrous dysplasia, where the native cortex, reactive bone, and endosteal scalloping can be demonstrated clearly. The poorly mineralized area of abnormal bone also appears classical with CT. MRI can demonstrate the shape and size of the lesion, and returns a low signal intensity in T1- and T2-weighted images as they tend to have a lower water content. In the case of fracture with haemorrhage, or cystic changes, a more hyperintense signal on T2-weighted images is seen.

Pathological features
The gross appearance of the lesion shows a yellowish gritty fibrous tissue with some trabeculae of bone scattered throughout. The surrounding rim of bone is usually intact. Microscopically, the thin trabeculae of bone are surrounded by a fibrous stroma of spindle shape cells. The pattern of the trabeculae is haphazard. There is minimal osteoblastic rimming, unless it is associated with fracture, and there is no cellular atypia or pleomorphism.

Treatment and outcome
Asymptomatic lesions do not require any surgical treatment, but they will need to be monitored to assess for progression, risk of pathological fracture, deformity, or rarely, malignant changes. Bisphosphonate therapy, especially pamidronate, has been shown to have some good effect in reducing bone pain, and also induce healing of the lesion with thickening of the cortex and ossification of the lesion.

Surgical treatment of fibrous dysplasia is indicated for symptom control, correction of deformity, fixation of fractures, and non-union of fractures. Curettage and bone grafting had been used to fill up the defects. In weight-bearing bones with a large defect, internal fixation with or without cortical grafting had also been shown to have good results. In severe bony deformity, ostectomy and internal fixation may be required to straighten and strengthen the skeleton. External fixation using monaxial or circular frame has also reported good results, especially in severe deformity or shortening. Utilizing the circular frame technique, distraction osteogenesis has been shown to achieve good length correction. Autologous fibula strut grafting can also be used and can achieve good results. Pathological fractures in non-weight-bearing bones can usually be treated non-operatively, but in the weight-bearing lower limb may require fixation. Patients with large lesions, or severe polyostotic disease, often require multiple surgeries for progressive deformities.

Osteochondroma (Box 2.5.6)
Osteochondromas are benign cartilaginous neoplasms found in any bone that undergoes enchondral bone formation. They account for 35% of benign bone tumours and 9% of all bone tumours. There is a higher incidence in male patients (3:1) and generally affects patients younger than 20 years old. The most common locations for solitary osteochondromas are the distal femur, proximal tibia, proximal humerus, and pelvis.

Box 2.5.5 Fibrous dysplasia
♦ Slow-growing lesion where normal bone marrow is replaced by metaplastic woven bone and fibrous tissue; usually seen
before the age of 30

- Usually asymptomatic or can present with bone pain, stress fractures, pathological fractures, and gradual limb deformity
- Fibrous dysplasia appears as a well-circumscribed diaphyseal lesion with a ‘ground-glass’ appearance
- Surgical treatment indicated for symptom control, correction of deformity, fixation of fractures, and non-union of fractures.

Clinical presentation

The majority of patients are asymptomatic and the lesions are noted as incidental findings. Pain is usually caused by direct mass effect on the overlying soft tissue where it can cause irritation to surrounding tendons, muscle, or neurovascular structures and a bursa may form over the lesion. Pain can also indicate malignant transformation. The lesions tend to stop growing when a patient reaches skeletal maturity; increase in size of the lesion in adults is a sign of possible malignant transformation.

Hereditary multiple exostoses (HME) is an autosomal dominant condition that affects one in 50 000; it results in formation of multiple osteochondromas. If, in an affected family, an osteochondroma has not formed in a patient older than 12 the condition is unlikely to manifest itself. The condition is associated with short stature and long bone deformities particularly affecting the forearm and knee. Operative treatment is advocated to prevent and reduce progression of deformity and functional impairment.

Radiological features

Plain radiography is the modality of choice for identifying osteochondromas (Figure 2.5.6). They have the appearance of a pedunculated or sessile lesion with well-defined margins that blends imperceptibly with host bone. They usually point away from the growth plate, towards the diaphysis and are typically located at the metaphysis. Size varies from 2–15cm. Signs of malignant change can be fuzzy margins of the cartilage cap and the presence of lucent zones within the lesion. MRI can be useful in assessing for malignant change; in particular, the cartilage cap can be observed for irregularity and size. Normally the cap thickness decreases with age, therefore in adults with a cap greater than 1cm and pain, malignant transformation should be suspected.

Pathological features

Macroscopically, osteochondromas resemble cauliflowers, with a stalk that is continuous with the intramedullary bone topped by a cartilage cap. This cap is of varying thickness but reduces with age. Microscopically, osteochondromas derive from aberrant cartilaginous growth plate tissue which proliferates separate to the growth plate. This aberrant tissue remains subperiosteally where it may disappear or proliferate as an osteochondroma perpendicular to the growth plate. The cartilage cap is organized into a structure similar to the epiphysis and during skeletal growth the base of the cap undergoes enchondral ossification. Signs of malignant progression are an irregular surface to the cap with differing sizes of cartilage lobules and invasion into surrounding soft tissue. Malignant progression is usually to a low-grade chondrosarcoma.

Treatment and outcome

Treatment for an asymptomatic lesion is non-operative, the patient should be informed to return to clinic if the lesion becomes larger or painful. Resection of osteochondromas should be performed if it is symptomatic, displays suspicious features of malignant transformation, causes functional impairment, cosmetic deformity, or damages surrounding structures. During resection all of the cartilage cap and perichondrium should be removed to prevent recurrence.

Malignant transformation of solitary osteochondromas is rare and occurs in less than 1% of patients. However, patients with multiple lesions have a higher rate of malignant transformation of 5%. The local recurrence rate after resection of osteochondroma is less than 2%.
Enchondromas are benign cartilaginous neoplasms, and usually present as solitary lesions in intramedullary bone. Enchondromas account for 12% of benign bone neoplasms. Solitary enchondromas are more common in patients aged 20–40 years and are often incidental findings; multiple enchondromas tend to affect 0–10 year olds. There is no sex predilection. Common sites for solitary lesions are the hands (especially the proximal phalanx) and feet, followed by humerus, femur, pelvis, and tibia.

Clinical presentation

Enchondromas are often incidental findings as they are generally asymptomatic; a growing lesion in the skeletally mature patient or pain in the absence of a fracture are generally highly suspicious for malignancy and should be further investigated.

Multiple enchondromas can also occur in three distinct disorders:

1) **Ollier’s disease**: a non-hereditary disorder where multiple enchondromas, identical radiographically to solitary lesions, are found in the metaphysis and diaphysis of long bones. It commonly has a unilateral distribution and causes limb deformity
2) **Maffucci syndrome**: a non-hereditary disorder, less common than Ollier’s disease, in which multiple enchondromas are associated with haemangiomas
3) **Metachondromatosis**: a rare autosomal dominant disorder consisting of multiple enchondromas associated with osteochondromas.

**Box 2.5.6 Osteochondroma**

- Also known as osteocartilaginous exostoses
- Most common benign bone neoplasm
- Pedunculated or sessile lesions typically located at the metaphysis of long bones
- Treat surgically if symptomatic
- Malignant transformation of solitary osteochondromas occurs in 1%, patients with multiple lesions have a higher rate of 5%.

Radiological features

Plain films reveal a long, oval, lytic lesion in the intramedullary canal; calcification within the lesion is common, often appearing as rings and arcs (Figure 2.5.7 and 2.5.8). Enchondromas tend to occupy the diaphyseal region in the short tubular bones and the metaphyseal region in longer bones. It can be difficult to distinguish between enchondroma and low-grade chondrosarcoma on plain x-rays; cortical breakthrough, soft tissue mass, deep endosteal scalloping of the cortex, location in the axial skeleton, and size greater than 5cm generally guide towards chondrosarcoma. CT scan is helpful to determine any endosteal cortical erosion; this modality is used at skeletal maturity to provide a baseline for future comparison.

**Fig. 2.5.7**
Typical appearance of an enchondroma of the proximal humerus. Note the stippled calcifications and ‘O-rings’ consistent with calcified cartilage.
Pathological features

Macroscopically, enchondromas are well-circumscribed lesions with discrete cartilage lobules measuring up to 1cm. Again they are difficult to tell apart from low-grade chondrosarcomas. Cytology is not helpful in determining between the two. Microscopically, enchondromas consist of multiple hyaline cartilage nodules separated by normal marrow with lamellar bone encompassing it, whereas low-grade chondrosarcoma consists of a mass of cartilage commonly permeating the marrow and trapping lamellar bone on all sides.

Treatment and outcome

Solitary enchondromas do not require surgical intervention but should be followed-up to monitor for malignant progression. Enlarging lesions in the skeletally mature or symptomatic patients should have intralesional curettage. Where malignant transformation is suspected, surgical treatment will vary from curettage to en bloc resection depending on the histological grade. Patients with multiple enchondromatosis should be monitored closely with regular follow-up clinics observing for symptomatic changes and cortical destruction in the lesions. Like solitary lesions, treatment depends on the histological grade of the tumour. Adjuvant therapy is not necessary.

Malignant transformation of solitary enchondromas is rare (less than 1%). In patients who have had intralesional curettage for solitary lesions, recurrence rates are less than 5%. In multiple enchondromatosis, malignant transformation can occur in up to 25% of patients.

Box 2.5.7 Enchondroma

- Benign cartilaginous neoplasm; commonly incidental finding
- Most common type of hand tumour
- Difficult to differentiate from low-grade chondrosarcomas; combine histology with radiology for maximum information
- Treat if symptomatic
- Malignant transformation of solitary enchondromas is rare (less than 1%).

Langerhans cell histiocytosis (Box 2.5.8)

Langerhans cell histiocytosis (LCH) is a very rare disorder characterized by proliferation of Langerhans cells and mature eosinophils in any tissue of the body. The most commonly affected sites are the skeleton (70%), skin, and lymph nodes; occasionally the liver, spleen, lungs and bone marrow are involved. LCH affects males more than females (2:1) and is more common in children younger than 15 years old; it has an unknown aetiology.

Clinical presentation

LCH has been divided into three distinct groups ranging from mildest to more severe:

1) Eosinophilic granuloma: children aged 5–15 years. A benign proliferation of Langerhans histiocytes occurring in a unifocal or multifocal manner that commonly affects the skeletal system
3) Letterer–Siwe disease: usually in infants less than 3 years old. The most malignant form, leading to widely disseminated clusters of Langerhans cells throughout the body. Characterized by fever, cachexia, otitis media, hepatosplenomegaly, skin rash, generalized multiple lesions, and a poor prognosis.

**Radiological features**

Imaging studies alone are rarely enough to be diagnostic, and frequently biopsy is needed. Lesions can vary from diffuse osteopenia to focal, sharply-defined lesions. The classic radiographic findings of vertebra plana are enough to make a presumptive diagnosis without need for biopsy (Figure 2.5.9). They include: vertebral collapse, maintenance of disc spaces, lack of extraspinal spread, and lack of soft tissue mass. Respiratory involvement can be evident on plain films acutely as interstitial infiltrate in the mid zones and lung bases; older lesions show a honeycomb appearance. Patients with an apparent solitary lesion should be screened to rule out any further lesions with a bone scan.

*Click to view larger*

**Radiological features**

Langerhans cell histiocytosis of the spine causing vertebra plana in a 12-year-old boy. A) Anteroposterior and (B) lateral views showing collapse of T3.

**Pathological features**

Microscopic features can vary with different proportions of eosinophils and histiocytes from one lesion to another. Criteria to form a diagnosis are at least two of either: proliferation of eosinophilic histiocytes on light microscopy, demonstration of X bodies by electron microscopy, positive OKT6 immunological marker, or immunohistochemical reactivity for S100 protein.

**Treatment and outcome**

Solitary bone lesions can resolve spontaneously or after biopsy. Other treatment modalities that are used include injection of steroid and curettage with or without internal fixation with grafting. Cutaneous lesions respond well to PUVA (psoralen plus ultraviolet) treatment. Treatment of more widespread disease is with chemotherapy, a regimen of moderate dose methotrexate, prednisolone, and vinblastine is used.

Patients should be followed up for at least 5 years as even in isolated LCH recurrences can occur in as many as 10%.

Signs of a poor prognosis include: young age at the onset of disease, involvement of multiple organ systems, rapidity of disease progression, and especially liver, respiratory, or haematological dysfunction.

**Box 2.5.8 Langerhans cell histiocytosis**

- Very rare disorder characterized by proliferation of Langerhans cells and mature eosinophils into any tissue of the body
- Imaging studies alone are rarely diagnostic; frequently biopsy is needed
- Isolated bone lesions can be treated with curettage; more widespread disease will require systemic treatment
- Monitor for recurrence; poor prognosis if multiple organ involvement.

**Chondroblastoma (Box 2.5.9)**

It is a rare and distinct tumour, accounting for approximately 4% of primary benign bone tumours composed of immature chondroblasts within a scanty chondroid matrix. Chondroblastoma is located in epiphyseal secondary ossification centres. The tumour does not heal spontaneously, can behave aggressively, and has a low but real risk of metastasizing; surgical removal is required.

**Clinical presentation**

Most patients are males, with a peak incidence in the second decade of life. The commonest presenting symptom is pain with
local tenderness and loss of function.

Examination usually reveals local tenderness, and can show reduced range of motion or fixed deformity in the joint adjacent to the lesion. Because of the lesions’ proximity to joints, patients are commonly misdiagnosed as having intra-articular pathology such as labral or meniscal tears. When the proximal tibia or distal femur is involved an effusion may be detected in the adjacent knee joint.

Chondroblastoma most commonly occurs in the distal and proximal femur, the proximal humerus, and the proximal tibia.

**Radiological features**

Investigation with x-ray radiography should be performed, and chondroblastoma has a distinctive radiological appearance as a well demarcated lytic lesion with a thin sclerotic margin of increased bone density, almost always confined within the bone cortex (Figure 2.5.10). Occasionally the tumour breaches the cortex or has ill-defined margins; cortical destruction may be seen in aggressive tumours. Tumours are confined in epiphysis in 40% of cases; in the remainder of cases the tumour extends to the adjacent metaphysis.

**Pathological features**

Macroscopically, chondroblastoma is most often contained by the periosteum, forming a surrounding sclerotic rim. Tumours can invade the adjacent joint, often through intra-articular ligaments such as the ligamentum teres or cruciate ligament. Chondroblastomas are lobulated with pink haemorrhagic areas of soft tissue interspersed with grey-blue chondroid tissue. The chondroid tissue may or may not be calcified.

Microscopically, chondroblastoma has distinctive pathological features. The predominant cell type is round or polygonal chondroblasts with eosinophilic cytoplasm and grooved coffee-bean like or indented nuclei, together with multinucleated osteoclast-like giant cells.

**Treatment and outcome**

There is no accepted standard treatment for chondroblastoma. Curettage, either alone or with cryotherapy, or packing the cavity with bone graft or polymethylmethacrylate has been described.

En bloc resection with reconstruction may be necessary when there is extensive aggressive disease and intralesional excision would leave a large bony defect.

Radiation is not used due to the tumour’s low sensitivity to radiation and possibility of inducing a secondary sarcoma.

Successful radiofrequency ablation of chondroblastoma under CT guidance in locations which are challenging to access surgically, such as the femoral head, provides an alternative therapeutic option, but care must be taken to avoid damage to adjacent hyaline cartilage.

Eighty to 90% of patients with chondroblastomas treated with curettage make a full recovery without recurrence or metastatic disease. A proportion of patients are left with residual pain and limited range of motion. Although a relatively high rate of recurrence has been reported, ranging from 8–21%, this may reflect inadequate treatment and re-curettage usually results in cure.

**Box 2.5.9 Chondroblastoma**

- Principally affects adolescents in their second decade
Occurs in epiphyses
Contains chondroblasts and multinucleate giant cells
Curettage or radiofrequency ablation.

The rate of metastasis ranges from 0.8–6% and typically involves the lungs. Metastatic lesions have the same benign histology as the primary tumour. Malignant transformation, a controversial entity, is thought to occur in roughly 1% of chondroblastoma and is often resistant to resection. These patients have a poor prognosis.

Giant cell tumour (Box 2.5.10)

Giant cell tumour of bone (GCTB) is an aggressive and potentially malignant tumour that has been described as the most challenging benign tumour of bone. Its natural history varies widely, ranging from local bony destruction, local recurrence, to distant metastasis and malignant transformation.

GCTB accounts for 5% of all primary bone tumours and occurs most frequently in the distal femur, proximal tibia, proximal femur, proximal humerus, and the distal radius. Fifty per cent of lesions occur around the knee. It is slightly more common in females (ratio 1.5:1), usually presenting in the third and fourth decade of life. GCTB is more common in Asia and China, accounting for up to 20% of bone tumours, where it is also more common in men than women.

GCTB is a mesenchymal tumour originating from a neoplastic mononuclear fibrotic stem cell which coordinates the recruitment and activation of osteoclast-like giant cells, resulting in bone destruction.

Clinical presentation

Patients most often present with pain, local swelling, and warmth. Pathological fracture is the initial presenting feature in 15% of cases and is inevitable if presentation is delayed. Symptoms may be present for several months before presentation, by which time in one-third of cases the tumour exceeds half the bone diameter, has destroyed the cortex and reached the subchondral region.

Radiological features

The radiographic appearance of GCTB is of a purely lytic radiolucent lesion without matrix calcification located eccentrically in the epiphyseal region of the bone but often extending to the metaphysis (Figure 2.5.11). Most lesions have a blurred interface with surrounding bone. Cortical breakthrough and periosteal reaction may be seen. MRI has the benefit of illustrating soft tissue involvement. CT scanning can demonstrate mineralization and bony absence in the lytic region.

Fig. 2.5.11
Anteroposterior radiograph (A) of an aggressive giant cell tumour (GCT) in the distal radius of a 25-year-old male.
Anteroposterior radiograph (B) of GCT of the distal femur in a 50-year-old male; note the thinning of the surrounding cortices.
Anteroposterior radiograph (C) of an aggressive GCT of the proximal tibia in a 23-year-old female; the lesion has broken through the medial cortex.

Because of the risk of metastasis, chest x-ray should be performed on diagnosis.

Pathological features

Grossly, GCTB is a lytic lesion, with the affected part of the bone expanded and the cortex thinned, or bridged in advanced cases. GCTB is typically red-brown due to haemorrhage, spongy, and friable. Cystic cavities, which may be filled with blood, are often seen. Microscopically GCT results from neoplastic growth of undifferentiated mesenchymal cells of bone. There are two predominant cell types, multinucleated giant cells and mononuclear stromal cells, typically uniformly arranged.

The histological composition of GCTB is complex and shares similarities with other bone lesions which contain multinucleate osteoclast-like giant cells; aneurysmal bone cyst, chondroblastoma, giant-cell rich variants of osteosarcoma, and osteoid osteoma.

Treatment and outcome

The surgeon must decide on three variables for treatment of GCTB: 1) whether to use intra-lesional curettage or en bloc resection; 2) whether to use adjuvant therapy, such as phenol; and 3) what material to use to fill the defect.
The morbidity of en bloc resection makes it inappropriate for most GCTB, which are most often in the epimetaphyseal region, where en bloc resection would involve the articular surface. Therefore, the standard treatment for most cases of GCTB is intralesional curettage with or without adjuvant therapy and filling with bone cement (polymethylmethacrylate, PMMA). Adjuvant therapy, such as phenol, hydrogen peroxide, and cryotherapy, aims to remove microscopic tumour that may remain after curettage through their thermal (liquid nitrogen, PMMA) or chemical (hydrogen peroxide, phenol) toxicity.

The increased understanding of the molecular pathogenesis of GCTB as an osteoclastic resorptive lesion has led to the trial use of bisphosphonates, which are antosteoclastic, as an adjuvant therapy, with promising results.

En bloc resection is generally reserved for large, aggressive GCTB which have destroyed the cortex usually with a fracture. Tumours of the proximal femur and distal radius have a higher risk of local recurrence due to the difficult anatomy.

Radiation is an alternative when tumour resection is not possible or incomplete, e.g. in the pelvis, sacrum, or vertebra, and resection will result in neurological or functional morbidity. However, it is important to remember that radiotherapy increases the risk of malignant transformation.

The overall outcome for GCTB in large series is a disease-free survival of greater than 85%. Although recurrence is not fatal in most cases, the morbidity after multiple procedures and rate of secondary arthritis can be high.

**Box 2.5.10 Giant cell tumour**

- Benign lesion occurring predominantly around the knee; has metastatic potential
- Lytic radiolucent lesion without matrix calcification located eccentrically in the epiphysis
- Two cell types: multinucleated giant cells causing bone resorption and mononuclear stromal cells (neoplastic)
- Curettage with adjuvant treatment and cementation has lowest recurrence rate
- Metastasis is rare (2–3%) but has a poor prognosis if not removed surgically.

More mitotically active lesions are more likely to recur. Recurrent lesions are more likely to develop possibly life-threatening metastasis and patients with recurrences should, as part of the staging process, have a CT scan of the chest. Malignant transformation is seen in less than 10% of cases but has a poor survival. Pulmonary metastasis is rare, affecting 2–3% of patients with benign GCTB. The pathology of tumours that metastasize is identical to those that do not. Survival is not compatible with persistent pulmonary lesions and nodules should be removed surgically. When this is not possible, whole lung radiotherapy is recommended. Malignant lesions should be treated like sarcomas.

Follow-up with radiographs of the primary site and chest should be for at least 5 years, as cases of recurrence and metastasis have been reported many years after treatment.

**Osteoblastoma/osteoid osteoma (Box 2.5.11)**

Osteoblastoma accounts for less than 1% of all primary bone tumours. It is benign, although rare variants, termed malignant osteoblastoma or aggressive osteoblastoma exist. The term osteoblastoma is reserved for tumours greater than 1.5cm in diameter; those smaller than 1.5cm diameter are termed osteoid osteoma. Males are twice as likely to be affected as females and 80–90% of patients are under the age of 30.

Osteoblastoma can affect any bone but the most common site is in the posterior elements of the spine, which accounts for approximately one-third of all osteoblastomas. Long tubular bones are the second most common site (34% of cases, most often the femur, tibia, and humerus). Tumours in long tubular bones usually occur in the diaphysis or metaphysis, and rarely in the epiphysis. Tumours in the spine almost always involve the posterior elements, and may involve the vertebral body as well.

**Clinical presentation**

Almost all osteoblastomas present with pain, which is generally mild but progressive. Other common complaints are gait disturbance, swelling, warmth and tenderness. The pain may not respond to non-steroidal anti-inflammatory drugs, unlike osteoid osteoma. When found in the spine, parasthesiae, paraparesis, or scoliosis may be the presenting complaint. Presentation is on average 6 months to 2 years after onset of symptoms. Less often, osteoblastoma presents with atypical clinical features, such as weight loss, night pain, epistaxis, tooth impaction, and aspirin overuse.

**Radiological features**

Radiological features are non-specific and include osteosclerosis, osteolysis, cortical thinning, and expansion of bone.

Osteoblastomas in the spine are well-defined expansile osteolytic lesions that are variably calcified or ossified, most often arising from the posterior elements (Figure 2.5.12). Long bone osteoblastoma on radiographs show cortical expansion, sometimes extending to cortical destruction, and often have a periosteal reaction. CT scanning is the most useful scanning modality for osteoblastoma, although it does not provide a definitive diagnosis.
Osteoid osteomas on plain radiographs can be classified as cortical, subperiosteal, or medullary in location. It is generally a round or oval well-circumscribed lesion with a radiolucent nidus.

Definitive diagnosis of osteoblastoma on radiographs alone is rarely possible; it is more likely that osteoblastoma will be included in a list of differential diagnosis, including chondroblastoma, osteosarcoma, ABC, chondrosarcoma, osteomyelitis, giant cell tumour.

Pathological features

Grossly, lesions are gritty, friable, and red to tan in colour. The tumour–bone interface is generally sharp, with a rim of reactive sclerosis. Microscopically the classic description of osteoblastoma is of long interanastomosing trabeculae of osteoid or woven bone undergoing varying degrees of calcification, some trabeculae are calcified, others are pink immature osteoid. Trabeculae are surrounded by a single row of osteoblasts. The intertrabecular stroma is a loose fibrovascular tissue with capillary proliferation, a few osteoclast-like giant cells, and spindle cells. Mitosis is seen in less than 10% of cells. Osteoblastomas are known for their range of histological appearances sometimes making differentiation between osteoblastomas and osteosarcomas difficult.

Treatment and outcome

Osteoblastomas should be removed to prevent or arrest bone destruction and remove pain symptoms. Treatment is surgical and includes curettage ± grafting. For small osteoid osteomas, radiofrequency ablation has been used successfully. For larger lesions wide resection is indicated; this can be difficult with spinal lesions and therefore aggressive intralesional excision with fusion and internal fixation may be used instead. Following complete removal of the tumour recurrence is uncommon.

Periosteal chondroma (Box 2.5.12)

Periosteal chondroma is a slow-growing benign lesion found within or underneath the periosteum of tubular bones. It is usually situated in the proximal end over the metaphysis, but may occur anywhere along the diaphysis. The most common sites are the proximal humerus, proximal femur, and small tubular bones of the hands and feet, though the tumour can occur in almost any bone.

It is uncommon, representing less than 1% of all bone tumours, but is three times more common than periosteal chondrosarcoma. It is most common in men in the second decade of life, though can affect adults and children. Very occasionally multiple lesions are seen.

Clinical presentation

Pain and palpable swelling with local tenderness are the most common presenting symptoms, often with reduced function at the adjacent joint, although many lesions are non-painful and found incidentally on imaging performed for other reasons. One-third of cases are associated with a soft tissue mass, palpable swellings are non-tender and fixed to underlying bone. In contrast to enchondroma and osteochondroma, in which growth after skeletal maturity is cause for concern, continued growth of periosteal chondroma in adults occurs without malignant transformation and is not a worrying feature.
Benign neoplasm of bone that arises from osteoblasts
- 90% of patients under 30 years old; pain, often increasing over time
- Affects the long tubular bones and spine
- Expansile lesion with cortical thinning and periosteal reaction; variable ossification
- Radiofrequency ablation; curettage; wide resection for larger lesions.

Radiological features
On plain radiographs periosteal chondroma is seen as a sharply marginated, radiolucent, shallow, semi-lunar cortical concavity adjacent to the cortex, with scalloping as it erodes the cortex, and overhanging edges (Figure 2.5.13). There is variable calcification of the cartilaginous matrix, seen in roughly 50% of tumours and a sclerotic reaction of the cortex, which remains intact underlying the lesion. Focal calcification or ossification is seen in approximately one-third of tumours. Periosteal new bone forms buttresses overhanging the edges of the tumour. Lesions can have a blurred indistinct margin, or be surrounded by a thin cortical shell. Pathological fractures have not been reported. MRI is useful in the diagnosis of periosteal chondroma, showing a lobulated lesion bordered by a hypointense rim, indicating an intact periosteum.

Fig. 2.5.13
Typical radiographic appearance of periosteal chondroma in a 15-year-old male. Note the scalloping of the underlying cortex and peripheral areas of “buttressing” new bone arising from the mature cortex.

Radiographs are helpful in differentiating from osteochondroma, periosteal osteosarcoma, and periosteal chondrosarcoma. Periosteal chondrosarcoma is round and shows popcorn calcification, is usually larger than 5cm, does not have a sclerotic reactive bone rim on its cortical side, and is primarily exophytic. Osteochondroma does not have a rim of bone separating it from the medullary cavity. Osteosarcoma shows perpendicular spicules of calcification, not seen in periosteal chondroma. Other benign conditions that can involve the periosteum should also be considered.

Pathological features
Grossly periosteal chondroma is covered by a thin shell of periostium, is embedded in, and erodes the cortex without invading the medullary cavity. The lesion is composed of white-grey or blue, firm cartilagenous tissue. Tumours range from 1–10cm, but are usually less than 6cm in greatest dimension.

Histological examination shows a benign appearing lesion composed of hyaline matrix arranged in a lobular pattern with no atypical cellular elements. The matrix is separated by fibrous connective tissue or lamellar bone. Invasion of the surrounding soft tissues is not seen.

Unusual and atypical findings can result in misdiagnosis so careful clinical and radiological examination is required to avoid a wrong diagnosis.

Box 2.5.12 Periosteal chondroma
- Rare cartilage lesion located between the periosteum and cortex of proximal long bones
- Affects adolescents predominantly
- Sharply marginated, radiolucent concavity adjacent to the cortex
- Histologically benign cartilage separated by fibrous connective tissue or lamellar bone
- Periosteal chondrosarcoma/osteosarcoma are the two most serious differential diagnoses
Surgical excision if painful lesion.

Treatment and outcome

Asymptomatic latent lesions may be managed by observation—malignant transformation has never been reported. Painful lesions may be treated with by en bloc or marginal excision, or interlesional curettage. The most effective treatment is en bloc resection, which prevents recurrence. Where the functional morbidity from resection is high, curettage should be performed, although recurrences have been reported. Bone grafting may be used with a large defect. Very few incidences of recurrence are recorded, estimated as less than 5%.

Further reading

Introduction

Primary malignant bone tumours account for 1% of cancer deaths. The incidence for the three most common excluding myeloma is only nine per million of population per year. As a result all primary malignant bone tumours are best managed at one of the five centres directly funded by The National Commissioning Group.

All such patients are managed by a multidisciplinary team and, where appropriate, entered into national and international trials aimed at improving survival and achieving maximum function.

Patients present with a variety of symptoms including pain, swelling, and loss of function. In children and adolescents, making a diagnosis of ‘growing pains’ must be a diagnosis of exclusion, and all clinicians should investigate thoroughly patients that complain of ‘night pain’.

Patients presenting with malignant bone tumours usually have a mass which increases in size. This may happen slowly over a period of years or months or more quickly in a matter of weeks. These tumours are usually painless until the late stages. Any mass greater than 5cm in size that lies deep to the fascia and is increasing in size, should be investigated as a potential malignant tumour until proved otherwise. Again the management should involve a multidisciplinary team compromising the surgeon, and a radiologist, pathologist, oncologist, and radiotherapist. Again, for the best outcomes bone and soft tissue tumours are best managed in specialist centres.

Chondrosarcoma (Box 2.6.1)

Chondrosarcoma is a malignant tumour of cartilaginous origin, in which the tumour matrix formation is chondroid in nature.

Lesions are designated as primary when they arise de novo or as secondary when they occur within a pre-existing lesion such as an enchondroma or osteochondroma. The vast majority (greater than 85%) are primary central chondrosarcomas, designated as such based on their location centrally within the medullary cavity. A minority (up to 15%) of conventional chondrosarcomas develop from the surface of bone, most of them as a result of malignant transformation within the cartilage cap of a pre-existing osteochondroma. These are therefore called secondary peripheral chondrosarcomas. A minority (less than 1%) occur at the surface of bone, possibly of periosteal origin, and are designated periosteal chondrosarcoma. Their histology is similar to that of conventional chondrosarcoma.

Clinical presentation

Chondrosarcoma is the second most frequent primary malignant tumour of bone, representing approximately 25% of all primary osseous neoplasms.

The incidence rate of chondrosarcoma is dependent on patient age, peaking at eight cases per million of population in those aged 80–84 years. The incidence in children is low. Most tumours arise in patients older than 40 years. The exact cause of chondrosarcoma is not known. There may be a genetic or chromosomal component that predisposes certain individuals to this type of malignancy.

The following is a list of some benign conditions that may be present when chondrosarcoma occurs:

- Enchondromas
- Osteochondromas
- Multiple exostoses
- Ollier’s disease
- Maffucci’s syndrome: a combination of multiple enchondromas and angiomatas.
A slight male predilection exists, with a male to female ratio of 1.5–2:1.

Tumours are predominantly located in the pelvis, femur, humerus, ribs, scapula, sternum, or spine. In tubular bones, the metaphysis is the most common site of origin. The proximal metaphysis is more frequently involved than the distal end of the bone. Chondrosarcoma is rare in the hands and feet and if it occurs, does so as a complication of a multiple enchondromatosis syndrome.

The most common symptom at presentation is pain, which is often present for months and typically dull in character. It may be worse at night and classically described as being relieved by taking anti-inflammatories. Local swelling may be present, and when the tumour occurs close to a joint, effusion may be present, or movement may be restricted. The average duration of symptoms prior to presentation is 1–2 years. The tumour occasionally presents as a pathological fracture.

**Radiological features**

The distinction between benign and malignant cartilaginous lesions can be difficult. For the distinction between enchondroma and central grade I chondrosarcoma, conventional radiography is not reliable. Dynamic contrast-enhanced magnetic resonance imaging (MRI) shows greater sensitivity, although an absolute distinction between benign and malignant cannot be made on radiological grounds alone.

The locations and radiographic appearances of the different chondrosarcoma subtypes are often characteristic, with the mineralized chondroid matrix as a punctate or ring-and-arc pattern of calcifications that may coalesce to form a more radiopaque flocculent pattern of calcification and aggressive features of endosteal scalloping and soft tissue extension (Figure 2.6.1).

![Fig. 2.6.1](image)

Lateral radiograph (A) of the distal femur revealing a lytic lesion involving the metaphysis along with its calcification. There is cortical thickening and reactive periosteal changes. A coincidental traumatic fracture is seen above. Anteroposterior radiograph (B) of the left proximal humerus showing a large calcified tumour extending well down the medullary canal. Anteroposterior radiograph (C) of the right distal femur and knee joint showing a lytic destructive lesion with cortical thickening and marked bone destruction. Lateral view (D) showing the lytic destructive lesion. Anteroposterior (E) and lateral (F) views of a left proximal femoral chondrosarcoma. A large calcified lesion is evident with significant soft tissue extension.

Computed tomography (CT) and MRI are indispensable adjunct tools for optimizing tumour characterization. Evidence of a large unmineralized soft tissue mass associated with a lesion with radiological features indicative of a chondrosarcoma should raise the level of suspicion for dedifferentiation.

**Pathological features**

Central and peripheral chondrosarcomas are histologically similar, and for both, three different grades are discerned (grade 1 represents the least aggressive in terms of histological features, and grade 3 represents the most aggressive) which is at present the best predictor of clinical behaviour. Recurrence of low-grade chondrosarcoma bears the risk for tumour progression toward a higher grade or even dedifferentiation, with a severe adverse prognosis.

Central and peripheral chondrosarcomas differ at the molecular genetic level. The exostosin (EXT) genes, causing multiple osteochondromas, are involved in the origin of osteochondroma and peripheral chondrosarcoma. In contrast, in the far more common central chondrosarcoma, EXT is not involved, and the initiating event is still unknown.

In addition to conventional chondrosarcoma, several rare subtypes of chondrosarcoma are discerned, together constituting 10–15% of all chondrosarcomas. These include:

- Dedifferentiated chondrosarcoma (dismal prognosis)
- Mesenchymal chondrosarcoma (highly malignant lesion)
- Clear cell chondrosarcoma (low-grade malignant tumour).

**Treatment and outcome**

For all grades and subtypes of non-metastatic chondrosarcoma, complete surgical treatment offers the only chance for cure. Wide, en bloc excision is the preferred surgical treatment of intermediate- and high-grade chondrosarcoma cases. However, wide excision
can lead to considerable morbidity and a demanding reconstruction, depending on the location. On the other hand, in low-grade chondrosarcoma, extensive intralesional curettage followed by local adjuvant treatment, for example, phenolization or cryosurgery (liquid nitrogen), and filling the cavity with bone graft or PMMA (polymethylmethacrylate) cement has promising long-term clinical results and satisfactory local control. In some cases of low-grade chondrosarcoma, intralesional excision may not be adequate, for example, because of large size or an intra-articular or pelvic localization. In these cases, wide resection remains the preferable choice for local therapy. Metastases are rare in low-grade chondrosarcoma of the long bones. In the case of soft tissue involvement in chondrosarcoma grade I, wide en bloc resection is recommended.

In patients with multiple exostoses the development of secondary peripheral chondrosarcoma is rare (assumed in the literature to be less than 2%) and usually presents after skeletal maturity. Complete surgical removal of the cartilage cap with the pseudocapsule has excellent long-term clinical and local results.

Box 2.6.1 Chondrosarcoma

- For conventional low-grade chondrosarcoma confined to the bone, intralesional curettage with local adjuvant therapy (phenol application/cryosurgery/cementation) is an option to decrease surgical morbidity
- For intermediate- to high-grade tumours, clear margins are necessary to prevent recurrence
- Poor response to radiotherapy/chemotherapy.

Osteosarcoma (Box 2.6.2)

Osteosarcomas can be subdivided into intramedullary, cortical (either on or in), or arising in pre-existing pathology. Intramedullary osteosarcomas include high- and low-grade osteosarcoma as well as telangiectatic osteosarcoma. Cortical lesions are subdivided into surface lesions, such as the parosteal and variable grade periosteal osteosarcomas or the rare intracortical osteosarcoma. Secondary osteosarcomas occur in pre-existing irradiated tissue beds, infection, infarction, Paget’s, fibrous dysplasia, or other bony lesions. Less common lesions include multifocal osteosarcoma as well as soft tissue osteosarcoma.

Clinical presentation

Incidence is approximately five per million population, and three per million in those less than 20 years. Although described as bimodal, the majority of cases occur in the rapidly growing bones of children and young adults. Common sites for osteosarcoma are the metaphyses of the distal femur, proximal tibia, proximal humerus, proximal femur as well as the mandible. Despite micro-metastases, which are common, patients tend not to be systemically unwell. Mass and pain are the most common presenting features.

Radiological features

Plain film evaluation confirms the extent of mineralized bone destruction, the osteolytic and blastic nature of the lesion, periosteal elevation, secondary ossification and soft tissue extension. Bone destruction is more extensive than films portray but the diagnostic sensitivity, cost, and widespread availability of radiographic plain film evaluation makes it a mandatory initial imaging modality (Figures 2.6.2 and 2.6.3).
Fig. 2.6.2
Osteosarcoma of the proximal tibia in a 14-year-old female. A) Anteroposterior and B) lateral radiographs showing a mixture of ill-defined radiodense and radiolucent regions with periosteal new bone formation.

Fig. 2.6.3
Osteosarcoma of the distal femur. A) Anteroposterior and B) lateral plain radiographs revealing cloudy opacities and sclerotic regions. C) Bone scan showing increased uptake in the distal femur. D) MRI scan confirming the intramedullary extent of the tumour and a small soft tissue mass. No skip lesions were identified.

MR evaluation is of major benefit to assess the extent of intra- and extraosseous tumour infiltration. It also enables tumour relationship to neurovascular structures to be determined, which affects limb-salvage decision-making during preoperative planning. Tumour can be separate from, in contact with, displacing, effacing partially or completely encasing the neurovascular bundle. If vascularity integrity needs further description appropriate angiography is requested.

A bone scan and CT chest are used to detect multifocal sites and chest metastases respectively.

Pathological features

Conventionally osteosarcomas are mineralized centrally with more immature bone at the periphery. The heterogeneous behaviour of conventional osteosarcoma is represented in the cellular population. Most commonly mixed, cell type can also be predominantly osteo-, chondro-, or fibroblastic, affecting necrosis rates following chemotherapy. The presence of osteoid and malignant stromal cells is needed to diagnose osteosarcoma. Cells may have a lace, trabecular, or sheet-like pattern.

High-grade intramedullary osteosarcoma

These constitute 80% of all osteosarcomas leading to the descriptive use of ‘conventional’ or ‘classic’. They are the subtype upon which the majority of survivorship analyses are made. Most have penetrated the cortex and have an associated soft tissue mass, making this a stage IIIB lesion. This more common subtype presents with CT detectable pulmonary metastases in 20% of patients.

Telangiectatic osteosarcoma

An aggressive, osteolytic, expansile lesion that can radiologically appear identical to an aneurysmal bone cyst. They contain fewer, but highly malignant cellular elements and account for 3.5–11% of osteosarcomatous cases.

Multifocal osteosarcoma

Affecting multiple bones significantly worsens the prognosis. It is rare, and detectable with whole-body bone scan or perhaps in the
future, whole-body MRI. Metachronous lesions occur years after the primary lesion and are differentiated from recurrence by occurring at a different site. Multifocal lesions are in different bones. It is not yet discernable whether multicentric osteosarcoma represents multiple de novo tumours or multiple bone metastases within a narrow time window from a solitary bone primary site.

Skip metastases which are seen in 10% of lesions, are detectable in the same bone at the same time, but can be at differing stages of local bony destruction.

Parosteal osteosarcoma

Low-grade lesion classically over the posterior aspect of the distal femur or the proximal humerus. Differentiated from a sessile osteochondroma in that the osteosarcoma is on the bone surface and not in uniform continuity with the cancellous bone of the metaphysis. Seen more commonly in the third or fourth decade and slightly more so in females, with radiographic features of ossification and lobulation. Can be confused with synovial osteochondromatosis or myositis ossificans. Depending on the extent of bone involvement treatment is either by shark-bite resection or wide excision. Chemotherapy is only instituted if high-grade or de-differentiated areas are found on histological analysis.

Periosteal osteosarcoma

Unlike the other groups this tends to occur in the diaphysis of the long bones and consists mainly of chondroblastic cells. Ninety-five per cent involve the distal femur or proximal tibial meta-diaphysis. It is usually of intermediate grade, and typically arises from the anteromedial bone portion.

Secondary osteosarcoma

Classically arises in 1% of patients with Paget’s disease. Its diagnosis can be expedited by appreciating that soft tissue extension, detectable on MRI, is the hallmark of malignant transformation. The advanced age of pagetoid patients makes chemotherapy less tolerable, significantly worsening the prognosis for these patients. Less than 5% of secondary osteosarcomas occur in irradiated bone.

Treatment and outcome

Chemotherapy and surgery form the mainstay of treatment. Limb salvage is usually possible in up to 80% of patients. Prior to the introduction of chemotherapy mortality from osteosarcoma was approximately 85%, even with radical resection or amputation. This is a representation of its propensity to micro metastasize early in its natural history. Chemotherapy kills the malignant cells and aims to improve patient survivorship and ultimately cure. Surgery compliments this by obtaining a margin negative resection, followed by bony and soft tissue reconstruction.

New chemotherapy protocols, with appropriate surgery, have produced an approximate 75% survival at 5 years. There is no difference in survival if chemotherapy is administered prior or post surgery. This is in accordance with the presence of non-detectable lung micro-metastases and the tumour cell’s response to chemotherapy being ultimately responsible for the patient prognosis. Common chemotherapeutic agents include cisplatin, doxorubicin, ifosfamide, and methotrexate. Immunostimulants, immunotherapy, cytotoxic T-cells, and monoclonal antibody therapy treatments are ongoing but have yet to yield a reproducible and consistent survival improvement.

Surgical resection aims to achieve a complete tumour resection with an appropriate margin, without tumour spillage or neurovascular damage that may render a salvaged limb functionless. If this is not possible, amputation is considered. It is not a ‘failure’ to amputate and just as much careful preoperative planning, operative attention to detail, and postoperative care is warranted as any limb salvage operation.

The major factors associated with a bad prognosis in osteosarcoma are a poor response to chemotherapy (less than 90% necrosis), skip or pulmonary metastases (stage), and the tumour grade. Other poor outcomes are associated with large tumours, axial/pelvic and central tumours, older patients, and tumours in pre-existing pathological tissues. Patient survivorship for conventional osteosarcoma remains at 75% at 5 years. Of the total number of recurrences, approximately 5% occur after 5 years. Follow-up protocols vary but most patients need to be reviewed every 3 months for the first 2 years, 6-monthly up to 5 years, and then yearly reviews can continue.

Box 2.6.2 Osteosarcoma

- Incidence is five per million population, and three per million in those less than 20 years
- Subdivided into intramedullary, cortical (either on or in), or arising in pre-existing pathology
- Chemotherapy and surgery form the mainstay of treatment
- Prognosis depends on response to chemotherapy (less than 90% necrosis), skip or pulmonary metastases (stage), and the tumour grade.

Ewing’s sarcoma (Box 2.6.3)

Ewing’s sarcoma is a cluster of tumours consisting of intra- and extraosseous Ewing’s sarcoma, primitive neuroectodermal tumour (PNET), Askin’s tumour (PNET of chest wall), peristeal Ewing’s, and neuroepithelioma. Cell origin is primarily neural. The tumour
is often aggressive but is usually chemo- and radiosensitive.

**Clinical presentation**

The incidence is approximately two per million, affects 5–20-year-olds and has an increased prevalence in Caucasians.

Ewing’s sarcoma can present with localized features of pain, mass, and pathological fracture, as well as systemic constitutional symptoms of fever, weight loss, or malaise. The long bones, pelvis, vertebrae, ribs, or clavicle are most commonly affected, with the femur, tibia, humerus, and fibula involved in decreasing frequency. Like osteosarcoma, approximately 20% of patients present with metastatic disease.

**Radiological features**

Classically there is laminated periosteal ‘onion-skinning’ in the diaphysis of a long bone in association with a permeative moth-eaten bony radiolucent lesion (Figure 2.6.4). These appearances are also very similar to infection and with the raised inflammatory markers, can cause a delay in reaching the correct diagnosis.

![Click to view larger](image)

**Fig. 2.6.4**

Typical radiographic appearance of Ewing’s sarcoma of the proximal humerus: A) anteroposterior and B) lateral radiographs.

MR describes extent of marrow infiltration, soft tissue extension, solid and necrotic tumour elements, cortical thickening, and periosteal reaction.

**Pathological features**

The absence of osteoid formation can produce liquid pus-like material on biopsy of the soft tissue component. Sheets of small, undifferentiated, round cells with prominent nuclei and poorly visualized cytoplasm make other lesions such as lymphoma, myeloma, histiocytosis, rhabdomyosarcoma, metastatic neuroblastoma, small-cell osteogenic sarcoma, and mesenchymal chondrosarcoma all possible diagnoses. The Ewing’s groups of tumours have a 95% sensitivity of surface expression of p30/32 MIC2 antigen and CD99. The t(11;22) translocation is found in 90% of patients. PNET is differentiated from Ewing’s both histologically by Homer Wright rosettes as well as positive staining of the neural S100 marker with PNET lesions.

**Treatment and outcome**

Local, multicentric, and metastatic Ewing’s sarcoma is treated with a combination of systemic (chemotherapy) and local (surgery with or without radiotherapy) therapies. Chemotherapeutic regimens include the use of actinomycin, cyclophosphamide, doxorubicin, etoposide, and ifosfamide. These have improved surivorship and have necessitated local control measures in the last 30 years. The treatment modality depends on the patient medical status, tumour location, and extent of spread.

Long bone lesions that can be resected safely are amenable to joint reconstruction. Pelvic lesions can present particular challenges, especially in the paediatric population. Open growth plates mean that resection with or without joint reconstruction can leave children with considerable pelvic girdle and lower limb deficits. Resection (or indeed complete hemipelvic disarticulation), extracorporeal radiotherapy, and re-implantation is possible given the radiosensitive nature of Ewing’s sarcoma. Re-implantation techniques are similar to allograft implantation. Viable tumour cells are ablated using radiotherapy leaving the remaining scaffold available for host bone recolonization.

The presence of disseminated disease remains the most important factor in predicting survival. Approximate 3-year survival rates in patients with lung metastases on presentation are 40%, 70% in isolated disease, and 30% with disseminated disease. Any survivorship figures need to be interpreted with caution. Clearly small appendicular tumours have a completely different prognosis to large axial tumours or those located within the pelvis. Follow-up between both oncologist and orthopaedic surgeon follows the same regimen as for osteosarcoma.

**Box 2.6.3 Ewing’s sarcoma**

- Incidence is approximately three per million, affects 5–20-year-olds and has an increased prevalence in Caucasians
- Classically radiographs show laminated periosteal ‘onion-skinning’ in the diaphysis of a long bone
- Treated with a combination of systemic (chemotherapy) and local (surgery with or without radiotherapy) therapies; generally chemo/radio sensitive
- Three-year survival rate in patients with lung metastases on presentation is 40%, 70% in isolated disease, and 30% with
disseminated disease.

Myeloma of bone (Box 2.6.4)

Myeloma of bone is of haematological origin and is managed primarily by haematological oncologists. Causes have been attributed to radiation exposure and a genetic predisposition. If isolated it is termed plasmacytoma or multiple myeloma if disseminated.

Lesions produce a neoplastic single clone proliferation of plasma cells that produce a monoclonal immunoglobulin. The orthopaedic team is involved in managing the plasma cell-induced osteolytic skeletal destruction and secondary bony structural failure. Other medical ramifications include hypercalcaemia, anaemia, renal failure, hyperviscosity syndrome, or recurrent bacterial infections.

Clinical presentation

With an incidence of four per 100,000 per year, multiple myeloma is the most common primary bone tumour in adults. It is primarily a disease of patients after their fourth decade, with the median incidence at age 65. It is more common in black patients presenting with fever, pain, or weakness. It can be asymptomatic. Additional orthopaedic presenting complaints include axial, thoracic, or appendicular limb pain as well as secondary effects such as spinal cord compression or pathological fracture.

Extramedullary plasmacytoma presents as a soft tissue mass.

Normocytic, normochromic anaemia is found at diagnosis in approximately 70% of patients. Leucopenia and thrombocytopenia are less common. Erythrocyte sedimentation rate is often raised. Urinary Bence Jones protein and an aberrant serum paraprotein (or M-protein) is found in 90% of patients at presentation. Plasma electrophoresis enables quantitative measurement to secure a diagnosis and disease monitoring.

Differential diagnoses include metastatic carcinoma, lymphoma, monoclonal gammopathy of unknown significance (MGUS), smouldering multiple myeloma (SMM), acute leukaemia, or POEMS (Polyneuropathy, Organomegaly, Endocrinopathy, M-protein, Skin anomalies) syndrome.

Minimal diagnostic criteria consist of more than 10% plasma cells in bone or a plasmacytoma plus one of serum or urine paraprotein or lytic bone lesions. The International Myeloma Working Group has staged the disease using B2 microglobulin (MHC class I) levels as it is an overall marker for body tumour burden. Stage I is classified as a level less than 3.5mg/L, II lies between 3.5–5.5mg/L, and stage III more than 5.5mg/L.

Radiological features

Plain film evaluation demonstrates punched-out lytic lesions or fractures in 75% of patients at diagnosis (Figure 2.6.5). Technetium-99m-labelled bone scans are usually cold hence conventional radiographs are used for the detection of lytic lesions with no surrounding sclerosis. The lateral skull is classic for the ‘pepper-pot’ appearance. CT and MRI are more sensitive and may be useful when skeletal pain is atypical and radiographs show no abnormalities.

Pathological features

Histological analysis reveals large basophilic cytoplasmic plasma cells containing rounded or oval eccentric nuclei with clumped chromatin and a perinuclear halo.

Treatment and outcome

Most patients with focal plasmacytoma undergo surgery if feasible, radiation, and subsequent observation. Multiple myeloma presents challenges at multiple levels and care is targeted on disease control and suppression, the extent of which depends on the disease progression and patient status. The anaemia is managed with erythropoietin and bony destruction slowed by bisphosphonates.

Asymptomatic patients with low B2 microglobulin levels are observed. Symptomatic patients receive chemotherapy and haematopoietic stem-cell transplantation.
Orthopaedic input is usually at the pre-, impending, or postfracture stage. Fracture union in the presence of pathological bone proceeds at varying rates in comparison to normal bone. Long, locked intramedullary nails form the mainstay of operative treatment.

Depending on the stage, median survival is 62 months for stage 1, 45 months for stage 2, and 29 months for stage 3 disease. Follow-up is with haematologists with a low threshold for orthopaedic consultation.

**Box 2.6.4 Myeloma of bone**

- Neoplasm of haematological origin
- Plasmacytoma if isolated or multiple myeloma if disseminated
- Plain films demonstrate punched-out lytic lesions or fractures in 75% of patients at diagnosis
- Patients managed by haematologists; orthopaedic input is usually at the pre-, impending, or post-pathological fracture stage.

**Fibrosarcoma of bone or soft tissue (Box 2.6.5)**

Fibrosarcoma is a tumour of mesenchymal cell origin that is composed of malignant fibroblasts in a collagen background. It can occur as a soft tissue mass or as a primary or secondary bone tumour. Fibrosarcoma was diagnosed much more frequently in the past; it is now more reliably distinguished histologically from similar lesions, such as desmoid tumours, malignant fibrous histiocytoma, malignant schwannoma, and high-grade osteosarcoma.

The two main types of fibrosarcoma of bone are primary and secondary. Primary fibrosarcoma is a fibroblastic malignancy that produces variable amounts of collagen. It is either central (arising within the medullary canal) or peripheral (arising from the periosteum). Secondary fibrosarcoma of bone arises from a pre-existing lesion or after radiotherapy to an area of bone or soft tissue. This is a more aggressive tumour and has a poorer prognosis.

**Clinical presentation**

Fibrosarcoma represents 10% of musculoskeletal sarcomas and less than 5% of all primary bone sarcomas.

Fibrosarcoma of bone usually affects the metaphysis of long bones in patients over 50 years of age. Presenting features include pain, mass effect, decreased range of movement, and fracture. Pre-existing pathological lesions or irradiated tissue needs to be considered with increased suspicion.

Fibrosarcoma of the soft tissues usually affects a wider age spectrum of patients than fibrosarcoma of the bone does, with an age range of 35–55 years. It often arises in the soft tissues of the thigh and the posterior knee. It is generally a large, painless mass deep to fascia and has an ill-defined margin.

**Radiological features**

Typically, an osteolytic, metaphyseal, eccentrically placed lesion associated with cortical destruction and soft tissue extension, with a marked absence of ossification or mineralization. MRI is the best modality for examining soft tissue masses and providing information about the local extent, lesion size, and involvement of the neurovascular structures. Fibrosarcoma of bone typically has extrasosseous extension (Figure 2.6.6).

![Fig. 2.6.6](https://example.com/fibrosarcoma.png)

Fibrosarcoma of the distal femur. A) Anteroposterior and B) lateral plain radiographs showing destructive lesion. A CT scan of
Fibrosarcoma of the distal femur. A) Anteroposterior and B) lateral plain radiographs showing destructive lesion. A CT scan of the same patient (C) demonstrates that the tumour has broken through the cortex to form a soft tissue mass. Gross pathological specimen of the tumour (D).

Pathological features

Well-differentiated forms have multiple plump fibroblasts with deeply staining nuclei in a rich collagen background. Intermediate-grade tumours have the typical herringbone pattern, showing the diagnostic parallel sheets of cells arranged in intertwining whorls. A slight degree of cellular pleomorphism exists.

High-grade lesions are very cellular, with marked cellular atypia and mitotic activity. The degree of cellularity, nuclear atypia, and pleomorphism are used to classify fibrosarcoma into grades 1–3. The higher grade 3 lesions are deemed to be malignant fibrous histiocytomas. In fact, some pathologists believe that the division between malignant fibrous histiocytoma, high-grade osteosarcoma, and fibrosarcoma may be artificial.

Treatment and outcome

Grade 1 lesions are managed operatively without chemotherapy. Grade 2 lesions involve chemotherapy and resection. Grade 3 lesions follow malignant fibrous histiocytoma/osteosarcoma regimens. Radiation is administered in palliative cases and incomplete resections.

If all grades are included, primary fibrosarcoma of the bone has a worse prognosis than osteosarcoma, with a 5-year survival rate of 65%. In high-grade primary fibrosarcoma, the 10-year survival rate is less than 30%. Secondary fibrosarcoma is associated with a very poor outcome, the survival rate at 10 years being less than 10%.

For congenital fibrosarcoma of bone in children, the prognosis (which is related to age and to time to diagnosis) is much better, with the disease having long-term survival rates of greater than 50%.

Soft tissue fibrosarcoma is associated with a 40–60% survival rate at 5 years. The infantile form has an even better 5-year survival rate, in excess of 80%.

Primary lymphoma of bone (PLB) is a rare, malignant, neoplastic disorder of the skeleton. The vast majority of them are non-Hodgkin lymphoma (NHL), whereas primary Hodgkin lymphoma (HL) of bone is extremely rare.

Primary lymphomas of bone are uncommon malignancies (approximately 5% of primary malignant bone tumours and 5% of all cases of extra-nodal NHL). Comprehensive immunohistochemical studies are required to establish an accurate histological diagnosis of primary NHL of bone. Most cases of primary NHL of bone are classified as diffuse large B-cell lymphomas (DLBCL) in the World Health Organization (WHO) classification of haematological malignancies.

Clinical presentation

There is a marginal male preponderance. The incidence of disease is distributed fairly evenly in the second through to the eighth decades. Primary NHL of bone can arise in any part of the skeleton, but long bones (femurs, tibia) are the most common sites to be affected.

Patients with primary NHL of bone commonly present with local bone pain, soft tissue swelling, a mass, or a pathological fracture. Prolonged pain is the usual clinical symptom.

The WHO recognizes the following four groups of lymphoma involving bone:

1) A single primary bone site with or without regional nodes
2) Multiple bone sites but no visceral involvement
3) A bone lesion and involvement of multiple lymph node sites
4) Soft tissue lymphoma, with bone involvement detected by bone biopsy or marrow aspirate.

Groups 3 and 4 would most likely represent metastatic involvement of bone.

Radiological presentation

PLB tumours produce osteoclast-stimulating factors that cause lytic bone destruction (Figure 2.6.7). The most common
radiographic features include:
- Permeative, lytic pattern of bone destruction (74%)
- Metadiaphyseal location (69%)
- Periosteal reaction (58%)
- Soft tissue mass (80–100%).

Sequestrum formation is a feature of PLB that can help to differentiate it from most other diagnostic possibilities. Sequestra have been reported in 11–16% of patients with PLB. Finally, involvement of adjacent bones is seen in 4% of cases.

After biopsy of the bone lesion confirms the diagnosis of lymphoma, CT scanning of the chest, abdomen, and pelvis is needed to exclude distant spread. The CT scan may be combined with positron emission tomography (PET), which is emerging as a possible modality for initial staging and follow-up. Technetium-99m ($^{99m}$Tc) bone scintigraphy also can be used to look for additional sites of involvement.

Pathological features
The clinical features and radiological findings of PLB are usually non-specific, with the diagnosis relying principally on tissue histology.

The Rappaport classification system (1956) was based on light microscopic appearance. The Ann Arbor staging system, developed initially for HL, has been widely applied to the NHLs. This staging system is based on anatomic location and does not involve histology. Due to the advances of immunohistochemical markers there are now a myriad of new classification systems.

Treatment and outcome
Treatment for PLB often involves radiation therapy to control the tumour in the affected bone. In certain instances, surgical intervention for control of the primary bone lesion may be desirable or necessary. Several studies indicate that patients with primary NHL of bone have a favourable outcome, especially when treated by combined modality therapy.

Combined modality therapy includes a method of local control, usually radiation therapy, and a systemic treatment, usually combination chemotherapy. Recurrence at the initial primary site is uncommon. Late, distant soft tissue metastases to lung, liver, and brain account for most of the mortality and much of the morbidity.

Average survival is 19–27 months for low-grade lymphoma and less than 11 months for high-grade tumours.

Malignant vascular tumours of bone (Box 2.6.7)
Malignant vascular tumours are rare. Three variants of malignant vascular tumours of bone are commonly described: haemangioendothelioma (angiosarcoma), haemangiopericytoma, and epithelioid haemangioendothelioma.

Haemangioendothelioma/angiosarcoma
An uncommon malignant neoplasm characterized by rapidly proliferating, extensively infiltrating anaplastic cells derived from blood vessels and lining irregular blood-filled spaces. The term angiosarcoma may be applied to a wide range of malignant endothelial vascular neoplasms affecting a variety of sites. Angiosarcomas are aggressive and tend to recur locally, spread widely, and have a high rate of lymph node and systemic metastases. The rate of tumour-related death is high.

Box 2.6.6 Primary lymphoma of bone
- Most primary lymphomas of bone are B cell neoplasms (diffuse large B-cell lymphomas (DLBCL))
- Radiographic features include a permeative, lytic pattern of bone destruction
Combined modality therapy includes a method of local control, usually radiation therapy, and a systemic treatment, usually combination chemotherapy.

Clinical presentation
Bone angiosarcomas appear most often in adults (second to seventh decades of life). Bone and soft tissue angiosarcoma are also reported to be more frequent in males. Thirty-three per cent affect the axial skeleton, 33% in long bones, and the rest in the small bones of the hands and feet.

These tumours can be multifocal, or multicentric, involving multiple bones of the same extremity. Pain is commonplace. Presentation features include:

- Pathologic fractures (10%)
- Other intrinsic characteristics of a malignant vascular proliferation (e.g., bleeding, thrombocytopenia, or intravascular disseminated coagulation)
- Compression of adjacent neurovascular structures which leads to pain.

Radiological presentation
A solitary lesion (60% of cases) presents as a destructive lytic mass with irregular borders or a mixed lytic–sclerotic pattern and occasional bony expansion. It has a distinctive pattern of soap-bubble lesions because it frequently extends up and down the bone. CT scan is helpful in illustrating the permeative, invasive character of the radiographic lesions and shows their multiplicity.

Pathological features
The main problem in the diagnosis of angiosarcoma is histopathological recognition. Microscopic findings include the presence of vascular spaces which are lined by atypical endothelial cells, with significantly increased numbers. Higher-grade lesions are more cellular and abnormal mitoses.

Treatment and outcome
Surgical resection and radiation therapy are the standard treatment for localized disease. Treat high-grade lesions as malignant bone neoplasms, with a combination of radical en bloc excision followed by radiotherapy and/or chemotherapy.

All angiosarcomas tend to be clinically aggressive, difficult to treat, and are often multicentric. They have a high local recurrence rate and metastatic potential. They are often misdiagnosed, leading to a poor prognosis and a high mortality rate. The reported 5-year survival rate is around 20%.

Haemangiopericytoma
Haemangiopericytomas are rare, typically low-grade sarcomas.

As with angiosarcomas the aetiology of haemangiopericytomas is largely unknown; they have been reported secondary to radiation, chemical exposure, and, rarely, burns or scars.

Haemangiopericytoma is a malignant tumour of mesenchymal origin that occurs in the extremities. Tumour typically spreads via haematogenous dissemination, primarily to the lungs. Metastatic disease is usually the cause of death.

Clinical presentation
Haemangiopericytomas primarily manifest as slow-growing, painless masses in the extremities, commonly the femur and proximal tibia. They can also occur in the pelvic fossa and the retroperitoneum.

Most documented cases occur within the third to fifth decades. They have been documented in children.

Additionally, 35% of skeletal tumours with oncogenic osteomalacia have been reported to be haemangiopericytomas. Oncogenic osteomalacia occurs with bone or soft tissue tumours and refers to the musculoskeletal symptoms of cramping and diffuse bone and muscle pain associated with electrolyte abnormalities, most notably hypophosphatemia.

Radiological features
With plain radiography, bony lesions predominantly present as intramedullary lytic masses. They may be well circumscribed, with a periosteal reaction or sclerotic border. They also may display cortical destruction, producing indeterminate borders with a honeycomb appearance. Findings of soft tissue haemangiopericytomas on plain films are usually non-specific. Bone scanning is indicated to exclude other sites of disease in patients who present with a bony haemangiopericytoma. MRI ± angiography should be used to distinguish between vascular malformations and tumours.

Pathological features
Haemangiopericytomas are neoplasms of pericytes that form solid sheets and nests around irregularly formed vascular channels. The vascular lining is normal and is composed of a single layer of non-malignant endothelial cells. Pericytes are of mesenchymal
derivation and partially surround the endothelial cells of capillaries and small venules to assist blood flow regulation. These cells are located outside the connective-tissue compartment and are surrounded by their own basal lamina.

A diagnosis of haemangiopericytoma is made solely on the basis of architectural patterns exhibited histologically. Thus this type of tumour cannot be accurately distinguished from other neoplasms that have vascular characteristics, without such detailed histological information. The diagnosis of this tumour and evaluation of its clinical course remain complex challenges for tumour surgeons and histopathologists.

Box 2.6.7 Malignant vascular tumours of bone

- Three variants are commonly described: haemangioendothelioma (angiosarcoma), haemangiopericytoma, and epithelioid haemangioendothelioma of bone
- Aggressive lesions tend to recur locally, spread widely, and have a high rate of lymph node and systemic metastases
- Need aggressive surgical excision + adjuvant treatment (radiotherapy).

Treatment and outcome

Treatment of haemangiopericytomas is based on the grade of the sarcoma.

Low-grade bone tumours require surgical resection and are not usually treated with chemotherapy. High-grade bone tumours may be treated with chemotherapy, but because of the rarity of these tumours, the direct benefit of treatment is unknown.

Soft tissue haemangiopericytomas are treated with surgical resection and radiation therapy to decrease local recurrence.

Epithelioid haemangioendothelioma

A low- to intermediate-grade vascular tumour composed of epithelioid endothelial cells. Epithelioid haemangioendothelioma is an extremely rare vascular bone tumour with a slow growth and poor prognosis. It represents 1% of all vascular neoplasms and is locally aggressive. Other proposed terms have included 'sclerosing angiogenic tumour'.

Summary points

- Metastatic pathological fractures rarely unite, even if stabilized
- Never rush to fix a pathological fracture; traction or splintage will suffice while investigations are performed and surgical intervention discussed
- When surgery is indicated for spinal metastases, both decompression and stabilization are generally required
- Implants should allow immediate weight-bearing and last the lifetime of the patient
- Always use a multidisciplinary team.

Introduction

Bone is the commonest site for metastasis in cancer and is of particular clinical importance in breast and prostate cancers because of the prevalence of these diseases. At postmortem examination, 70% of these patients have evidence of metastatic bone disease. However, bone metastases may complicate a wide range of malignancies, resulting in considerable morbidity and complex demands on healthcare resources. Carcinomas of the thyroid, kidney, and bronchus also commonly give rise to bone metastases, with an incidence at postmortem examination of 30–40%. However, tumours of the gastrointestinal tract rarely (less than 10%) produce bone metastases.

Clinical presentation (Box 2.7.1)

This is typically in one of three modes:

- Acute admission with pathological fracture or neurological compromise
- Referral to clinic with unexplained musculoskeletal pain
- Referral from oncologist/breast care team (surgeon, radiologist, or oncologist).

Pain

Bone metastases are the most common cause of cancer-related pain. The pathophysiological mechanisms of pain in patients with bone metastases are poorly understood but probably include tumour-induced osteolysis, tumour production of growth factors and cytokines, direct infiltration of nerves, stimulation of ion channels, and local tissue production of endothelins and nerve growth factors. Although 80% of patients with advanced breast cancer develop osteolytic bone metastases, approximately two-thirds of such sites are painless.

Different sites of bone metastases are associated with distinct clinical pain syndromes. Common sites of metastatic involvement associated with pain are the base of the skull (in association with cranial nerve palsies, neuralgias, and headache), vertebral metastases (producing neck and back pain with or without neurologic complications secondary to epidural extension), and pelvic and femoral lesions (producing pain in the back and lower limbs, often associated with mechanical instability).

Hypercalcaemia

Hypercalcaemia most often occurs in those patients with squamous cell lung cancer, breast and kidney cancers, and certain haematological malignancies (in particular myeloma and lymphoma). In most cases, hypercalcaemia is a result of bone destruction, and osteolytic metastases are present in 80% of cases.

Secretion of humoral and paracrine factors by tumour cells stimulates osteoclast activity and proliferation, and there is a marked increase in markers of bone turnover. Several studies have established the role of parathyroid hormone-related peptide in most cases of malignant hypercalcaemia.

The signs and symptoms of hypercalcaemia are non-specific, and the clinician should have a high index of suspicion. Common symptoms include fatigue, anorexia, and constipation. If untreated, a progressive increase in serum calcium level results in deterioration of renal function and mental status. Death ultimately results from renal failure and cardiac arrhythmias.

Pathological fractures

The destruction of bone by metastatic disease reduces its load-bearing capabilities and results initially in microfractures, which cause pain. Subsequently, fractures occur (most commonly in ribs and vertebrae). It is the fracture of a long bone or the epidural extension of tumour into the spine that causes the greatest disability.

Compression of the spinal cord or cauda equina
Spinal cord compression is a medical emergency, and suspected cases require urgent evaluation and treatment. Pain occurs in most patients, is localized to the area overlying the tumour, and often worsens with activities that increase intradural pressure (e.g. coughing, sneezing, or straining). The pain is usually worse at night, which is the opposite pattern of pain from degenerative disease. There may also be radicular pain radiating down a limb or around the chest or upper abdomen. Local pain usually precedes radicular pain and may predate the appearance of other neurologic signs by weeks or months. Most patients with spinal cord compression will have weakness or paralysis. Late sensory changes include numbness and anaesthesia distal to the level of involvement. Urinary retention, incontinence, and impotence are usually late manifestations of cord compression. However, lesions at the level of the conus medullaris can present with early autonomic dysfunction of the bladder, rectum, and genitalia.

**Spinal instability**

Back pain is a frequent symptom in patients with advanced cancer and in 10% of cases is due to spinal instability. The pain, which can be severe, is mechanical in origin, and frequently patients are only comfortable when lying still.

### Surgical management of metastatic bone disease (Box 2.7.2)

The role of the orthopaedic surgeon in the management of metastatic bone disease, always part of a multidisciplinary team, falls into three principal categories (British Orthopaedic Association Guidelines):

1. Prophylactic fixation of metastatic deposits where there is a risk of fracture
2. Stabilization or reconstruction following pathological fracture
3. Decompression of spinal cord and nerve roots and/or stabilization for spinal instability.

Any surgical procedure should provide immediate stability, allowing weight bearing and as a general rule the fixation should aim to last the lifetime of the patient. The surgeon must assume that the fracture may not unite and should aim to stabilize all lesions in the affected bone. Furthermore, if there is the slightest doubt as to the underlying pathology, and in particular where there is a solitary bony lesion, then further investigations including scintigraphy, magnetic resonance imaging scan of the lesion, and percutaneous bone biopsy should be carried out before definitive surgery. This allows the detection of primary bone neoplasms or solitary renal metastases (these have good prognosis and should be treated like primary bone tumours).

**Box 2.7.1 Modes of clinical presentation—summary**

- Musculoskeletal pain
- Pathological fractures
- Neurological complications (cauda equina compression/spinal instability)
- Fatigue, anorexia, constipation secondary to hypercalcaemia.

### Fracture risk assessment

Where fracture is likely to occur, then prophylactic fixation should be performed prior to the administration of radiotherapy. It is essential, therefore, to have a reliable method of predicting the risk of a pathological fracture occurring.

In an effort to provide a reliable and reproducible measure of the risk of pathological fracture, Mirels devised a scoring system which is a useful aid to fracture risk assessment (Table 2.7.1). For scores of eight or above, the risk of fracture is high and prophylactic fixation should be carried out prior to radiotherapy being administered.

#### Table 2.7.1 Mirels’ scoring system for metastatic bone disease

<table>
<thead>
<tr>
<th>Score</th>
<th>1</th>

<td>&lt;1/3</td>
<td>1/3–2/3</td>
<td>&gt;2/3</td>
</tr>
</tbody>
</table>

Maximum possible score is 12; if lesion scores 8 or above, then prophylactic fixation is recommended prior to radiotherapy.

### Hip

Where destruction is limited to the femoral neck or head, a cemented hemiarthroplasty or total joint replacement is recommended as a primary procedure. Long stem femoral implants should be considered. Subtrochanteric fractures or lesions with limited bone loss are best stabilized by ‘reconstruction’ nails with locking screws up the femoral neck (Figure 2.7.1). This greatly reduces the
risk of subsequent femoral neck fracture.

Fig. 2.7.1
Asteroposterior views of right proximal femur (A) showing extensive metastatic destruction of subtrochanteric region and (B) after internal fixation with an intramedullary reconstruction nail.

Pelvis and acetabulum

The majority of pelvic lesions are treated with prophylactic palliative radiotherapy alone. However, acetabular reconstruction with pins and cement can be carried out where there is an imminent risk of failure of the socket.

Shoulder girdle and upper limb

Metastatic lesions or fractures of the scapula and clavicle are usually managed with radiotherapy alone. In the humeral head, significant destruction is, in most cases, best treated by hemiarthroplasty.

Shafts of major long bones (humerus, femur, tibia)

Intramedullary nailing is the procedure of choice with locking screws to give rotational stability and to prevent telescoping (Figure 2.7.2). Apart from the case of solitary renal metastases, the potential spread of tumour cells within the medulla by nailing is acceptable within the context of palliative treatment. The entire bone and operative site should be included in the postoperative radiotherapy field. Since these fractures are unlikely to unite, load-bearing, rather than load-sharing, devices should be used, and solid nails, of a greater diameter than may be used for purely traumatic fractures, may be considered. Packing of major bone defects with methylmethacrylate bone cement is useful in maintaining stability in some cases. All of the lesions in the affected bone should be stabilized to minimize the risk of further surgery being required. Reconstruction nails, stabilizing the femoral neck, are recommended in the femur.

Endoprosthetic surgery

Fig. 2.7.2
(A) Anteroposterior view of the left humerus showing interlocking intramedullary nail fixation for metastatic disease. (B) Intramedullary nail fixation for metastatic lesion of the proximal tibia (cement was also used).
Extensive bone destruction at the metaphyses of major long bones is sometimes so great that reconstruction can only be achieved using custom or modular endoprostheses (Figure 2.7.3). However, major surgery such as this has to be balanced against the likely timeframe of survival of the patient.

---

**Adjuvant therapy**

Radiotherapy is generally palliative, and often given as a single fraction. It can produce effective bone healing and sclerosis and, when given prophylactically, can prevent pathological fracture occurring. It will not, however, cure pain of a ‘mechanical’ nature, and only 30–40% of pathological fractures will unite even after radiotherapy. It is recommended that following nailing or other surgical procedures in patients with metastatic bone disease, radiotherapy to the affected bone and operative field (unless field sizes are excessive) should be considered by the appropriate specialist within the context of the multidisciplinary team. The spinal cord is radiosensitive, and this may limit the scope for adjuvant treatment of the axial skeleton.

Endocrine therapy, bisphosphonates, and chemotherapy may all have a role in the management of patients with metastatic bone disease.

---

**Box 2.7.2 Surgical management of metastatic bone disease—summary**

- Prophylactic fixation of metastatic deposits when there is a risk of fracture
- Stabilization or reconstruction following pathological fracture
- Decompression of spinal cord and nerve roots and/or stabilization for spinal instability
- Use Mirels’ scoring system for fracture risk assessment.

---

**Treatment for spinal metastatic bone disease**

Over the last two decades there has been considerable improvement in the implants available to manage structural deficiency of the spine, notably pedicle screws, cages, and plating or rodding systems. The objectives of surgery are:

- Maintenance of, or restoration of, spinal cord/nerve root function
- Preservation of, or restoration of, spinal stability
- Preservation of as many normal motion segments as possible.

Treatment of spinal metastatic disease may involve radiotherapy ± surgery:

**Indications for radiotherapy**

- No spinal instability
- Radiosensitive tumour
- Stable or slowly progressive neurology
- Multilevel disease
• Surgery precluded by general condition
• Poor prognosis
• Postoperative adjuvant treatment.

Indications for surgery

• Spinal instability evidenced by pathological fracture, progressive deformity, and/or neurological deficit
• Clinically significant neurological compression, especially by bone
• Tumour insensitive to radiotherapy, chemotherapy, or hormonal manipulation.

Conclusion

The prognosis for patients with metastatic bone disease is steadily improving. The orthopaedic surgeon should never assume that a lytic lesion, particularly if solitary, is a metastasis and appropriate tests should always be done to exclude a primary bone neoplasm. Management of metastatic bone disease should always be done in the context of a multidisciplinary team.

Cervical spine disorders

Summary points

♦ Degenerative cervical spine disorders may manifest clinically with axial neck pain, radiculopathy, myelopathy, or a combination of these clinical symptoms
♦ The findings on radiographs and MRI are pertinent if they correlate with the clinical symptoms
♦ The initial treatment for patients with degenerative cervical spine disorders is conservative, including non-narcotic analgesics, anti-inflammatory medications, exercise program, physiotherapy, and occasional injections
♦ Surgical indications include significant radicular pain despite conservative treatment, profound neurologic deficits, and presence of significant myelopathy
♦ Surgical treatment for cervical radiculopathy includes laminoforaminotomy, anterior cervical discectomy and fusion (ACDF), and artificial disk replacement, and surgical treatment for myelopathy includes anterior discectomy and/or corpectomy with fusion, posterior laminoplasty, and posterior laminectomy and fusion. The surgeon should be familiar with the specific indications as well as advantages and disadvantages of each procedure.

Introduction

Degenerative disorders of the cervical spine may present as any combination of neck pain, radiculopathy, or myelopathy. A careful history and physical examination is essential, as each diagnosis requires different treatment options and prognoses. This includes proper interpretation of patients’ complaints, a thorough physical examination, and an appropriate selection and review of diagnostic tests. In addition, various other aetiologies such as neoplastic, infectious, and inflammatory processes must be considered. This chapter will describe the history, physical examination, and treatment for degenerative disorders of the cervical spine.

History and physical exam

A patient presenting with degenerative cervical disc disease typically presents with axial neck pain, radicular symptoms, myelopathic symptoms, or a combination of any of these. Patients with axial neck pain may present with pain referred to the shoulder, upper arm, or interscapular area (Figure 3.1.1) and, if so, these symptoms should not be confused with radicular symptoms associated with nerve root involvement. These patients may also complain of neck stiffness, muscle spasm, or headache. Upper cervical radiculopathy involving the C3 or C4 nerve root may be confused with axial neck pain, as the pain is typically in the neck and the trapezius muscle. Occipitocervical pain, particularly with neck rotation in elderly patients, may be a sign of degenerative atlanto-occipital or atlanto-axial joint pain.

Fig. 3.1.1
A composite map of pain distribution from zygapophyseal joint injections. (Reproduced from Dwyer et al. (1990).)

In the setting of degenerative disease, radicular symptoms may be caused by a herniated disc, chronic disc degeneration with osteophyte formation, or instability within the spinal motion segment. While most patients will present with signs and symptoms consistent with involvement of a single nerve root, multiple roots are occasionally involved. Paresthesias generally develop in the early stages of compression. As the inflammatory process continues, radicular pain follows. Pain is typically exacerbated with
Valsalva manoeuvres, neck extension, and when rotating the head toward the symptomatic side. Reproduction of pain with hyperextension and lateral rotation toward the symptomatic side is diagnostic and referred to as a positive Spurling’s sign (Figure 3.1.2). This decreases the size of the intervertebral foramen, further impinging the involved nerve root. This can also be accomplished with axial compression, but the latter is less reliable. An additional reliable indicator of cervical radiculopathy is the shoulder abduction relief sign, in which the ipsilateral shoulder is abducted, relieving the tension of the affected nerve root. A positive finding corresponds to the relief of the radicular symptoms. Similarly, axial traction of the neck may relieve radicular symptoms, also by increasing the dimension of the neural foramina.

Fig. 3.1.2
Spurling’s sign is positive if the arm symptoms are reproduced by hyperextension and lateral rotation toward the symptomatic side.

Each cervical nerve root has its own characteristic pain distribution and motor deficits (Figures 3.1.3–3.1.7). Compression of C3 or C4 will manifest with pain about the posterior neck, occiput, and over the trapezius muscle and shoulder. Occasionally, C4 radiculopathy is referred down the anterior superior chest. C5 radiculopathy typically radiates down over the shoulder to the lateral aspect of the proximal arm. Patients will complain of fatigue or frank weakness in shoulder abduction and overhead activities, as the deltoid is almost purely innervated by the C5 nerve root (while the biceps has dual innervation from both C5 and C6). The biceps reflex primarily indicates C5 pathology. C6 radiculopathy involves neck pain radiating across the biceps, anterior arm, the radial aspect of the forearm, and the dorsum of the thumb and index finger. Weakness affects the biceps and/or wrist extensors. The extensor carpi radialis longus and brevis are innervated by C8, while the extensor carpi ulnaris is primarily innervated by C7. Therefore wrist extensor weakness may reflect either C6 or C7 pathology. The brachioradialis reflex is most directly affected by C6 compression. C7 radiculopathy is associated with pain along the posterior shoulder and arm, posterolateral forearm, and the middle finger. However, involvement of the index and ring fingers, as well as the first web space, can also be seen. The triceps muscle is most commonly affected, resulting in weakness and a diminished reflex. Unlike shoulder weakness, however, weakness of the triceps muscle is an infrequent complaint, unless the patient uses the muscle repetitively. Patients with C8 radiculopathy describe pain along the ulnar border of the arm and forearm to the small finger, often involving the ulnar half of the ring finger. Motor deficits may be noted with abduction, adduction, and flexion of the fingers. Intrinsic muscle atrophy of the hand is frequently seen in chronic cases.

Fig. 3.1.3
Dermatomal distribution in the neck and the upper extremity.
C8 radiculopathy.

The symptoms of cervical myelopathy may include gait difficulties, decreased manual dexterity, paresthesias, urinary urgency or frequency, spasticity, or weakness. In contrast to cervical or lumbar radiculopathy, pain is not a common presenting symptom. The gait disturbance is an early presenting complaint and the symptoms are usually insidious and slowly progressive. The characteristic stooped wide-based gait of the elderly is a common end result. Complaints involving clumsy or numb hands suggest upper extremity involvement, which may occur concurrently with, or follow, gait changes. Manual dexterity deficiencies will often silently progress until the patients are surprised at the lack of their ability to complete routine activities of daily living. Hand weakness may also be present, which typically manifests as decreased grip strength. Patients may have coexistent cervical and/or lumbar stenosis, in which case the clinical presentation may manifest as both upper and lower motor neuron lesions.

There are multiple physical examination findings consistent with cervical myelopathy. The finger escape sign is tested by asking the patient to hold all digits of the hand in an adducted and extended position. A positive finding is elicited when the two ulnar digits fall into flexion and abduction within 30s. In the grip and release test, the patient is asked to form a fist and then release all digits into extension, then to rapidly repeat the sequence. If the patient is unable to perform this motion 20 times within a 10-s period, the test is positive. To perform the Oppenheim test, a sharp object is run along the crest of the tibia. Extension of the great toe is a positive finding. The Babinski sign is a specific indicator of cord compression and is also positive when the great toe extends. It is elicited by running a sharp object distally along the lateral border of the plantar aspect of the foot and medially across the metatarsal heads. A Hoffmann reflex is strongly indicative of cervical cord impingement. It is present when the fingers and thumb flex in response to rapid extension of the distal interphalangeal joint of the long finger. Patients with spinal cord compression at C8 may exhibit the inverted radial reflex where, by tapping the distal brachioradialis tendon, a diminished reflex is elicited with a reciprocal contraction of the finger flexors (Figure 3.1.8). L’Hermitte’s sign refers to the perception of a generalized electric shock involving the upper and lower extremities as well as the trunk with flexion of the neck (Figure 3.1.9). The scapulohumeral, or Shimizu, reflex is a very sensitive test which is elicited by tapping the tip of the spine of the scapula. The test is positive if there is brisk scapular elevation with abduction of the humerus. Finally, clonus may appear several weeks following cord compression. A positive test is defined as more than two repetitive beats during sudden wrist or ankle dorsiflexion.

**Diagnostic tests**

Patients with symptomatology relating to their cervical spine are often initially sent for plain radiographic evaluation. However,
Degenerative changes are exceedingly common in the aging population and are very non-specific. Plain cervical radiography is therefore more useful in ruling out more threatening diagnoses such as neoplasm, or traumatic situations that might result in axial, coronal, or sagittal malalignment.

Magnetic resonance imaging (MRI) is the test of choice for patients with radiculopathy or myelopathy, as both the sensitivity and specificity are high. Readily demonstrated is cervical stenosis and secondary soft tissue abnormalities such as disc herniations, ligamentum flavum hypertrophy, facet hypertrophy, or other less common causes. It should be noted that there is MRI evidence of nerve root compression in as many as 19% of asymptomatic individuals, therefore radiographic abnormalities must be correlated with the patient’s history and physical exam findings. In patients with long-standing cervical myelopathy, MRI may also reveal intrinsic cord pathology such as atrophy or oedema. Limitations of MRI are difficulty in distinguishing soft tissue versus bone as in ossification of the posterior longitudinal ligament (OPLL) and less accurate assessment of bony foraminal stenosis.

Computed tomography (CT) is also a non-invasive study and is better at demonstrating bony abnormalities, as cortical margins are much more distinct than those seen with MRI. Therefore, stenosis secondary to osteophytes, hypertrophy of the uncovertebral joints, or hypertrophy of the zygoapophyseal joints are readily demonstrated with CT imaging. While axial images are helpful, 45-degree oblique reconstruction views will better assess the foramina and bony foraminal stenosis. CT myelography is an invasive study that precisely demonstrates the degree of spinal cord deformation and mechanical blocks to the flow of cerebrospinal fluid. A filling defect of myelographic dye on an oblique projection is a typical finding of nerve root compression (Figure 3.1.10). The combination of MRI and CT gives accurate imaging of bone and soft tissue landmarks and makes myelography rarely needed clinically.

**Natural history**

The natural history of axial neck pain without neurological involvement is generally favourable and surgical intervention is not thought to result in better outcomes than conservative treatment measures. Non-operative treatment in patients with isolated neck pain is therefore recommended. The natural history of cervical radiculopathy was elucidated in a classic study published in 1963 by Lees and Turner. They conservatively followed 51 patients that initially presented with radicular pain. Of the ten patients with 10–19-year follow-up, three had only a single pain episode and no recurrence of symptoms, while three continued to have persistent mild symptoms. Only four were found to have more troublesome symptoms. No patients went on to develop myelopathic symptoms. These findings support the practice of initial conservative treatment in patients presenting with radiculopathy. The natural history of cervical myelopathy is highly variable. Some patients have a protracted course with only mild symptoms, while others go on to develop progressive disability.

**Treatment options**

As mentioned previously, patients with axial neck pain and/or radicular symptoms should be initially treated non-operatively. This should include non-narcotic analgesics, anti-inflammatories, a soft collar, and progressive exercises. Physical therapy modalities such as heat and ultrasound may make the patient more comfortable, although it is unclear if this has any significant advantage over the natural history. In the setting of neck pain without neurological involvement, cervical fusion procedures offer unpredictable results and should generally be avoided. Some surgeons favour the use of discography and fusion but controversy exists regarding the specificity of cervical discograms and fusion for axial neck pain.

If radiculopathy is present, the same non-operative treatment should be given for 2–3 months. A brief course of systemic corticosteroids may help alleviate symptoms and allow the natural history to take its course. Steroid injections, either in the epidural space or targeted toward isolated nerve roots, may also be effective both from a diagnostic and a therapeutic standpoint.
Traction is often helpful, as it allows a compressed nerve some temporary relief and likely promotes recovery. Care should be taken to avoid traction that results in extension of the patient’s neck, which narrows the spinal canal and foramina, often resulting in increased symptoms. A cervical collar may be placed in the reverse position such that the narrow portion is anterior, leaving the neck in a slightly flexed position. In patients with radiculopathy, surgical intervention is indicated after several weeks of non-operative management (as outlined earlier) or if signs or symptoms worsen. The exception is the patient presenting with profound muscle weakness. These patients may need early intervention in order to maximize the chances of root recovery.

There is a minimal role for conservative treatment in patients with myelopathy. In patients with cervical stenosis and little or no significant myelopathy, conservative treatment or regular interval observation may be appropriate. As the natural history is that of slow stepwise deterioration, surgical intervention is generally required. Patients with mild to moderate symptoms can be expected to have a greater recovery of function, although some patients with severe symptoms can recover to a significant degree. It is important, however, that these patients understand that the surgical goal is to halt progression of their symptoms and that improvement is not predictable. If it is decided that both the cervical and lumbar spine require decompression, the cervical spine should be addressed first, followed by lumbar decompression at a later date.

### Surgical techniques

Depending on a variety of factors, cervical disc disease can be approached either anteriorly or posteriorly. A patient with isolated radiculopathy (without significant neck pain) attributable to a lateral disc herniation or foraminal stenosis is typically treated posteriorly via a laminoforaminotomy (Figure 3.1.11). In this procedure, the medial 50% or greater of the ipsilateral facet joint is removed and the nerve root is decompressed under direct vision. Any anterior pathology that may be present need not be addressed as long as the extent of the nerve root is decompressed. Advantages of this approach are in the relatively low surgical morbidity and the fact that the motion segment is not destabilized (thus, a fusion procedure is avoided). Potential disadvantages include continued segmental degeneration, the possibility of incomplete decompression, and the inability to restore disc (and therefore foraminal) height. Anterior cervical discectomy and fusion (ACDF) is preferred in patients with radiculopathy or myelopathy associated with segmental kyphosis and significant neck pain. The spondylotic segment is distracted about 2mm, providing additional decompression of the foramen, which is then stabilized with bone graft (Figure 3.1.12). This approach typically directly addresses the compressive pathology on the cord or nerve root, restores disc (and foraminal) height, negates the possibility of repeat disc herniation, and minimizes the neck pain that might have been originating from the previously mobile segment. Disadvantages include the increased morbidity and operative time in harvesting autograft (allograft may also be used), decreased neck motion, complications related to plate utilization, possible non-union, and the possibility that a fused segment may accelerate adjacent segment degeneration. Cervical disc replacement is emerging as an additional treatment option for cervical radiculopathy. It offers many of the advantages associated with anterior neural decompression, while segmental motion is theoretically maintained. Early biomechanical and clinical studies are encouraging; however, long-term results are unknown.

**Fig. 3.1.11**

A diagram showing posterior laminoforaminotomy technique: A, the lamina and the facet joint are thinned with a power burr; B, laminotomy may be enlarged with a Kerrison rongeur; C, extension of laminotomy laterally with a curette; D, the facet joint is thinned laterally to remove about 50 per cent of the joint; E, the remainder of the facet joint is removed using a curette; F, laminotomy defect.
Fig. 3.1.12
Smith–Robinson tricortical iliac crest fusion technique. Following diskectomy, the interspace is distracted about 2 mm and the middle of the endplate is drilled to allow vascular flow to the graft. The graft is inserted about 2 mm countersunk from the anterior margin of the vertebral body.

Various surgical options are also available for patients presenting with isolated cervical myelopathy (without significant neck pain). These patients usually have cord compression from large osteophytes or OPLL, often extending posterior to the vertebral body. This situation necessitates partial or complete corpectomies followed by strut grafting. Alternatively, cervical spondylotic myelopathy can be treated posteriorly with multilevel laminectomy; however, postlaminectomy instability and kyphosis is a concern. Laminectomy and fusion is, therefore, another option. An additional posterior option is laminoplasty. While there are multiple specific techniques described, they all generally involve ‘opening’ the lamina of multiple levels in a trapdoor-type fashion, preserving the paraspinal musculature and facets. With this approach, motion is better maintained as compared to fusion procedures (but not entirely preserved) and the procedure is technically less demanding. A significant concern associated with laminoplasty procedures is the notion that it may result in increased postoperative neck pain in some patients. As a general rule, posterior approaches are preferred when decompression is required at more than three levels and when cervical lordosis is maintained. If there is two- to three-level involvement, an anterior approach is preferred. If a kyphotic deformity is present, an anterior approach is mandatory. If multilevel corpectomy and strut grafting is performed, a combined anterior and posterior approach should be considered to provide a biomechanically-sound posterior segmental fixation construct.

Conclusions
When evaluating patients with cervical degenerative conditions, it is essential to obtain a thorough history, provide a detailed physical examination, and obtain appropriate testing. With this information, the physician should be able to provide the vast majority of patients with a proper diagnosis and supply counselling on the natural history of the disease process. Most often, non-operative treatment is the preferred initial treatment and may be curative. Surgery is indicated only after an adequate trial of conservative management, or in patients presenting with cervical myelopathy. Various surgical approaches are available once surgery is decided upon, each approach having its own set of advantages and disadvantages. The ultimate decision should be based upon the patient’s diagnosis and symptoms, the site of the primary pathology, the number of segments involved, the patient’s sagittal alignment, and the surgeon’s preference. Regardless of the diagnosis or surgical approach, patients must be made fully aware of the potential limitations of a proposed intervention, in addition to the benefits. Only then will the probability of a successful procedure from the standpoint of both the physician and the patient be optimized.

Degenerative disease of the thoracic spine

Summary points

- Thoracic degenerative disease is an uncommon problem and is often misdiagnosed.
- Posterolateral approaches such as transpedicular or lateral extracavitary reduce morbidity associated with thoracotomy while avoiding the risk of neurologic injury associated with posterior laminectomy.
- Correct preoperative identification of level is crucial and requires specific imaging, such as full-length MRI or CT.

Introduction

Degenerative changes of the thoracic spine are common, and are probably universal by the age of 50. In most cases these are asymptomatic beyond some loss of physical height and an increase in thoracic kyphosis. Two main clinical entities exist: thoracic disc herniation and thoracic spinal stenosis.

Thoracic disc herniation

Introduction

This was first described in association with paraplegia. In practice, many thoracic herniations are asymptomatic. The difficulty is to find those that are clinically significant. This is made more difficult by the wide range of presenting symptoms.

As diagnostic imaging has progressed, surgical treatment for patients with severe persistent symptoms has also improved. Using a conventional laminectomy, it is difficult to obtain adequate disc removal without manipulation of the spinal cord. Over a third of patients were left with persistent symptoms or worsened neurological deficits when laminectomy alone was used. Since the 1980s, new techniques such as anterior (transthoracic) and lateral extracavitary decompression and expanded posterior approaches such as costotransversectomy or transpedicular resections have improved results and reduced complications. Advances in thoracoscopic techniques have led to reports of video-assisted minimally invasive approaches to the anterior thoracic spine.

Incidence

The annual incidence of symptomatic thoracic herniations has been estimated at one per million of the population (much less frequent than in the cervical or lumbar regions). A prevalence of 15–37% has been documented by both autopsy and imaging. Surgically treated thoracic herniations comprise only 0.15–4% of all disc surgeries.

Ninety-five per cent of thoracic disc herniations occur at or below the T6–T7 vertebral level. The remainder occur at any level. They mainly occur in the fourth and fifth decades in both sexes and require special care.

Aetiology

About 50% of cases are said to be traumatic. Recent research suggests that lumbar disc herniations are mainly of genetic origin, but no such research has been done on thoracic discs. Intradisc calcification is seen in up to 50% of patients. Scheuermann's kyphosis has been noted as an associated diagnosis. Neurological deficits secondary to these lesions are probably due to a combination of vascular disturbance and direct mechanical compression of the spinal cord. Approximately two-thirds of herniations are central, with the balance occupying a paracentral or lateral position. Intradural disc herniations have also been described.

Presentation and diagnosis

Symptomatic thoracic disc herniations can be associated with a variety of initial complaints. The array of attributed local and radiating pain symptoms can result in lengthy delays in diagnosis. Patients may present with prior workup and treatment for disorders including cholecystitis, renal colic, cardiac disease, endometriosis, and lumbar disc disease.

Examination

Neurological abnormalities are predictably limited to the lower extremities or bowel and bladder function. Upper motor neuron signs in the lower extremities such as clonus and Babinski reflexes may be found, particularly in patients with gait abnormalities, lower-extremity weakness, or bowel and bladder complaints. A concordant level of change in sensitivity to pinprick may be identified. Abdominal reflexes may be absent. Differential diagnosis in patients with myelopathic symptoms should include systemic causes of upper motor neuron weakness, such as multiple sclerosis or amyotrophic lateral sclerosis. These can occur concomitantly with a thoracic disc herniation, and will contribute to a poor neurological outcome with surgical treatment.

Imaging

Plain radiographs should be obtained on all patients. These may demonstrate abnormalities such as disc calcification or narrowing.
of a disc space. Changes associated with Scheuermann's disease, such as end-plate irregularities, Schmor's nodes, and vertebral body wedging, may also be present.

Computed tomography (CT) myelograms or magnetic resonance imaging (MRI) are definitive investigations. The frequent occurrence of thoracic disc herniations in asymptomatic patients requires careful correlation of clinical complaints with the radiological findings.

Identification of level

Identification of level is essential for patients being considered for surgical treatment, and this is not easy. This can be done either by a sagittal MRI showing both the sacrum and the herniation on a single cut, or by an anteroposterior topogram reconstructed from the CT scan to demonstrate the ribs at each level, allowing a precise count of thoracic and lumbar vertebrae. This is a critical aspect of presurgical preparation.

Treatment

The treating physician must establish that surgery holds a reasonable expectation of improvement for the patient (Box 3.2.1).

Box 3.2.1 Decision and treatment in thoracic disc herniation from various studies

- 37% of asymptomatic volunteers have herniations demonstrable via MRI
- Of 55 patients with herniations, without motor deficit:
  - (15) 27% eventually underwent surgery
  - 77% of those treated non-operatively (31/40) returned to work
- Transthoracic decompression: ~90% of those treated do well
- Costotransversectomy/transpedicular approach: slightly less good outcomes
- Lateral extracavitary approach (LECA):
  - Significant improvement in pain and neurological status in 15/20 patients
  - 18/33 experienced at least one complication
- Minimally invasive version of LECA: limited results.

Problems and complications

Incomplete removal of the herniated disc fragments

It is our opinion that centrally located herniations with neurological deficits are best treated via an anterior thoracotomy approach. Adequate exposure for complete decompression of the spinal cord is difficult to achieve via a costotransversectomy or a transpedicular approach, particularly for calcified disc herniations, which can extend intradurally. These issues may contribute to the somewhat lower numbers of patients with complete neurological recovery and pain relief following posterior decompressions than for those undergoing transthoracic excision.

Wrong level

Identification of level is essential for patients being considered for surgical treatment. It is not always easy to identify the correct level from images. This can be done either by a sagittal MRI showing both the odontoid process and the herniation on a single cut, or by an anteroposterior topogram developed with the CT scan to demonstrate the ribs at each level, allowing a precise count of thoracic and lumbar vertebrae.

Pulmonary complications

Haemothorax and pneumothorax are recognized potential complications of a transthoracic approach.

Thoracic spinal stenosis

Introduction

While stenosis of the lumbar spinal canal and intervertebral foramen is well recognized, thoracic spinal stenosis remains a comparatively rare entity. Like lumbar stenosis, thoracic spinal stenosis occurs when degeneration produces enlargement of structures surrounding the dural sac, with secondary compression of the neural structures. Compression may be posterior, from the ligamentum flavum and facet joint capsules, or anterior, from the intervertebral disc or posterior longitudinal ligament. Patients with congenitally narrow canals are particularly at risk for developing these problems.

Classification
Spinal stenosis may be developmental or acquired through degenerative processes. It may also occur at a stress riser above a previous spinal fusion (iatrogenic).

**Presentation and diagnosis (Box 3.2.2)**

Symptoms may vary from those of lumbar spinal stenosis due to the potential involvement of the spinal cord. However, lumbar spinal stenosis must still be considered in the differential diagnosis, as these patients may present with similar complaints and lumbar stenosis is much more common.

**Box 3.2.2 Clinical presentation of thoracic spinal stenosis**

- **Sensory:**
  - Stocking distribution of sensory changes
  - Activity related lower limb pain
  - Usually bilateral
- **Motor:**
  - Above T9—spastic paresis
  - Below T9—flaccid paresis
- **Reflex:** mixed response
- **Bladder:** 40% bladder dysfunction.

Sensory abnormalities of the lower extremities occur in virtually all patients, often in a stocking or other non-dermatomal distribution. Some patients demonstrate a thoracic sensory level. Activity-related lower-extremity pain or dyesthesia is reported by the majority of patients, and 30–40% have bowel and bladder dysfunction. In one series, lesions above T9 tended to show spastic paresis whereas those with lesions in the region of T11–T12 have a flaccid paralysis.

Approximately 50% of patients demonstrate spasticity in the lower extremities, although there appear to be somewhat higher rates of paresis. This may be due to concomitant lumbar stenosis, with a secondary loss of lower-extremity reflexes.

**Investigation**

Diagnosis is confirmed by myelogram/CT scan or by MRI. It is important to determine whether the primary compression is due to anterior structures (e.g. ossification of the posterior longitudinal ligament or a herniated disc) or posterior structures (ligamentum flavum and facet capsule hypertrophy). As with a herniated thoracic disc, accurate determination of the spinal levels involved is critical. Complete three-dimensional imaging of the lumbar spine should be performed to ensure that a more caudal lesion is not present.

**Management**

Observational treatment may be sufficient for patients with myelopathy without incapacitating claudication or weakness. However, in most of the patients we have diagnosed with this condition, weakness and gait abnormality with or without lower extremity claudication is already present. We believe that these patients should be offered surgery aimed at decompression of the spinal cord.

The decision of whether to proceed with anterior or posterior decompression depends on the location of the spinal cord compression. Most of the patients described in the literature have posterior compression due to hypertrophy of the posterior structures, which can be treated by laminectomy. Careful technique is required, with the use of a burr to thin the posterior bone. The remaining soft tissue is then gently elevated off the dura with curettes and a small pituitary rongeur. Use of Kerrison rongeurs should be limited to the 1- to 2-mm punches in the areas adjacent to the facets and lateral to the cord. The decompression must be wide enough to include the medial aspects of the facet joints and must include all potentially compressive levels. Fusion of these patients is not generally required because of the stability provided by the thoracic cage.

Patients with anterior compression should be treated with anterior transthoracic decompression of involved segments.

**Results**

All series are small. About 70–80% will experience improvement or good resolution of neurological symptoms with adequate decompression. Patients can develop recurrent symptoms despite initially successful surgical treatment. This can be due to recurrent bone formation at the operated level or degeneration at additional spinal levels. Therefore, these patients require regular follow-up with re-imaging of appropriate levels for recurrent symptoms.

**Further reading**

Summary points

- Classification of back pain has proved challenging
- This is important both for clinical practice and research
- MRI scanning is important for radicular pain but can be difficult in back pain patients as there is such a high incidence of asymptomatic abnormality.

Introduction

Low back pain is one of the most common presenting complaints in orthopaedic practice. Often the cause of the pain is not understood, and consequently the diagnosis and the explanations given to patients are inconsistent. This causes uncertainty and, in some cases, prolongation of symptoms. Back pain is sometimes the presenting complaint where there is serious underlying pathology. It may be difficult or impossible to distinguish these cases from the generality of back pain complaints. Progress has been made in our understanding of back pain complaints, and it is now possible to give a structured approach to management for which there is at least some evidence.

The principal objectives of the clinician are to identify those patients with serious underlying pathology, and to try to place the rest in clinical groups relevant to the available treatment options. Generally these are non-operative, and these methods are emphasized in the chapters in this section. Surgery has a definite role in the management of root pain, particularly in the presence of progressive neurological deficit or neurogenic claudication. The place of surgery in the management of some cases of back and referred pain, which has failed to respond to conservative management, is more controversial.

Classification

A number of clinical and pathologic classifications have been reported. We use a scheme elaborated in 1990 based on history, examination, and magnetic resonance imaging (MRI). Plain x-rays have little value in this area.

Fairbank–Hall (1990) classification

Type 1: ‘simple’ or ‘non-specific’ low back pain

This is the common type of back pain. Attacks occur acutely, and often for no obvious reason. Precipitating factors are often normal everyday events or actions. The vast majority of attacks will improve within 6 weeks, and are generally handled in family practice, by physiotherapists, chiropractors, or osteopaths. If the symptoms are prolonged or severe, specialist advice is sought. The majority of pain is felt in the lumbar spine, but there may be referral to buttocks or thighs, occasionally to the lower legs. Pain tends to be worst when sitting, and is often better with activity. Treatment is activity. Attacks are self-limiting, although they may be recurrent. Generally people will improve with or without intervention because the natural history is good. A whole variety of treatments can be helpful for pain relief and functional recovery. None of these, however, cure or prevent recurrence. Details of management can be found in Chapter 3.4.

Type 2: persisting back pain-related disability, ‘chronic’

The interface between type 1 and type 2 is indistinct. Type 2 has chronic persistent symptoms that may/may not vary in severity. Often the onset is insidious and flare ups may be anticipated by the patient. The pain is back dominant and often refers into the thigh or even further down the leg depending on severity—so-called thermometer pain. It tends to be unresponsive to a wide variety of simple conservative management. There is a trend toward managing these patients in specialized rehabilitation programmes (see Chapter 3.4) based on cognitive behavioural principles. A small number of these patients may be suitable for spinal fusion or spinal stabilization. This is discussed in Chapter 3.6. Hall has further developed this scheme to distinguish patients who are likely to benefit from rehabilitation from those likely to benefit from pain management.

Type 3: root pain

These patients have back and leg pain in a dermatomal distribution with or without correlating neurological deficit. L5 can usually be distinguished from S1 in the distribution in the foot. L4 usually has a strong component of anterior thigh pain. In classical disc prolapse, the back pain precedes the leg pain, which eventually predominates. It is not usually possible to distinguish lateral recess stenosis from disc herniation clinically. Surgery provides quicker relief of leg pain and function, but not better long-term recovery. Management is discussed in Chapter 3.7.

Type 4: neurogenic claudication

Patients in this group present with walking-related back and leg pain. They are usually middle-aged or older, but it can occur in the young as well. These patients are intolerant of standing and walking, and relief is usually obtained by sitting, squatting, or lying.
Often there is a flexed posture in walking and their symptoms are helped by any wheeled device such as a supermarket trolley or pushchair. In most, the symptoms do not deteriorate with time. Surgical management is an option for those with severe restriction of walking. Management is discussed in Chapter 3.8.

Type 5: ‘Not classified above’ (includes tumour, infection, vertebral collapse, deformity, inflammatory and chronic pain syndrome)

These patients have symptoms that do not fit easily in other groups. Any patients with unusual or persistent symptoms or pain which cannot otherwise be explained fall into this group. Sometimes it is clinically impossible to distinguish those patients with serious pathology, including infection and tumours from those without. The management of those with pain related to systemic pathologies is discussed in Section 2.

Diagnosis

History

Diagnosis is made mainly on the basis of history, and so time must be spent with patients listening to their complaints. This process may be aided by proformas and computer-based interview systems. As so much depends on the history, it is essential to give the patient time to tell their story and to listen to what they are saying. History-takers should bear the following points in mind when listening to their patients.

Age

Back pain is common from the age of 16 onwards. However, it is rarely severe in teenagers and tends to be most bothersome in our middle years (30–55). Serious pathology (infections and tumours) can occur in all ages but is more common in people outside this age range than within it. Therefore, patients presenting with back pain who are younger than 16 or older than 55 should be reviewed with particular care. Symptomatic disc prolapse is uncommon in teenagers and unusual over the age of 60. Neurogenic claudication is most common over age 60, unusual below the age of 40, but can occur even in teenagers with developmental spinal stenosis. Insufficiency fractures occur most often in those over age 70. Spondylolysis and spondylolisthesis may manifest themselves at any age, but they tend to cause back pain in patients under the age of 40 and neurogenic symptoms in older patients. Management is discussed in Chapter 3.17.

Pain pattern

Pain from a specific level in the spine (e.g. a metastasis) is usually referred about two segments distal to its source in the cranial part of the spine (Figure 3.3.1). The referral tends to be further from the source of the pain in the caudal part of the spine. This pain does not, in general, go to the front of the trunk or lower limb. Localization of the source level may be aided by percussion or palpation of the spine (although, curiously, pain from discitis, which is often severe, is not always exacerbated in this way).

Click to view larger

Fig. 3.3.1
Pain patterns arising from single vertebrae affected by fractures or metastases.

The clinician should be familiar with the concepts of referred pain and root pain, and the distinction between them.

Referred pain is characterized by variation in distribution with severity: the worse the pain, the further it will felt down the lower limb ('thermometer pain'). Referred pain usually radiates posteriorly towards the knee, although in chronic cases it may go further down the leg. Referred pain is difficult, because it varies with sensitivity and is not associated with reliable clinical signs.

Root pain is usually dermatomal, although there are significant individual variations. Historically a variety of methods have been used to derive dermatome charts (Figure 3.3.2). Sometimes these can be confirmed by examination by light touch and pinprick testing. Root and referred pain can coexist. Some patients will have entirely root pain in a classical distribution without back pain.
Pain felt on the front of the thigh, if it emanates from the spine, is generally from the L3 or L4 roots. L5 root pain usually radiates to the dorsomedial aspect of the foot. S1 root pain spreads to the lateral side and the sole of the foot. There are frequent variations of pattern in clinical practice. Coughing and sneezing tend to exacerbate root pain due to disc prolapse.

<table>
<thead>
<tr>
<th>Dermatome chart.</th>
</tr>
</thead>
</table>

Patients with neurogenic claudication have difficulty in defining the site and nature of their symptoms. Some deny that they experience pain at all, preferring such terms as ‘heaviness’. The distribution of this pain is a poor guide to the nerves involved. Bilateral lower-limb pain implies a central lesion. This may be central stenosis, a central disc prolapse, or a tumour affecting the cord, conus, or cauda equina.

The term ‘myofascial pain’ describes a wide variety of musculoskeletal symptoms. These have characteristic pain patterns which may be small and localized. One such syndrome has trigger points over the posterior iliac crest and an associated pain pattern. These pains may respond to a local anaesthetic injection. Copious literature on this topic can be found in rheumatological texts.

If a pain drawing is used to identify pain patterns, some will have widespread bodily symptoms. This could be related to systemic pathology (inflammatory, thyroid, etc.). If systemic pathology has been excluded and there is associated disability and distress, then chronic pain syndrome should be considered. This needs specialist management. Many clinicians have been caught out, dismissing a patient’s symptoms of serious underlying pathology as psychogenic.

Pain from the hip is often confused with back pain. It is usually felt in the groin and/or over the greater trochanter. It can radiate over the front of the thigh to the knee. Occasionally it is felt just in the knee, notably in children. Uncommonly, hip pain is experienced in the buttck alone. Hip pain is usually exacerbated by getting out of a chair, as well as by walking, although in the early stages of osteoarthritis of the hip continued exercise can relieve pain after the initial painful movement. These symptoms can be fully evaluated by examining the hip. Gauvain’s test, in which the extended leg is gently rolled by the examiner while the patient is lying and relaxed, produces either pain or involuntary ipsilateral abdominal contracture. Rotation in flexion or abduction may also reproduce hip pain.

Diurnal and longer-term fluctuations in back pain

Night pain is common in degenerative spinal conditions so specificity is poor. However, it is also a feature of pain from fractures, metastases, and infections. It is the quality of the night pain that differs. Intractable pain at night necessitating the person to get out of bed, which is not responsive to pain relief, should raise suspicion of possible serious pathology. Especially if there are other red flags in the history.

Scoliotics tend to have fatigue pain which becomes worse through the day. Ankylosing spondylitis is characterized by severe and prolonged morning stiffness (all patients with back pain report morning stiffness to a greater or lesser extent).

Walking-related pain

Root pain is usually exacerbated by walking (and often just while standing still). Neurogenic claudication has a variable walking distance from day to day. The patient or spouse may notice a flexed posture during walking. Sometime it is easier walking up hill. Riding a bicycle may be easier than walking if severely restricted. Many patients find it much easier to walk while pushing a supermarket trolley or wheeled walker. It is often not possible for these patients to ‘walk through’ the pain as vascular claudicants can. Neurogenic claudication may be distinguished from vascular claudication by the duration of recovery. Vascular claudicants can usually carry on walking after 1–3min, whereas cauda equina claudication requires 5–20min for recovery.

Sitting-related pain

Many chronic back pain patients are intolerant of sitting; there are many theories related to this incriminating the disc, ligaments, muscles, and facet joints. Driving more than 1000 miles a week is a possible risk factor for chronic back pain. Sitting tends to
relieve the pain of neurogenic claudication.

**Gender**

The overall incidence of back pain is similar in men and women. The prevalence of disc degeneration, disc prolapse, and lytic spondylolysis and spondylolisthesis is more common in males. Degenerative spondylolisthesis is more common in females.

**Occupation**

Back pain is common in the working age group regardless of employment status or occupation. Work is good for the health of those with back pain. Modern healthcare encourages the use of ‘fit notes’ rather than sick notes, i.e. establish what the person can do, and modified hours/duties to make work manageable. Heavy manual work is not as strong a factor as is often assumed. Disc degeneration is universal and largely driven by genetic factors. Individuals with more severe disc degeneration than their age-matched contemporaries are more likely to have back pain. Sitting and exposure to vibration are limited contributors to prevalence. Back pain undoubtedly presents more of a problem to members of social classes 4 and 5 because their work tends to be more physical and therefore harder to do with back pain. Social service payments depend on inability to work. The structure of workman’s compensation systems has a profound effect on the incidence and duration of back pain disability. The longer an individual is off work, the less likely he or she is to return to work. There are also strong confounding factors, such as smoking and litigation following actual or perceived injury to the spine. Training in manual handling may be of importance in making work more comfortable. There is some evidence that fitness programmes in the working environment can lead to significantly shorter sickness absence. In modern work environments it is rare to find jobs at the extreme of the ergonomic envelope for spinal loads.

**Onset of symptoms**

The nature of the original onset of symptoms and how an attack starts is worth analysis. Type 1 pain usually starts acutely, frequently while performing normal activities. Often patients will admit that there was no obvious precipitating factor to an attack. Insufficiency fractures usually precipitate acute pain if they are symptomatic (only about 25% of osteoporotic crush fractures cause pain). Disc prolapse almost always start with an insidious onset of back pain followed at a later stage by root pain. The delay in onset of root pain varies from minutes to years. The appearance of the root pain may be accompanied by reduction or loss of the back pain.

There is an expectation amongst patients and their doctors that a precipitating cause for their back pain can always be found. Litigation may be a factor in this quest. In a study at the Canadian Back Institute, 70% of 6000 non-compensation responders to a questionnaire were unable to identify a specific injury to account for the onset of their symptoms.

**Pain type**

The words used to describe back pain are often culturally determined. Some descriptive terms, such as ‘burning’, ‘pins and needles’, or ‘numbness’, may be associated with radicular pain, whereas ‘cramp’ or ‘ache’ tends to relate to vascular, neurogenic claudication or referred pain. These terms may have some value in eliciting the source of pain in the individual, but they have resisted useful analysis.

**Smoking**

Smoking has been shown to be a risk factor in pseudarthrosis following spinal fusion. An association between smoking and disc degeneration has been established. The relationship to back pain, however, remains unclear. Heavy smokers often have poorer social circumstances and if employed have more physical occupations. It is likely that psychosocial factors will have greater predictive value for back pain related disability than smoking.

**General medical questions**

Some systemic conditions may present with back pain. Tuberculosis and other infections, metastases, lymphomas, pancreatitis, or a leaking aortic aneurysm can all cause pain in the back. Pain arising from metastases and from infection is frequently unremitting and may be worse at night. The patient should be asked about past history of cancer, weight loss, eating habits, disturbances of digestion, bowel and bladder function, night sweats, drugs, and allergies. Diabetes mellitus, hypothyroidism, osteoporosis, osteomalacia and other metabolic bone diseases, psoriasis, and pregnancy may all be factors in the development of back pain. Any patient with an unusual history should be listened to and examined with particular care.

**Family history**

Disc degeneration is genetically driven. Disc prolapse patients frequently have affected first-degree relatives. There is some epidemiological data linking disc degeneration to back pain, particularly if it is earlier or more extensive than expected by age. It is likely that response to pain has important genetic elements. Family patterns of psychosocial factors have an influence on perceived disability.

**Psychosocial factors (yellow flags)**

Listening to the patient is the most effective way of assessing the psychological component of a patient’s history. Patients with strong psychosocial factors have the same range of pathologies as those who do not. It is the response to pain which differs, not the pathology. These should always be screened during back pain assessments. Psychosocial questionnaires are widely used and have been shown to add value. Examples can be found in The Back Pain Revolution (see ‘Further reading’). In particular, high levels of disability, worklessness, and high healthcare utilization should raise concern. The structure of the social services payment...
system is an important factor in the rise in back pain disability in developed countries. Litigation over personal injury claims has long been recognized as having an important effect on treatment outcome and reported disability. For those with significant pain-related disability, a comprehensive biopsychosocial assessment by a clinician or multidisciplinary team is recommended as early as possible, and certainly before any surgical management is considered. Combined physical and psychological management has been shown to be effective in reducing disability, distress, medication usage, and healthcare utilization.

Chapter: Non-operative management of non-specific low back pain (types 1 and 2)

Summary points

- Back pain is common
- Most attacks are self-limiting
- Exercise and fitness programmes seem to be the most effective intervention
- CPP programmes are effective for chronic back pain and should be introduced early.

Introduction

Most people will experience back-dominant pain of a non-specific nature at some time in their life. The severity of the episodes varies within and between individuals. Persisting symptoms and recurrences are common. For the majority (type 1) the natural history is of improvement, in pain and function, over a few months regardless of intervention. Beyond this time the majority will no longer consult but will continue to experience back pain symptoms at a lower level. However, 7% will develop persisting back pain-related disability (type 2). For these, the resultant cost to the individual, healthcare, and society is significant.

There are many studies demonstrating that specific spinal structures, such as disc, facet joints, ligament, and muscle, can produce back pain. Symptoms from these structures are more severe in the back but may refer to the leg. Non-specific low back pain clearly has a physical basis. Many theories regarding specific pathologies exist, but none have stood up to the rigor of research. Furthermore, spinal imaging of asymptomatic people frequently demonstrates degenerative change. Despite extensive research, clinicians cannot identify specific back pain pathologies in the majority of people with back-dominant pain. Pain only explains 10% of the variance of back pain-related disability. There is emerging evidence from Hong Kong that disc degeneration earlier or more extensive than expected by age group has a relationship with back pain, but causation has not been established.

There is no known prevention or cure for low back pain. Evidence-based interventions can provide short-term benefit of small to moderate magnitude. The focus of intervention is symptom management, and prevention of persisting back pain-related disability. It may be that subgroups of non-specific low back pain respond differently to different interventions.

Initial management (type 1)

Patient/public education

From the outset it is essential that the person with back pain understands the normality, non-specific nature, good prognosis, and self-care options. An explanation, specifically addressing the concerns of the individual, reinforced by evidence-based patient information is reassuring and empowering for most. The back book is one such example, which is widely used in the United Kingdom. A large media campaign in Australia demonstrated sustained improvements in the population’s back pain beliefs by providing positive messages about back pain.

Pharmacological symptom relief

Pharmacology is commonly used in an attempt to make back symptoms more manageable. Consideration needs to be given to the risks versus benefits. Compliance with medication is a problem and repeated review of effectiveness and side effects is essential. Guidelines consistently recommend regular paracetamol and/or non-steroidal anti-inflammatory (NSAID). For those with moderate/severe symptoms, weak opioids, tricyclic antidepressants, or muscle relaxants may add benefit. In those with the most severe symptoms, strong opioids may be required for pain relief. If the need for strong opioids persists, then an early, comprehensive, biopsychosocial assessment is strongly recommended.

Non-pharmacological symptom relief

There is evidence supporting the effectiveness of manual therapy (physiotherapy, osteopathy, or chiropractic) and the McKenzie method in reducing pain and disability. The effect sizes, however, are small to moderate. The profession delivering manual therapy seems to be less important than the competence of the individual clinician. For those who prefer non-pharmacological pain relief, acupuncture and massage have been shown to be effective. Ongoing treatment beyond a few months has not been shown to add any additional value.

Optimizing activity including work

Everyone with non-specific low back pain should be advised to remain active. All normal activities are good for back pain. When symptoms are severe, activity should be modified rather than stopped. There is no evidence that one type of exercise is superior to another. Compliance with exercise is likely to be improved if the recommended activity is enjoyable and practical for the individual. Back fitness programmes (supervised, individual, graded exercise delivered in groups) are cost-effective in improving functional ability.
The bothersomeness of back pain is greatest in the age group of the working population. Work is good for our health and can be therapeutic for those with back pain. Where work is difficult to maintain, short-term modified hours or duties may be helpful. It is important that any modification advised is accompanied by a planned progression, clear timescales, and progress reviews. Ergonomic work environments have been shown to improve comfort and satisfaction.

**Biopsychosocial screening**

Psychological factors are an important part of the low back pain experience. They contribute to the progression from type 1 to type 2 back pain and have been identified as important barriers to resolution.

For those who fail to return to normal activities by 4–6 weeks, a comprehensive biopsychosocial assessment is recommended. The predictive value of psychosocial factors, yellow flags (Box 3.4.1), has been demonstrated. Questionnaires combined with a detailed clinical interview explore the functional and emotional impact of back pain. Efficient screening will identify around 85% of those who will go on to develop persistent back pain-related disability. Establishing the level of risk is important, but engaging those at risk with biopsychosocial intervention is key to influencing their outcome.

**Box 3.4.1 ‘Yellow flags’ for biopsychological screening**

- **Unhelpful beliefs:**
  - Activity will cause pain/injury
  - Recovery is not possible
  - Pain is caused by a serious health condition (cancer)

- **Maladaptive behaviours:**
  - Excessive use of medication, rest or passive interventions
  - Withdrawal from normal activities including work

- **Compensation:**
  - History of claims
  - Lack of financial incentive to return to work

- **Diagnosis/treatment:**
  - Conflicting diagnosis

- **Iatrogenic diagnosis:**
  - Leading to fear or catastrophizing
  - High healthcare utilization
  - History of failure to respond to intervention

- **Emotions:**
  - Fear of pain/disability
  - Depression and/or anxiety
  - Low self efficacy

- **Family:**
  - History of abuse
  - Over-/undersupportive family
  - Family history of pain related disability/worklessness

- **Work:**
  - Belief work is harmful
  - Unhappy/unsupportive work environment
  - History of excessive sick leave
  - Low job satisfaction.

**Investigation**

Spinal imaging is unlikely to change the diagnosis, management, or outcome in people with non-specific low back pain. Degenerative changes are commonly found and correlate with age, but only weakly correlate with pain and do not explain disability. It requires large epidemiological studies to show a relationship with earlier than expected or more extensive than expected disc
degeneration. Imaging for reassurance has been shown to improve satisfaction, but not to achieve reassurance. There is morbidity associated with imaging non-specific low back pain. In addition, future healthcare costs are greater due to increased healthcare-seeking behaviour. Where systemic pathology is suspected, spinal magnetic resonance imaging (MRI) is highly sensitive and adds value in excluding this possibility. MRI is essential for surgical planning, in the small number of people who are being considered for spinal fusion, disc replacement, or other disc focused intervention.

**Back pain treatments which are no longer recommended**

Over the years, a wide variety of treatments for back pain have evolved. Internationally, there is consensus in back pain guidelines against the use of the following treatments (due to evidence of ineffectiveness, lack of effect, or lack of evidence of effectiveness): bed rest; exercise therapy; injection of therapeutic substances (epidural, facet injections); electrotherapy (interferential therapy, laser, short-wave diathermy, transcutaneous electrical nerve stimulation (TENS), ultrasound); lumbar supports, mattresses, or traction.

### Management of persisting pain-related disability (type 2)

Persisting non-specific low back pain is common. Over time, most return to normal activities despite pain. In some (7%), pain has a dramatic impact on lifestyle and function and results in cognitive, emotional, and behavioural changes. It is the interaction between pain and psychology which differs, not the duration or pathology. There is strong evidence that structural changes have little meaning in the context of back pain disability. Pain behaviours are learnt and may be altered. Intervention aims to adjust behaviour and empower the person to cope better with the symptoms of back pain.

Recent evidence has demonstrated changes within the brain and raises the possibility of cortical reorganization and degeneration. Equally, this raises the possibility of reversing the process. As yet, the studies of the brain in people with type 2 back have small samples, which limit generalizability, but the findings are encouraging. Dorsolateral prefrontal cortex degeneration has been shown to correlate with level of depression. Animal studies have also demonstrated inflammatory and neuropathic alterations to dorsal horn of cord with degeneration of the inhibitory interneuron system. This has not been replicated in patients. Alteration to central pain memories has also been proposed.

For those who are at risk of persisting back pain-related disability, combined physical and psychological interventions (CPP) have been shown to be effective in reducing disability, distress, healthcare utilization, and improving return to work. Initially less intensive, CPP (<30h, often uniprofessional) provides good results for most. The more costly, higher intensity CPP (>60h) is best reserved for those who have a limited response to less intensive CPP (see Table 3.4.1).

Cauda equina syndrome

Summary points

- Cauda equina syndrome is a devastating consequence of cauda equina compression
- The most common cause is a large disc herniation in the presence of a narrow vertebral canal
- Expeditious decompression can prevent the syndrome when some urinary function is preserved.

Introduction

Cauda equina is a well-known but rarely diagnosed condition. Untreated, the consequences of this syndrome for the patient are devastating. Poor results can occur even with expeditious treatment. It is a frequent cause of negligence litigation. It is important that clinicians are aware of its presenting features and the pitfalls surrounding diagnosis. Patients with severe back pain may go into retention because of severe pain without cauda equina syndrome (CES). It is sometimes difficult to distinguish the effects of severe pain from true cauda equina compression. If in doubt seek help and an emergency magnetic resonance scan. If the symptoms are of rapid evolution, this is a surgical emergency. If the onset is slow, it is more difficult, but an early magnetic resonance scan is very helpful in identifying the aetiology. Cauda equina compression can occur when there is a large, and particularly central, disc prolapse in association with a relatively narrow vertebral canal. CES may come on insidiously and incompletely. On other occasions, it may have an acute onset and profound deficit. Other causes of CES include: tumours, both primary and secondary; fractures where the lumbar canal is seriously distorted; infections with epidural pus; and haematomas, either spontaneous or as a complication of spinal surgery.

Clinical presentation

Symptoms

- Severe pain in the back and/or either one or both legs. Sometimes there is not such severe pain, so be careful in excluding the diagnosis
- Unilateral or bilateral perianal numbness is a strong warning symptom of cauda equina compression. Altered sensation wiping the perineum is commonly noticed
- Urinary symptoms: these may range from frequency and nocturia, through to urgency and dribbling, to retention, and in some cases complete incontinence
- Faecal symptoms: these range from prolonged straining at stool to faecal incontinence
- Sexual: relates to loss of sexual sensation and, in males, impotence. This is not often a presenting feature but may be a feature of chronic onset. This is the major long-term symptom along with urinary incontinence

Signs

- Sensory: ranges from unilateral to bilateral alteration in perianal sensation to complete anaesthesia. The end of an unravelled paper-clip is a helpful aid to assess loss of pinprick sensation
- Motor: there are no reliable motor signs
- Reflex: there are no reliable reflex signs; often ankle reflexes are reduced or lost
- Anal tone: rectal examination will reveal poor or absent anal tone and loss of capacity to squeeze the examining finger.

Management

- CES should be managed in secondary care
Urgent imaging (magnetic resonance imaging, radiculogram or myelo-computed tomography can all be used) should be available within 8h of admission.

Urgent surgical treatment is needed by a surgeon familiar with or supervised by a surgeon experienced in these lesions (all neurosurgical units and orthopaedic units with trained spinal surgeons). Surgery should ideally be performed within 24h of onset of symptoms, but where onset is unclear or incomplete as soon as possible after diagnosis and imaging. Our current practice is to operate as quickly as feasible. If this means in the middle of the night when surgical skill may be worst, then the operation should wait until first thing in the morning.

Surgical decompression is by a bilateral laminectomy with discectomy (some surgeons use a unilateral discectomy but we do not recommend this).

Surgical management of chronic low back pain

Summary points

♦ A very small proportion of back pain patients respond to surgical treatment
♦ Patient selection is poorly defined
♦ The rationale of treatment ranges from immobilization (fusion) to claimed restoration of normal movement (disc replacement and flexible fixation).

Introduction

Patients with chronic low back pain are frequently referred to orthopaedic surgeons. The majority of these patients do not require surgical treatment, and should be managed by non-operative means. A small proportion may benefit from surgical stabilization of the spine or disc replacement. This chapter is concerned with the rationale for this approach, investigation, surgical methods, and the results.

The surgeon and patient have to take a decision after weighing up the risks and benefits of the procedure (often hard to define) against the disability. Spinal fusion may be regarded as either an attempt to speed up the natural progress of degenerative changes towards a functional ankylosis or a prevention of progressive deformity or instability. The aim is to reduce the severity of back pain and improve functional ability.

The evidence on which to base these decisions is developing. Several randomized trials of spinal fusion have now been completed. In Sweden, trials showed an outcome advantage of fusion over conventional physiotherapy, but could show no difference between three different surgical techniques. In Norway and in the United Kingdom, studies could show no advantage of surgery over intensive rehabilitation. These trials have caused controversy, especially in the United States, where there are high rates of surgery for back pain.

‘Soft’ fusion using a variety of posterior devices has been practised for 20 years, but no large trial completed. The rationale remains experimental, not least because of our poor understanding of intersegmental biomechanics in relation to pain. Many ingenious devices have been developed to alter these, but results are anecdotal. In the Spine Stabilisation Trial in the United Kingdom, there was a small subset of patients who had the Graf procedure. This was underpowered, and there was no obvious advantage seen in these patients of surgery over rehabilitation and they required more revision surgery. Surgery was quicker with fewer complications than spinal fusion.

Disc replacement has evolved in the last 30 years, with cohort studies only reported until two Food and Drug Administration-approved trials. The Charité study was against a BAK (Bagby and Kuslich) anterior cage procedure (now abandoned) that showed non-inferiority. The ProDisc study showed non-inferiority using an unvalidated version of the Oswestry Disability Index over 360-degree fusion. Both these trials show a non-statistically significant advantage to disc replacement and it is likely that they were underpowered. No study against rehabilitation has been reported yet. Surgeons should consider the difficulties of selecting patients and the high risks of revision surgery before recommending this procedure.

Rationale

It is assumed that back pain may be generated from the low back by ‘mechanical’ means or through a source of ‘inflammatory’ agents (usually assumed to be the intervertebral disc) irritating neural tissues.

♦ Mechanical back pain is generated by movement, and may be controlled by rest or immobilization by external splintage (corsets, braces, plaster), or internal splintage (fusion, with or without internal fixation, or limitation of movement by special implants). In some cases there may be instability of the spine, actual or perceived, which can be controlled by spinal fusion
♦ Inflammatory pain may be managed surgically by excision of a whole disc, or at least a substantial part of it, and replacement of it by allograft or autograft bone, cages made of various materials containing bone, or artificial disc prostheses designed to replace either the nucleus or whole disc
♦ Both mechanical and inflammatory pain may be involved in patients with previous root decompression surgery.

Unfortunately, reality has not always followed expectation, and the results of treatment have varied considerably. Carragee used discography to identify ‘best bet’ patients for spinal fusion. Only 27% met his strict criteria of success compared with 72% of a control-spondylolisthesis group (Box 3.6.1).

Box 3.6.1 Indications for back pain surgery
Where non-operative treatment has failed
♦ Where a clear rationale for surgery can be made supported by high quality evidence
♦ Where contraindications are excluded
♦ Where there is a clear understanding of the risks and benefits of intervention.

Spinal instability

Spinal stability is a much abused term. There are at least four ways in which this can be conceived:

1) In mechanical terms, as summarized in White and Punjabi’s (1990) definition of stability
2) In temporal terms, where symptoms wax and wane more or less predictably with time. Some patients report increasing frequency and duration of attacks of pain
3) In perceptual terms, where the spine feels unstable although no abnormal motion or position can be detected by conventional radiography
4) In postural terms, where the spine is unbalanced.

White and Punjabi defined stability as ‘a condition of the spine under normal physiological loading where there is neither abnormal strain nor excessive or abnormal motion in the functional spinal unit’. The functional spinal unit is a motion segment, consisting of bone, disc, and bone, as well as its supporting joints, ligaments, and muscles. Instability is the loss of the ability of the spine under physiologic loads to maintain relationships between vertebrae in such a way that there is neither damage or subsequent irritation to the spinal cord or nerve roots and, in addition, there is no development of incapacitating deformity or pain from structural changes.

Perceived or functional instability is sometimes called ‘instability syndrome’. The patient complains of giving way, getting stuck, a ratchety flexion in the spine, and, occasionally, a sensation of disconnection of the top of the body from the bottom. Panjabi has recently published a hypothesis based on the concept of a single trauma or cumulative microtrauma causing subfailure injuries of the ligaments and embedded mechanoreceptors leading to disturbed muscle control. Harris has suggested that mismatch between expected and actual proprioceptive information may be a potent source of ‘distress’ in the central nervous system, experienced as pain. There is a strong body of evidence suggesting proprioceptive dysfunction in chronic back pain patients.

Sagittal balance

Humans stand and walk best if they can keep their frame in balance, which means, when standing, the head is over the hips, which in turn are over the heels. In other words, the gravity line goes through the cervicothoracic junction and the lumbosacral joint. Deviations from this (usually forward) overload the posterior lumbar musculature and require compensatory hip extension and knee flexion. All may be well at skeletal maturity, but loss of balance may follow kyphosis due to disc degeneration and fractures. Imbalance has become increasingly recognized as an important cause of back pain. Surgery can be used to correct imbalance by osteotomy or facetectomy during fusion, but milder cases may well respond to rehabilitation and exercise.

Spinal stenosis

There is anecdotal evidence that adults with spinal stenosis have a long history of back pain. Arguably the flexed posture these individuals adopt may be a contributory factor to sagittal imbalance. There is experimental evidence that these individuals are at more risk of trouble with their backs if they have a disc prolapse.

Assessment of instability

A good history is essential. The ‘ideal’ patient for spinal fusion, may have some or all of the following characteristics: a non-smoking ‘normal citizen’; no litigation outstanding or other potential secondary gains from his or her pain; a clear history; and a crescendo of symptoms, but with pain-free or low pain intervals. Some patients with recurrent attacks of pain report prodromal symptoms preceding an attack. Surgeons have tried many methods to identify good responders: for example, a trial period in external splintage, or a rational response to discography. External fixation has also been tried, but has not proved popular because of complications and poor predictive ability. Flexion–extension radiographs have been used for many years, but their value is very limited. Standing views may be of value if the gravity line or whole body can be included. This approach remains experimental.

Confounding factors

Failures of the surgical approach can be attributed to two main areas: the patient and the surgical methodology.

The patient

A technically correct operation achieving a solid fusion may not relieve pain, and indeed it can make it worse. There may be a variety of reasons for this.

1) Patient selection. Often significant psychosocial factors contribute to the extent of pain-related distress and disability. Even the most experienced surgeons can be caught out. Some surgeons make use of psychological questionnaires to aid
in the selection of patients, but there is no good study to show that using these methods improves results. Ideally a pain psychologist should identify the degree of psychosocial involvement before the surgeon embarks upon surgical treatment. Pain-related distress should be treated first.

2) Poor recognition of sagittal imbalance
3) The wrong levels may be selected for surgery
4) Smoking cigarettes has been associated with a high pseudarthrosis rate in many studies
5) Involvement in litigation or worker’s compensation has long been recognized as being associated with poor clinical results.

Surgical methodology

The objective of most procedures is to obtain a solid bony fusion, avoiding damage to the surrounding soft tissues. A wide variety of methods are available, and comparisons between them are difficult. Posterolateral fusions tend to be easier to perform, but are probably less reliable in terms of both fusion rates and in immobilizing a segment (or functional spinal unit). Interbody fusions, either from the back or from the front, are more likely to fuse with instrumentation, but are technically more difficult to perform, and carry a higher risk of complication. Spinal instrumentation has evolved rapidly, increasing in complexity and expense. It has been difficult to demonstrate that its use has any advantage. Some studies, but not all, suggest that the use of instrumentation increases the fusion rate. Unfortunately this is not necessarily accompanied by an improvement in clinical results. The evidence base would support the use of uninstrumented posterolateral fusion as the best option with lowest complication rate.

**Discography**

It is likely that a significant proportion of patients have discogenic or segmental pain. Proponents of this view use provocative discography to identify painful segments. Discography can identify segments where pain is reproduced by injection of saline into the disc and adjacent normal discs. It identifies patients with inappropriate responses (over-reaction to local anaesthetic or skin penetration by needle) and inappropriate or multilevel response to disc injection. The ‘normal’ disc is usually pain free when injected. There is a large literature on this, but many studies are flawed. Carragee’s studies are a good starting point. He was able to demonstrate only a predictive value for discography of 50–60% in spinal fusion patients.

**Use of instrumentation**

The objective of treating these patients is to relieve symptoms and improve function. In theory this requires that a fusion be achieved. There is a close, but by no means total, correlation between fusion and pain relief.

There remains considerable uncertainty surrounding internal fixation. This may be unnecessary for a single-level posterior fusion, but may be useful if more than one level is involved. Certainly the experience with spinal fusion for scoliosis would support this view. Large trials are probably necessary to resolve these issues.

Management of nerve root pain (syn: sciatica, radicular pain)

**Summary points**

- Radicular pain can be diagnosed clinically and confirmed by imaging
- Pain caused by disc herniation can be very severe, but often resolves without intervention
- Surgery is often successful if non-operative treatment fails.

**Introduction**

True nerve root pain has a lifetime prevalence of less than 5%. Lumbar-sacral nerve root pain radiates in the distribution of one or more dermatomes and may be associated with neurological deficits. Although back pain may coexist, the severity of the leg pain predominates. The most common cause is disc prolapse (also called herniation). The majority are at L4/L5 or L5/S1. However, other pathologies which have the potential to compress or irritate a nerve root include tumour, infection, or neuritis. It has become clear in the last few years that disc degeneration and the proportion of degenerate discs that is herniated is driven by genetic factors. Genetics explains 60% of the variance, with minimal contributions from environmental factors such as smoking and trauma. This means that family history should always be explored. There is evidence that mechanical compression of a nerve root results in sensory and/or motor deficits. The onset, duration, and extent of the pressure have been shown to be important. However, compression alone does not cause pain. Some degree of inflammation/irritation must exist for nerve to refer pain. The pathophysiology of nerve root pain is not fully understood. Research has explored the chemical effect of the nucleus pulposus coming into contact with a nerve root, in particular the dorsal root ganglion. A large number of inflammatory and signalling substances, including cytokines (especially tumour necrosis factor, TNF), nitric oxide, and nerve growth factor have been suggested to play a role. There may be an immunological element as well, as the nucleus is normally avascular. It is likely that mechanical and biochemical factors act together, altering intraneural permeability, intraneural blood flow, and nutrition, resulting in degeneration of nerve fibres and reduced nerve conduction.

**Clinical features (Box 3.7.1)**

Root pain caused by disc prolapse is usually preceded by back pain. The interval varies from a few minutes to years. Leg pain usually predominates in a dermatomal distribution. Pain is exacerbated by coughing and sneezing, walking, and standing. Night pain is common. Pain may be relieved by lying and flexing the spine. Root pain (sciatica) can be extremely severe, and associated with numbness and paraesthesia. Weakness may be experienced with poor push-off, flapping gait, and foot drop. The appearance of foot drop is sometimes associated with pain improvement. Perineal numbness, and associated bladder or bowel symptoms are important indicators of cauda equina syndrome but the latter may be associated with pain severity and analgesic intake.

**Box 3.7.1 Features of root pain caused by disc prolapse**

- Back pain precedes leg pain
- Leg pain usually predominates
- Leg pain is in a dermatomal distribution
- Pain is exacerbated by:
  - Coughing and sneezing
  - Walking and standing
  - Night pain is common
- Pain may be relieved by:
  - Lying
  - Flexing the spine
- Weakness may be experienced with:
  - Poor push-off
  - Flapping gait
  - Foot drop.

Examination should include an assessment of sensation to both light touch and pinprick (the end of a paper-clip is effective). Straight-leg raising is restricted. I prefer to flex the hip and knee first, and then gradually and gently extend the knee. This allows
Straight-leg raising is restricted. I prefer to flex the hip and knee first, and then gradually and gently extend the knee. This allows assessment of hip pain, and is unfamiliar to experienced patients with illness behaviour. Weakness should be sought particularly in extension of the great toe and foot, foot eversion, and knee extension. Ankle and knee reflexes must be recorded.

Imaging is best done by magnetic resonance (MR). If this is unavailable or contraindicated, computed tomography or myelography may be used. Disc herniations are seen in up to 25% of normal scans, so it is essential to interpret the scan in light of the clinical picture. Large discs tend to respond better to treatment than small ones. Attention should be paid to the vertebral canal diameter. Small canals give more trouble than large ones. Look out for other contributing factors to nerve pain such as lateral recess and exit foraminal stenosis (Table 3.7.1).

Data from Weber (1983).

Natural history

Nerve root pain caused by disc herniation usually gets better. Unfortunately the time scale is unpredictable. Clinical practice, observational data, and now some useful randomized controlled trials have given reasonably clear guidance on management. No non-operative treatment comes out better than natural history. However, explanation and analgesia, possibly combined with muscle relaxants, are important. Epidurals (either spinal or caudal) do not alter natural history, though the short-term relief of root pain may be convenient for some. Surgery may be indicated from 8 weeks from onset, unless there is evidence of cauda equina involvement or progressive neurological deficit, when surgery is indicated straight away. This is informed by a number of trials, including the SPORT study, and, most recently Peul and colleagues, who compared an early with delayed surgical strategy. All of these favour early surgery over non-operative care in the short/medium term. The patient has to weigh up the risks (persisting pain, nerve damage, cauda equina damage (rare but devastating), dural tears, and recurrence) against (90%) benefit of relief of nerve root pain but not back pain. Earlier studies give a recurrence rate of 10% in 10 years, but Peul and colleagues found 20% at 2 years. There is evidence from one trial that traditional disc space curettage produces inferior results to simple fragment removal. It should be emphasized that these trials are done on patients with clear-cut indications. In clinical practice this not always the case, and there are many studies showing poor outcome when the McColloch criteria are not met (see Box 3.7.2).

Box 3.7.2 Clinical criteria for the diagnosis of a disc rupture causing acute sciatica *

1. Leg pain (including buttock pain and pain radiating below the knee) must follow a radicular distribution and be the dominant complaint when compared with back pain
2. Neurological symptoms (paraesthesia or weakness) should be present in a radicular distribution
3. Straight-leg raising must be significantly reduced
4. Neurological signs (motor, sensory, reflex, and wasting) should be present in a radicular distribution

Indications for discectomy

The prerequisite for any surgical procedure is a precise diagnosis in a patient who is positively motivated to recover from surgery. Not only must the clinical syndrome be obvious (Box 3.7.2), but there must also be a clearly defined, unequivocal lesion on imaging that corresponds, anatomically, with the clinical root level. Where MR imaging is readily available, it has become the imaging modality of first choice.

Strong indications for surgical intervention

- Bladder and bowel involvement, i.e. the cauda equina syndrome: in these patients an acute massive disc herniation causes bladder and bowel paralysis that probably requires immediate surgical excision for the best prognosis
- Progressive motor deficit: in the face of progressing weakness, it is wise to intervene early with surgical excision of the disc herniation.

Relative indications for surgical intervention

- Failure of conservative treatment is the most common reason for surgical intervention for the symptomatic lumbar disc herniation. Conservative treatment should last for at least 6 weeks and not more than 3–4 months, and result in improvement in
the patient’s symptoms and signs

- Very rarely, one will encounter a patient who does not respond to any form of pharmacological or physical pain control within a few days to a few weeks of the onset of sciatica. Their severe incapacitating pain merits urgent surgical consideration.
- Conservative treatment can also fail in that the patient experiences recurrences of the sciatic syndrome.
- Significant motor deficit with significant positive straight-leg raising test: if a patient has grade 3 (or less) motor strength with or without significant straight-leg raising reduction, surgery may be indicated. Weber has shown that these patients eventually recovered just as well with non-surgical intervention. Often these patients are in extreme pain and will not wait for the benefits of conservative care. Occasionally, these patients present with a history of severe pain which has resolved while the neurological deficit has increased. This rare patient is also a surgical candidate. Important points about surgical technique are made in Box 3.7.3.

Box 3.7.3 The principles of surgical intervention for symptomatic disc prolapse

- You are not performing disc surgery, you are decompressing a nerve root.
- You must leave the nerve root freely mobile and undamaged.
- You must leave behind as little scar as possible.
- You must not create further instability in the motion segment.

Lumbar disc herniation in the adolescent patient

The young patient with a disc herniation is a special problem. Because of the high proteoglycan content of the discal material (responsive to chymopapain) and the prevalence of disc protrusions rather than disc extrusions in this age group, I recommend that the optimum treatment is chemonucleolysis rather than surgical intervention. Unfortunately chymopapain is not currently available, although there are hopes that it may return to the market. Surgery can be effective but the recurrence rate is significantly higher than with chymopapain.

Recurrent lumbar disc herniation

The patient who has successful relief of sciatica after disc excision has a 5–20% chance of a recurrent disc rupture causing sciatica. Unfortunately, most recurrent disc herniations are at the same level and same side, and scar tissue from the previous surgery introduces a new element in diagnosis and treatment. Scarring ‘tacks’ down the dura to the back of the disc space so that a smaller amount of herniated nuclear material is capable of producing a significant amount of pain and neurological deficit in the relatively immobile nerve root. Because of the immobility of the scarred dura, transdural ruptures, although rare, can occur. Almost invariably the scar between the dura and the disc restricts migration of the recurrent disc fragments, i.e. on exploration they are routinely found opposite the disc space.

Determining the anatomic level by clinical assessment can be difficult because some neurological changes are residual from the prior lumbar disc herniation, and the dura may not simply be immobilized, it may be distorted from the scar tissue, leading to root involvement lower than usual for the level of the lumbar disc herniation (e.g. a recurrent L4–L5 lumbar disc herniation may affect a number of sacral roots).

Investigation can be difficult to interpret because of the scar tissue. It may be helpful to enhance the MR examination with gadolinium. The surgery is also difficult and prone to complications such as missed lesions, dural tears, and neurological damage. A basic principle in any repeat surgery is to gain as wide an exposure as possible.

Conclusion

Surgical discectomy and/or decompression to relieve sciatica is an operation with clear-cut indications and is usually followed by a high level of success. Microsurgical techniques facilitate the exercises but will not improve an overall success rate of 80–90%. In the end, the decision to operate on a patient with a lumbar disc herniation and/or lateral zone stenosis is largely dependent on patient preference and rarely on necessity. In the short term, however, surgery will result in less pain and improved function compared with conservative care.

Further reading

Summary points

- Neurogenic claudication is a common symptom
- Back pain and leg pain occur with standing and walking
- Spinal stenosis may be developmental or acquired or a combination of both
- An important spinal differential diagnosis is loss of sagittal balance
- There are many causes, both medical and orthopaedic, that may contribute to difficulty with walking and poor outcomes from surgical treatment.

Introduction

Spinal stenosis was described in 1954 by Verbiest. It causes a syndrome that is usually easy to recognize. It includes difficulty with walking (neurogenic claudication). Once considered rare, it is now clear that this syndrome occurs frequently with advancing years. Verbiest recognized two forms: developmental and acquired. Developmental stenosis may be localized to a single level or involve the whole spine. It is almost universally present in achondroplasia. People with narrow canals are probably more likely to encounter trouble with back symptoms than those with wide canals, although the evidence for this statement is not robust. Acquired stenosis is associated with distortions of the spinal canal and exiting nerve root canals. This is secondary to disc degeneration causing narrowing of the disc space, disc bulges, and herniations. This in turn distorts facet joints, which degenerate and throw out osteophytes. The ligamentum flavum loses its elasticity and tends to crumple and thicken, occupying the vertebral canal and compressing the thecal sac and nerve roots. All of this is more marked when the lumbar spine is extended, particularly during standing and walking, and less marked when sitting or squatting. Many patients find they cannot lie on their back and have to sleep in a fetal position.

Clinical presentation

Generally symptoms develop gradually. Some just have back pain, but most have unilateral or bilateral leg symptoms. Most report pain, but some have difficulty in finding words to describe a sensation of heaviness, loss of function, or even giving way. Usually the pain appears after standing or walking for a time. The period may vary from day to day as does the severity. Relief occurs with sitting or squatting. Again this varies but may take 10m or more to recover—much slower than vascular claudication. Many are helped with walking aids such as a supermarket trolley. The main differential diagnoses are those conditions which affect walking and balance. Be especially alert to loss of sagittal balance.

Management

- Investigation is by imaging of the lumbar spine, usually with magnetic resonance imaging. Where this is unavailable, computed tomography or myelography are inferior substitutes. It is important to exclude other causes of claudication, such as peripheral vascular disease
- Non-operative treatment includes explanation, which can often be highly effective; simple analgesics such as paracetamol and sometimes non-steroidal anti-inflammatory drugs. One trial has supported the use of gabapentin; epidural steroids may help; walking aids including portable seats and all-terrain rollators with a seat fitted; light rucksacks (many find carrying shopping in bags increases their symptoms)
- Surgery involves decompressing the cauda equina, lateral recesses, and exit foramina, depending on the radiological anatomy, clinical symptoms, and signs. This can be achieved by a variety of techniques ranging from laminectomy to microdecompression. There is controversy concerning the use of fusion either with or without implants. Fusion is more commonly employed in the United States than elsewhere. It is more likely to be used if the patient has a degenerative spondylolisthesis. This condition most commonly occurs at L4/L5, and is much more frequent in women than in men
- There are a range of devices that can be inserted between the spinous processes to maintain the motion segment in flexion. The role of these devices and their duration of action remain controversial
- The outcome of surgery depends on comorbidity and age. Patients over 80 tend to have worse outcomes (but they also have more comorbidity). As a rule of thumb, 70% of patients will have a good outcome. Even so, few will obtain the walking capacity of their fit contemporaries. Complication rates vary, but for decision making I tell patients 5% will be worse off and may regret the decision to proceed with surgery. This may be due to root damage, cauda equina damage, impaired vascularity, infection, and recurrence. It is not always possible to tell why outcome is poor in a particular case, but it is important to ensure that the decompression was complete. Loss of sagittal balance is sometimes a cause of poor outcome.

Summary points

- Incidence 2–4/1000
- Idiopathic most common pattern
- Sagittal and coronal balance are critical for management of spinal deformity.

Introduction

This chapter gives an overview of the spectrum of spinal deformity, its classification, and the broad principles of management.

Historical review

Spinal deformity has been recognized at least since the Egyptian civilization. Various forms of external traction, bracing, and manipulation have been used to treat these deformities with doubtful benefit. It has been recognized that there are extraordinary deforming forces at work, particularly during growth.

Epidemics of tuberculosis and poliomyelitis in the developed world in the early part of the twentieth century precipitated considerable advances in the management of spinal deformity. Both poliomyelitis and tuberculosis are responsive to public health measures. This is not the case for other forms of scoliosis, despite school screening programmes in some countries. The cause or causes of adolescent idiopathic scoliosis, the most common form of scoliosis, remain elusive.

The convention is to describe the magnitude of curves by Cobb angle, and the direction of convexity (right or left). Scoliosis surgeons usually view erect radiographs as if seen from behind. Radiographs give a two-dimensional view of the spine. Scoliosis is a complex deformity involving rotation of the apical vertebrae out of the curve. This means that at the apex the vertebral body lies lateral to the tip of the spinous process. The experienced eye is familiar with this rotation, and it should be borne in mind when considering the nature and severity of the deformity.

A scoliosis is best seen with the patient bent forward sufficiently to place the apex of the curve on the skyline. If the spine is rotated, this is reflected in a rib hump in the thoracic spine or a loin hump in the lumbar spine (Figure 3.9.1). This is formalized into the Adams forward-bending test. Surface topography is useful for defining and monitoring the changing shape of the back during growth and after treatment. It can reduce the use of radiography, and may detect a deteriorating curve earlier than is the case with radiographs. A variety of commercial systems are in use, including ISIS2 (Figure 3.9.2), although there is no standard for data presentation. ISIS2 offers improved precision and sensitivity to change of rib hump measurements and truncal asymmetry.

Fig. 3.9.1
Adams forward bending test: A) erect; B) flexed.
Sagittal profile and the capacity to keep the head over the hips when standing still are crucial elements in understanding spinal deformity. The spine is usually lordotic at the apex of the curve. Some believe that the lordosis is the underlying cause of the curvature. Kyphosis is an important deformity which is sometimes more dangerous to the spinal cord than scoliosis (Box 3.9.1). The thoracic and sacral regions of the normal spine have physiological kyphosis, which in pathological situations can become excessive. The cervical and lumbar spines are normally lordotic. Loss of lordosis in both parts of the spine can be painful—the so-called flat-back syndrome. If any part of the spine becomes excessively kyphotic, without the capacity to compensate through lordosis, sagittal balance is affected. A localized kyphosis (kyphos or gibbus), for whatever reason, poses a particular threat to the spinal cord. Kyphosis can be assessed clinically by the same methods used for the assessment of scoliosis. Surgical treatment of kyphosis carries a higher risk to spinal cord function compared with surgery for scoliosis.

Box 3.9.1 Kyphosis

- Angular kyphosis secondary to congenital hemivertebrae, tuberculosis, and occasionally fracture tends to progress, even after skeletal maturity, and will cause spinal cord compression
- In general, spinal cord compression due to kyphosis requires anterior decompression and stabilization. Some cases also require posterior fusion
- Surgical correction of kyphosis due to Scheuermann’s disease is rarely indicated, and the result is not always rewarding
- Correction of kyphosis carries a significant risk to spinal cord function.

Clinical evaluation and examination

History

The history should establish the first identification of the deformity and its evolution. Family history is important. The obstetric history, childhood illnesses, and the onset of menarche (the first menstrual period), if relevant, should be reviewed. Many curves are painless, but night pain, rest pain, or fatigue pain should be identified. The patient should be checked for neurological and cardiopulmonary symptoms, and asked about analgesic usage and absence from school or work.

It is useful to establish how aware the patient is of the curve, as this may have a bearing on subsequent management. The distress that a curve causes to the patient and his or her family may be out of proportion to its severity.

Examination (Box 3.9.2)

The examination of scoliotic patients should be carried out with care. Adolescent females in particular are often unused to doctors and are embarrassed to undress. The parents or carers should be present if possible. Gowns may reassure the patient, but conceal vital signs.

Examine the undressed patient from behind while he or she is standing up. Then ask the patient to perform forward and side bending to review the shape of the rib hump and spinal mobility. Assess the level of the pelvis. If the pelvis is tilted, it is sometimes useful to use blocks to level it before assessing the spine. A plumb line from the vertebra prominens should fall through the natal cleft. Deviations from this should be recorded, with the direction measured in centimeters (trunk shift). Sagittal balance should be assessed to ensure the head is over the hips with knees extended.

Signs of puberty are useful for the assessment of growth potential. In girls, pubic hair and breast development occur at the start of the adolescent growth spurt, and menarche towards the end of it. In boys, pubic hair appears before the start of the growth spurt.
Auxillary hair appears at the end of growth in both sexes.

Note any deviations from the normal pattern of curve, and identify the site of any pain by asking the patient to point this out. It is important in the growing child to record height on a growth chart. Some also make regular records of sitting height and weight.

The whole skin should be seen to check for café au lait spots (neurofibromatosis type 1, Chapter 1.13) (Figure 3.9.3). Check for hairy patches, nevi, and dimples in the midline over the spine (present in spinal dysraphism). Note the presence and type of foot deformities, lower-limb asymmetries, truncal and breast asymmetries, skull/facial asymmetries, and handedness.

A neurological examination is important. Focus on evidence of long tract signs (reflexes and plantar responses), evidence of asymmetric muscle wasting, the presence of abnormal abdominal reflexes, posture, gait, and cranial nerve abnormalities.

**Investigations**

**Radiography**

Radiography should be used with caution, particularly in the growing child. Low-dose regimens, fast films, and rare earth screens should be used. Eos claims to involve 10% of this exposure only (http://www.biospacemed.com/). Gonadal shielding can be used after an initial unprotected film. Erect anteroposterior and lateral radiographs, using long plates where necessary, are taken at the first encounter. Supine lateral bending films are only indicated just before surgery to help define the curve for instrumentation. Bone age can be determined by an anteroposterior radiograph of the left wrist, but the Risser sign and the presence of a vertebral ring apophysis provide a good indicator of spinal growth potential.

**Spine shape**

Surface topography has been used to record the shape of the back. A variety of devices from simple to complex are available. The scoliometer measures tilt in degrees; the body contour formulator is a device to transfer shapes onto paper. Surface topography systems, such as Quantec and ISIS2, measure elements not seen on radiographs.

**Imaging**

Magnetic resonance imaging (MRI) is used in patients with pain, where the aetiology is uncertain, and where there is suspicion of tumor or infection.

**Principles of management (Box 3.9.3)**

**Prevention and early detection**

School screening is widely used in some countries. However, its value is questioned in other countries, including the United Kingdom. Detection depends on awareness of scoliosis amongst school doctors, physical education teachers, and ballet teachers, as well as parents. Parents often do not see their teenage children undressed, and so these ad hoc methods can result in late presentation of curves. School screening leads large numbers of teenagers and anxious parents overloading a busy service. Screening also depends on the value of and compliance with early bracing, as it is assumed that this treatment prevents progression of the more severe curves. These issues are discussed in Chapter 3.14.

**Non-surgical techniques**

Apart from bracing and plaster jackets, traction is sometimes used for preoperative correction of stiff or large curves. Many centres
have abandoned these techniques, except for the most severe curves. Halo pelvic traction was a very powerful technique which has largely been abandoned. Halo femoral or halo chair traction is sometimes used in very severe curves. Preoperative Cotrel or dynamic traction is used still in some centres, but there is little evidence of efficacy.

Box 3.9.2 Investigation

The spinal cord should be investigated (usually by MRI) in the following patients:

♦ Those with congenital scoliosis (20% have anomalies, including syrinx, cord anomalies, tumours, diastematomyelia)
♦ Those with abnormal skin markings over the spine or café au lait spots
♦ Those with early-onset idiopathic scoliosis and adolescents presenting younger than 11 years
♦ Those with painful scoliosis
♦ Probably all those having surgery.

Box 3.9.3 Scoliosis

The principles of management include the following:

♦ The greater the potential for growth, the greater the ultimate deformity is likely to be
♦ Periods of rapid growth are often associated with rapid deterioration of the curve
♦ Spinal fusion arrests spinal growth over the fused segment except, possibly, in younger patients, where a posterior fusion does not prevent continuing anterior growth (the crankshaft phenomenon)
♦ The ‘rib hump’ tends to deteriorate with growth, even after a successful spinal fusion
♦ Lung development (elaboration of alveoli) is completed by the age of 7 years. Thereafter the lungs only increase in capacity during normal growth
♦ In general, curves starting at an age of less than 7 years may become sufficiently severe to affect respiratory function
♦ Vital capacity is likely to be less than predicted (calculated from arm span) in curves with a Cobb angle greater than 70 degrees. Significant respiratory dysfunction only occurs in curves with Cobb angles greater than 100 degrees
♦ The cosmetic consequences of scoliosis mainly relate to the size of the rib hump, trunk imbalance, effects on the waistline and pelvic obliquity, and differences in shoulder height. These do not always relate clearly to the site or severity of the scoliosis
♦ In general, thoracic curves are not painful, although some patients (especially adults) complain of fatigue pain. Occasionally this is sufficient for them to opt for surgery. Continuous pain in a child or adolescent is an alarm signal for serious pathology
♦ Thoracolumbar and lumbar curves may well cause pain, especially in adults, which may be sufficient to warrant the risks of surgery. Pain is more likely when one vertebra translates laterally on the one below it and with loss of sagittal and coronal balance.

Surgical techniques

Most techniques depend on obtaining a solid fusion. In posterior surgery, it is vital to destroy the apophyseal (facet) joints. Autologous bone graft is best, but allograft and artificial materials avoid problems with the bone donor site. Unfortunately there is a tendency for the rib hump to recur following fusion, whatever system is used, especially in the younger patient with growth potential. The common surgical techniques used in spinal deformity surgery are described in the rest of this section.

Epiphysiodesis and growing rods and titanium ribs

Epiphysiodesis has a limited place in the management of early-onset idiopathic scoliosis. It involves damaging convex growth plates with a view to preventing progression in the young child. Subcutaneous distraction rods can be distracted at regular operations, but there is a high incidence of complications. Other surgeons use a Luque ‘trolley’, where two rods are fashioned into a U-shape. These are placed with the bend at each end of the curve, and wired onto the laminae. In theory this allows the rods to slide on one another as the spine grows. Titanium ribs (VEPTR) are designed to serially distract the thorax to develop respiratory function.

Box 3.9.4 Curve progression

♦ Curves with Cobb angles greater than 30 degrees at skeletal maturity progress in adult life at a rate of up to 1 degree/year. There is considerable individual variation, but in general the larger the curve, the more it is likely to deteriorate
♦ All interventions should be viewed as a balance between risk and benefit against the probable outcome if the curve is left untreated
The risks of inducing spinal cord damage up to and including paraplegia during and after surgery vary with different deformities. It is essential that these risks are discussed with patients and their families before embarking on surgical treatment.

- The selection of implant and surgical approach depends on the skills of the surgeon (i.e. what he or she is accustomed to using) and what health service resources can afford. The best results depend on good technique and careful bone grafting. There is still considerable argument about the optimum implant. However, there is no doubt that an implant of some sort is required in most cases.

Costoplasty (thoracoplasty)

These procedures are designed to reduce the size of the rib hump by resecting, transposing, or even transplanting ribs, and are often used at the end of growth. The excised ribs sections can be used as bone graft.

Fusion in situ

This is used where correction is likely to cause spinal cord damage. In the past, prolonged decumbency on a plaster bed was used. Now a well-fitting plaster cast is the norm. A fusion in situ may result if a plaster cast is used (but by no means always), implants are removed because of evidence of spinal cord damage intraoperatively.

Harrington system

The Harrington system is a distraction rod with hooks at each end (Figure 3.9.4) widely used from 1950 to 1980. Good corrections can be obtained, but these may be partially lost before the fusion becomes solid. This technique has not been very successful in derotating curves. It has been enhanced with sublaminar wires (Figure 3.9.5).

</tr>
</thead>
<tbody>
<tr>
<td>Fig. 3.9.5</td>
<td>Harrington rod used with sublaminar wires.</td>
</tr>
</tbody>
</table>
Luque system

Eduardo Luque of Mexico City was the first to promote the use of sublaminar wires. The rods can be contoured so that their lower ends are driven into the pelvis (Galveston technique, Mehdian technique). This is especially valuable in neuromuscular curves with pelvic obliquity. The Hartshill rectangle system uses sublaminar wires. This has been promoted for the fixation of all types of scoliosis, but it is difficult to use and fixation to the pelvis is unsatisfactory. Now it is used to supplement other systems particularly when bone quality is poor. A current sublaminar tape system (universal clamp) shows promise where bone quality is poor.

Double-rod systems

The Cotrel–Dubousset (CD) system was the first specifically designed for the treatment of adolescent idiopathic scoliosis. It depends on contouring a knurled rod in the concavity of the curve. This is secured by hooks and pedicle screws to the spine, and correction is obtained by rotating the rod so that its curve lies in the sagittal plane. A second rod is then placed on the convexity of the curve and secured to hooks and cross-links. This system is adaptable to a wide variety of applications. The Texas Scottish Rite Hospital (TSRH) and Isola systems uses similar techniques, but are engineered using a smooth rod.

The Universal Spine System (USS2) uses side-opening screws and hooks, and a smooth rod which allows the rod to be contoured into the shape required (Figure 3.9.6). The spine can then be pulled onto the rod, obtaining the correction (similar to the Luque method). Variations on these methods are constantly been developed but the extra gains in correction are obtained at high cost.

Anterior systems

The Dwyer system was the first system designed for anterior surgery and was a most important development. It uses titanium screws and staples, which are crimped onto a titanium cable placed in tension around the convexity of the curve. It risks kyphosing the spine. Zielke (VDS) system uses a 4-mm threaded rod which allows selective tightening of each level (not possible with the Dwyer system once the screw head has been crimped onto the cable) and a derotation device which allows superior correction. The disadvantage of this system is that the threaded rods are fiddly and the rod-tightening process is tedious. The rod fracture rate was 10–20%. The Webb–Morley system used a soft rod which is placed in tension like the Dwyer cable, but each screw can be individually adjusted. The TSRH system and latterly the USS2 have also been adapted to the front of the spine (Figure 3.9.7). Here it is possible to use a rod-rotation manoeuvre to obtain correction, as well as pulling the implants onto a prebent rod.
Risk management (Box 3.9.4)

Spinal surgery has become one of the leading specialities involved in litigation (second to obstetrics in the United Kingdom). Good practice and risk management should become second nature to a spine surgeon. Litigation often arises where patient’s expectations of the outcome of a procedure are not matched to reality. The surgeon should give a reasoned account of the possible natural history of the condition (not always easy to do) and a careful explanation of the risks as well as the benefits of a procedure. Careful and regular record-keeping is essential, especially where difficult decisions are involved and when things are going wrong. The consent process is often prolonged, and may be aided by counselling by non-medical practitioners (we use experienced physiotherapists) and contact with other patients who have had similar procedures.
Idiopathic scoliosis

Summary points

- Idiopathic scoliosis is the most common type of scoliosis
- It affects predominantly adolescent females
- Management depends on severity, cosmesis, and prognosis.

Introduction

Terms used in the discussion of scoliosis are defined in Table 3.10.1. Curve patterns are summarized in Table 3.10.2.

</table>

**Incidence**

About 80% of new cases of scoliosis have adolescent idiopathic scoliosis (AIS). Infantile and juvenile idiopathic scolioses comprise 0.5–4% and 7–10% respectively of all idiopathic scolioses. In the 1950s the incidence of infantile idiopathic scoliosis in Europe was high compared with that in North America; current figures are comparable. Up to 10% of adolescents have minor scolioses of less than 10 degrees. The incidence of these small angles is equivalent in boys and girls. A Cobb angle of 10 degrees is generally accepted as the criterion above which a scoliosis exists. The larger the curve, the greater is the female-to-male ratio (Table 3.10.3).

**Aetiology**

The aetiology of idiopathic scoliosis remains elusive. Most work has focused on AIS, and it is clear that a complex and probably multifactorial process is involved. Naturally occurring scoliosis in vertebrates is seen almost exclusively in humans, although a number of animal models for the condition exist. There are many observed differences between convexity and concavity, but it is difficult to distinguish those factors that may be causing the curve from those that may result from it. Current thinking is that there is a defect of central processing or control which plays on a growing spine whose susceptibility to deformation varies from one individual to another. Girls may be more vulnerable to this process because they have a shorter and more rapid adolescent growth of spine than boys. Genetic studies have now identified areas of interest on various chromosomes that predispose to scoliosis and may prove to be the most important aetiological factor.

**Classification**

A spectrum of curve patterns has been classified, either to aid decisions of surgical management or (in one case) to define bracing decisions. There has been increasing interest in the sagittal as opposed to the coronal profile of the spine. Classification by surface topography is still poorly defined, although this is likely to be important in assessing outcome. The Cobb angle (the coronal profile of the spine) remains pre-eminent, although this angle is only one component of a complex change following treatment or observation.

A reliable method of classification is anatomical, describing the direction of the convexity of the curve and the level of the apical vertebra and is widely used whereas the King–Moe classification (Figure 3.10.1), which divides thoracic curves into five types, is now less used. Limitations of the King–Moe classification include poor reliability and the fact that only the coronal plane is considered and scoliosis is a three-dimensional deformity.

Fig. 3.10.1
King–Moe classification system for idiopathic scoliosis: type I, primary lumbar curve greater than the compensatory thoracic curve; type II, primary thoracic curve with compensatory lumbar curve; type III, short pure thoracic curve; type IV, long C-shaped thoracolumbar curve; type V, double thoracic curve with extension into cervical spine and compensatory lumbar curve.

Lenke and coworkers have also developed a classification designed to help surgical decisions in response to dissatisfaction with the King–Moe system. This classification considers structural versus compensatory curves and introduces for the first time the sagittal plane and as important modifier. This system is now widely used but its complexity and poor reproducability often precludes day to day use in the clinical setting for all but the most common curve patterns.

**Natural history**

There have been a number of retrospective reviews of untreated AIS, although most of these series are small. The detailed review by Weinstein in 1999 is an excellent source for these. It is unlikely that further reviews of the natural history of this condition will be possible, as treatment is widely available. It might be self-evident that the more severe the curve at skeletal maturity, the more problems arise, but this accurate generalization is often wrong in individual cases. At one time it was claimed that curves did not progress in adults, but this is clearly not the case for curves greater than 30 degrees. Even so, progression is unpredictable with one adult progressing by 8 degrees and another by 80 degrees. An annual increment of 1 degree can be expected for curves greater than 40 degrees at skeletal maturity. Double curves, lumbar curves (without thoracic cage support), and curves in association with imbalance tend to progress more rapidly.
Cardiorespiratory function

This is not usually an issue in AIS, although an untreated early-onset curve may be bad enough to affect vital capacity. Curves of less than 70 degrees have no measurable effect on vital capacity. Significant reductions in vital capacity occur in curves greater than 100 degrees and, if severe enough, may eventually cause cor pulmonale and shortened life expectancy.

Cosmesis

This is a crucial consequence of AIS. Thoracic curves are associated with a rib hump dependent on the degree of rotation of the apical vertebra. The rib hump ranges from the trivial to the very conspicuous and often it is an oblique shoulder line or pelvis that causes a problem. The distress caused to the patient is very variable, and some will find the risks of surgery justified for very small humps. Others prefer to tolerate a deformity which can be concealed with appropriate clothing. The level of distress should not be underestimated (Figure 3.10.2). It is often the justification for prolonged non-operative treatment and much major surgery in this area. We studied the assessment of cosmesis and developed a scoring system which relates to assessment by independent reviewer. Patient perception may bear only limited relation to the severity of the curve. The Scoliosis Research Society Score attempts to quantify the cosmetic impact of the deformity allowing studies to be performed although little has been published in this important area.

![Click to view larger](Fig. 3.10.2)
A) Appearance of an untreated right-sided 60-degree thoracic curve. B) Lateral view of the thoracic spine showing the lordosis seen in idiopathic scoliosis. This is an important element in the cosmetic deformity.

Lumbar curves are usually less conspicuous than thoracic curves, although they can have an adverse effect on the waistline. Double curves tend to be inconspicuous, but are more prone to progression. Truncal imbalance may cause distress. Curve progression may be associated with loss of height in adults.

Pain

Back pain is common, and there is limited evidence that scoliosis is a major cause of back pain. Thoracic curves in general do not cause significant pain in adolescents, although some do experience apical pain. There is deterioration in the thoracic curve in some adults, especially during pregnancy, and they may experience significant pain.

Thoracolumbar and lumbar curves are more likely to cause back pain. Relief is often provided by lying and precipitated by standing or walking as the day goes on. This is one of the most common reasons for scoliosis surgery in adults, and occasionally in adolescents. Pain is more likely when translation (lateral subluxation) occurs, where one vertebra moves laterally on the one below. This may occur in both primary and secondary curves.

Pregnancy

There is little evidence that the management of pregnancy should be altered in any way because of treated or untreated scoliosis. Epidurals may not be possible if the lumbar spine has been fused posteriorly. Pregnancy may be associated with additional curve progression, but studies have shown variable results.

Neurological problems

Spinal cord compression is a not a problem in untreated AIS. Secondary degenerative changes in the lumbar spine may cause root compression.

Progression during growth
Understanding the potential for progression is the key to management. The probability for progression depends on the following:

- Growth potential
- The severity of the curve
- The site of the curve.

**Growth potential**

A growth chart is the easiest way to see growth potential. Menarche is an important landmark for spinal growth, which occurs most rapidly in the first year premenarche. The Risser sign is the best radiological indicator of growth potential. If the iliac apophysis has not appeared, or has only just appeared, curves are more likely to progress (Risser 0 or 1; see Table 3.10.1).

**Curve severity**

The larger the curve at presentation, the more inevitable is progression. Sixty-eight per cent of curves in the range 20–29 degrees will progress in children with Risser signs of 0 or 1. Curves of over 30 degrees almost invariably progress if there is significant growth potential. Curves of over 50 degrees at skeletal maturity will progress during adult life with an annual increment of at least 1 degree. Some curves in the range 30–50 degrees will progress in adults.

**Site of curve**

Double curves are more likely to progress than single curves as are lumbar curves and thoracolumbar curves without thoracic cage support.

**Management**

Management options are observation, bracing, and surgery. Exercises and physiotherapy regimens are widely used but evidence for efficacy remains anecdotal. Plaster beds and localizer casts are of historical note.

Risks and benefits have to be carefully considered against the severity and potential for deterioration for each individual. The clinician has to be clear on the expectations of patients and their families, and on their capacity to comply with treatment. Careful counselling is essential, and this may require more than one visit to the clinic before treatment is initiated.

**Initial assessment**

A full history includes birth history, age of menarche, childhood illnesses, and family history. Symptoms of the curve, including pain and deformity, and how it originally was discovered should be noted. Pain, if present, needs a full evaluation. Commonly this may be fatigue or apical pain. The pain may be remote from the curve and, especially in adults, irrelevant to it. Pain severity is assessed by its effects on daily life and analgesic intake (if any). Sometimes there may be neurological symptoms of significance such as paraesthesia or numbness. Where relevant, a history of interventions is essential.

**Examination**

Height, weight, sitting height, and span should be recorded on a growth chart. Look at the facies, eyes, and palate. The shape and relative height of the shoulders should be noted, as well as the position of the scapulae. A plumb line from the vertebra prominens allows measurement of any truncal imbalance. Lordosis and kyphosis should be reviewed. Examination should include an assessment of the deformity and its flexibility. The forward-bending test allows assessment of the site and severity of any rib hump (see Chapter 3.9; Figure 3.10.1). Leg length, limb asymmetry, and foot deformities should be noted, and a full inspection of the skin for hairy patches, skin tethering or dimples, and café au lait spots should be performed. Look for evidence of joint laxity. A careful neurological examination should be carried out, paying particular attention to lower-limb reflexes and abdominal reflexes. Cord anomalies may occur without neurological signs or with very subtle signs. Assess the stage of puberty. Pubic hair appears in boys before their growth spurt. Axial hair appears when there is little or no spinal growth in both sexes.

**Radiography**

All efforts should be made to minimize exposure of the growing child to radiation. There is good evidence that excessive radiography in children increases cancer risk in later life. A request for imaging should be justified by a defined therapeutic gain in every case. The spine is assessed by standardized erect anteroposterior and lateral radiographs. Long cassettes should be used if available. Both views should ideally show the head to the proximal femur. Various techniques, including rare-earth screening, have been developed to minimize radiation requirements. Some centres have used coned lateral views of the lumbosacral junction to identify a spondylolysis, but the number of exposures needed to pick up each case is not justified. Supine anteroposterior bending or traction radiographs are needed to define the flexibility of the curve if surgery is impending, but not as part of curve monitoring. In some cases, such as small infants, supine radiographs are best. Comparable views are needed to detect progress.

Follow-up anteroposterior radiographs are widely used, unless the unit is equipped with a device to measure surface topography such as ISIS (see Chapter 3.9; Figure 3.10.2) or Quantec. There is some evidence, at least for ISIS, that curve progression can be identified earlier than radiography, as the ‘rib hump’ leads the development of the scoliosis. This method can significantly reduce radiation exposure.

If the curve is painful, of early onset (under 10 years), morphologically unusual or there is any evidence of neurological abnormality (e.g. hairy patch, dimple, absent abdominal reflex, or lower-limb or foot asymmetry), the spinal cord should be investigated. Many
centres routinely perform magnetic resonance imaging (MRI) of the entire neural axis in the presence of any spinal deformity to rule out spinal dysraphism which is present in 3% of so-called ‘idiopathic curves’. Before any surgery, MRI scan is mandatory. These abnormalities include Arnold–Chiari malformations, syrinx, tethered cord, and diastatomyelia. Computed tomography is rarely indicated in adolescent idiopathic scoliosis.

Counselling

Patients and their parents will need a careful explanation of the condition. In many cultures the majority of people have never heard of the condition. Parents require reassurance that they have not failed in their duty of care to their child. Curves can appear remarkably quickly, so that large curves can present in families familiar with the condition and with a sibling already affected. It is worth checking siblings with a forward-bending test if they are available in the clinic. Parents may rarely see their teenage children’s backs. Patients’ organizations for scoliotics exist in many countries, and some families obtain considerable support and comfort from them (examples are http://www.sauk.org.uk; http://www.srs.org/). Many surgeons have systems in which their experienced patients counsel new ones, particularly those considering surgical treatment. This system needs to be monitored with care to prevent inaccurate or insensitive advice being given.

Treatment options

Treatment options are observation, bracing, or surgery. The surgeon needs to consider the natural history of the curve, and the aspirations and expectations of the patient and his or her family. Treatment places considerable demands on all family members. Some interventions are difficult to sustain in a dysfunctional individual or family. Generally the child or adolescent will decide which treatment option is chosen. If this different from the expectations of the rest of the family, long-term resentments can arise. The family practitioner needs to be kept closely informed of the clinician’s advice.

Observation

Positive aspects

Generally this option is safe. A small curve with a low probability of progression is easy to monitor. The younger child with a small curve may need to be viewed every 4–6 months, depending on growth rate. The passage of time allows the family to absorb the implications of other treatment options.

Negative aspects

The timing of intervention, particularly bracing, may be difficult. In retrospect it is easy to see when treatment has been instituted too late.

Bracing

Many braces have been designed for the treatment of scoliosis. Controversy exists as to what a brace is actually doing (see Chapter 3.14).

Positive aspects

Much controversy surrounds brace treatment. There is one controlled trial comparing the patients of surgeons with a high threshold to bracing with those with a low threshold, which shows small but significant advantages in the treatment group. More recently, a meta-analysis of bracing and natural history papers came out in favor of bracing.

Negative aspects

Brace compliance may be poor. A review suggests that the full conventional regimen of wearing the brace for 23h per day is best. This is difficult for most teenagers, although younger patients usually comply better. Most regimens allow the brace to be removed for sports. Brace wearing from a very young age to adolescence is not usually needed. This regimen may be bitterly resented by the child, and can become a cause of emotional warfare between the child and his or her parents. Blame is then assigned if the regimen fails and surgery is required. Bracing compliance varies with culture and is much more difficult in hot countries. Some studies of brace compliance have cast doubt on how much the brace is actually worn (a conspiracy between children and their parents), while other studies show good accord between compliance and diary. Much depends on the quality of the brace maker and the support services for the families. Braces are expensive, and may need to be changed frequently in a rapidly growing child.

Surgery

The objective in most cases is to fuse the spine in the best possible position. In the past this was achieved using either plaster beds or localizer casts, and required prolonged immobilization (up to a year). These operations were dogged by high pseudarthrosis rates, and were confined to a few dedicated surgeons and patients. The first successful spinal implant was the Harrington rod, which was developed in Texas in the late 1940s and early 1950s during a horrendous poliomyelitis epidemic. Many other implant systems have followed.

Positive aspects

Modern surgical treatment allows early mobilization and often avoids the need for postoperative jacketing and bracing. The pseudarthrosis rate is low; indeed, it is now almost unheard of in AIS.
Negative aspects

This is major surgery with a small but significant risk of spinal cord damage. The Stagnara wake-up test was an important advance, but has been superseded by the clonus test and, more generally, by various forms of spinal cord monitoring. The wake-up test involves voluntary movement of the feet and hands during the surgery. The clonus test exploits the normal phenomenon that clonus can be elicited during the normal waking process. If it is absent, it suggests an interruption of the normal reflex pattern.

Spinal cord monitoring can be sensory, motor, or both. Sensory monitoring is easier and is widely used. Potentials evoked by peripheral nerve or distal spinal cord stimulation are detected by an epidural or cortical electrode. Motor evoked potentials are detected peripherally following magnetic transcranial stimulation or direct stimulation of the spinal cord. Anaesthetic techniques may have to be adjusted to make this possible.

None of these methods are foolproof. The incidence of complication is difficult to determine, although in the 1970s the Scoliosis Research Society collected data suggesting that the risk of paraplegia was 1%. This figure may be too high with current methods, although it is widely used by scoliosis surgeons when counselling their patients for surgery. Early infection is fortunately rare, although a high incidence of unexpected infection has been found with normally non-pathogenic organisms such as Propionibacterium acnes when rods are removed late for pain. Patients should therefore be warned of this late complication as part of the consent process.

Spinal instrumentation and spinal fusion

Preinstrumentation era

Up to the 1950s, none of the various attempts that had been made to develop implants for the stabilization of the spine had been successful. The majority of spinal fusions were obtained by prolonged immobilization in plaster beds or with the use of plaster localizer jackets. Spinal fusion was first described in 1911 by Hibbs and Albee independently in the United States. Fusion, usually using autograft, is an essential component of spinal surgery. If fusion is not used, or fails, the implants will inevitably fail eventually. In the 1940s Allen, in the United Kingdom, developed a bottle-screw device for the instrumentation of scoliosis.

Harrington rod era

This device was developed in Texas in Harrington’s garage. It was the surgeon’s response to the overwhelming poliomyelitis epidemics of the time, which resulted in aggressive and progressive spinal deformities in small children. It consists of a distraction hook, where the upper hook can be moved away from the lower hook on a ratchet. The hooks were initially placed under the laminae. It was immediately successful, although Harrington did not publish until he was sure of the results. Although some modifications were made to the system, it has remained a gold standard for subsequent spinal implants (Figure 3.10.3).

Anterior spinal surgery

Unfortunately, although impressive results were obtained with the Harrington rod, it was not ideal for treating the severe postpolio deformities. Again, it was this condition which, in the late 1960s, led Dwyer, in Australia, to develop his screw and cable system for use on the front of the spine. This was one of the first orthopaedic implants to be made of titanium. This approach revolutionized spinal surgery, although it was many years before anterior spinal surgery became widely adopted. Credit for this goes to Hodgson, a British expatriate surgeon in Hong Kong, who combined Dwyer instrumentation with the Harrington rod. The anterior approach proved to be a most effective method in the management of deforming spinal tuberculosis. Figure 3.10.4 shows the use of a Webb–Morley implant which evolved from the Dwyer system.
Segmental fixation

Once again it was poliomyelitis which precipitated Eduardo Luque of Mexico City to develop a technique based on an earlier Portuguese idea of sublaminar wires. The wires were passed under the lamina of each segment and over a pair of stainless steel rods, which were contoured to the desired shape of the spine. Each rod was bent at right angles at one end (L-rod). This proved to be a productive, economical, and powerful technique for the management of neuromuscular scoliosis. It has been used for all types of scoliosis.

It is a powerful method, but has gained a reputation for a high risk of spinal cord damage. This relates not only to the sublaminar wires, but also to the possibilities offered for overvigorous correction. The technique was modified by adapting it to Harrington rods. This allows the spine to be pulled onto a bent Harrington rod to obtain correction without too much distraction—the Harri–Luque technique. This depends on a modification of the Harrington rod where the rod locks into a square rather than a round socket in the lower hook. This has proved effective in the management of AIS, although it has been superseded by later methods.

Luque rods were also modified to allow pelvic fixation—the Galveston technique. This is still used in the management of neuromuscular curves. Another modification is the joining of the two rods into a rectangle. A variety of versions of this are available, including the Hartshill rectangle.

Double-rod systems

Cotrel and Dubousset (CD) in France developed a whole new concept of correction of scoliosis. Cotrel tried various modifications of the Harrington system including a link between the distraction rod on the concavity and a compression rod on the convexity. This produced a better correction of the curve. He came to realize that this had been obtained at the expense of increasing the rotation of the curve. Although others had appreciated this before, scoliosis surgeons began to realize the importance of rotation of the spine. Dickson in Leeds revitalized the concept of lordosis as an important component of the thoracic deformity of idiopathic scoliosis. He promoted the Harri–Luque concept on the contoured rod.

The CD system of instrumentation was the outcome of Cotrel’s ideas. Here the spine is connected to a contoured knurled rod by a series of hooks and screws in its neutral position. The rod on the concavity is rotated away from the curve, the normal sagittal profile of the spine is recovered, and the implant is locked into position. Distraction and compression can be used subsequently. This system is widely used.

CD has been superseded by the so-called third-generation systems, including Texas Scottish-Rite Hospital (TSRH), the Universal Spine System (USS), Colorado, Legacy, and others. These rely on two rods and increasingly an emphasis is placed on apical translation and derotation with more advance rod connection mechanisms. The concave rod can be contoured and the spine is then pulled towards the rod. There is some evidence (notably for the USS system) that this method improves derotation compared with the CD system (Figures 3.10.5 and 3.10.6) although the benefit of more recent innovations and the use of pedicle screws in isolation are under evaluation.
The revolution in spinal implants has had some important consequences:

1) These powerful techniques probably increase the risks of spinal cord injury compared with a simple Harrington rod procedure, although in most cases the improved correction is self-evident. However, this is counteracted by improved techniques, reduced operative time, and state-of-the-art spinal cord monitoring techniques.

2) Pseudarthrosis has become an increasingly rare risk with the advances in surgical technique summarized previously. However, none of these techniques is possible without strict adherence to classical methods of spinal surgery. These include scrupulous subperiosteal dissection out to the tips of the transverse processes, excision of facet (apophyseal) joints, and bone grafting. Autologous bone is best, although other sources of bone can be used. It should be placed on laminas and transverse processes which have been carefully decorticated.

3) Infection remains a matter of concern, particularly since the introduction of double-rod systems. In our practice, removing the implant (assuming that the fused area has united) usually cures late pain. There is some evidence of immunological suppression after major spinal surgery. There is also a strong suspicion that more metal increases the risk of infection. We, and others, have grown Propionibacterium acnes from cases developing pain several years after apparently successful surgery. At this stage removal of the metalwork resolves the problem (Figure 3.10.6).

Infantile idiopathic scoliosis

This condition is distinct from AIS. It is much less common, and is more frequent in boys than girls. The direction of the curve is more frequently to the left. Many of the curves improve or even resolve with observation. Curves with marked rotation are much less likely to resolve, as was demonstrated by Mehta. She found that a measurement reflecting the difference of angulation of the ribs at the apex of the curve was higher in those whose scoliosis progressed (Figure 3.10.7).
Rib–vertebral angle difference (RVAD). In this example RVAD = 60 – 30 degrees = 30 degrees. If RVAD is greater than 20 degrees, the curve is likely to progress.

Conclusion

There is a diversity of views amongst scoliosis surgeons on decision management in the large ‘grey area’ between patients presenting with small curves and little growth potential (where most parties agree that no intervention is needed) and large curves with much growth potential (where surgical intervention is beneficial). Honest discussion with the family is essential, with a careful weighing of risk and benefit of natural history versus intervention. Surgical treatment and bracing both carry serious risks. Future developments require large trials of operative and non-operative management, the development of outcome measures relevant to appearance and cosmesis, and the longer-term issues of pain and disability. Technology to assess surface topography needs further development to enable the effects of time and treatment to be presented to patients and their families.

Congenital scoliosis and kyphosis

Summary points

- Congenital scoliosis and kyphosis accounts for about 20% patients with spinal deformity
- Associated with other developmental anomalies of neuraxis, cardiovascular and urogenital systems.

Introduction

Congenital scoliosis and kyphosis are deformities of the spine in the coronal and sagittal planes caused by failures of formation or segmentation of the spine, or combinations of both. They are due to a combination of genetic and environmental factors (e.g. alcohol). The notochord appears to be a key structure in pathogenesis. The Pax-1 gene is required for the formation of the ventral parts of the vertebrae during primary segmentation and border formation between structures of the vertebral column. Reduced or impaired Pax-1 gene expression may lead to failure of segmentation (i.e. border formation) and subsequent vertebral fusions. Vertebral malformation is usually apparent on radiographs or on prenatal ultrasound examination. They are frequently related to other mesodermal and ectodermal anomalies, which often arise from the same segments. Cardiac anomalies are commonly associated with congenital scoliosis, which is often first identified from radiographs taken to manage the cardiac problem. At least 20% of cases of congenital scoliosis have anomalies within the vertebral canal, including syrinx formation, and a divided spinal cord. When this occurs, a diastematomyelia may be found. This is a sagittal fibrous or bony band dividing the vertebral canal, dural sheath, or spinal cord.

Embryology

The body axis is established during gastrulation. Cells migrate through the primitive streak and the three layers of the embryonic disc are generated. At about 16 days, some cells pass through the anterior tip of the streak (called Hensen’s node) to give rise to the notochord. The overlying ectoderm becomes the neural plate, later the neural tube. The paraxial mesoderm differentiates into 42–44 small epithelial spheres with central lumina (somites) in a craniocaudal sequence (Figures 3.11.1A and 3.11.2A). The first five (occipital) somites appear in stage 9 (about 20 days). The dorsolateral parts of the somites form dermomyotomes, while the ventromedial parts lose their epithelial structure and form sclerotomes. Cells from these areas migrate to surround the notochord and form the perichordal zone (Figure 3.11.1B).

Fig. 3.11.1
Transverse scheme showing somitic development at 3–6 weeks. A) The neural plate develops folds on both sides as the paraxial mesoderm differentiates into somites. The notochordal plate is in close apposition to the closing neural plate. B) The dorsolateral parts of the somites form dermomyotomes, while the ventromedial parts lose their epithelial structure and form sclerotomes. Cells from these areas migrate to surround the notochord and form the perichordal zone.
Fig. 3.11.2
Coronal scheme demonstrating the formation of the vertebral column. A) Sclerotome cells migrate towards the midline to form the perichordal zone. B) Cranial (low cellular density) and caudal (high cellular density) areas form the sclerotomes. The perichordal zone is still unsegmented. C) Dense and loose areas develop in the perichordal zone. D) The dense areas in the perichordal zone develop into intervertebral discs and the loose areas develop into vertebral centra.

The lateral part of each sclerotome shows a division to loose cranial and dense caudal halves in stage 13 (about 28 days) (Figure 3.11.2B). The loose cranial halves contain the spinal nerves, dorsal roots, ganglia, and the intersegmental vessels, while the dense caudal halves give rise to the lateral processes (ribs and transverse processes) and neural arches of the vertebrae.

At stage 14 (about 32 days), the perichordal zone also shows zones of high and low cell density axially (Figure 3.11.2C). The zone of high cell density contributes to the formation of intervertebral discs, whereas the low-density areas develop into the centra of the vertebrae. Two somites contribute to each vertebral body on both sides. The only deviation from this rule is the five occipital somites forming basiocciput, which becomes the clivus.

Chondrification of the vertebral column begins at 6 post-ovulatory weeks in the vertebral bodies and progresses dorsally and ventrally to the neural arches and rib anlagen.

The first signs of ossification are detectable at about 9 weeks and at birth there are three ossification centres for each vertebra, one for the vertebral body and one for each neural arch. Bone union between these primary ossification centres begins during early childhood. At puberty, secondary ossification centres (apophyses) appear at the tips of spinous processes and vertebral endplates. Atypical vertebrae (atlas, axis, and sacrum) show special patterns of ossification. The notochord expands in the area of discs forming the nucleus pulposus. The notochordal cells disappear by about 10 years. Axial position and vertebral phenotype along the embryonic axis is an early event controlled by the combinatorial expression of Hox genes.

Clinical significance

Common vertebral congenital anomalies are spina bifida, hemivertebrae, wedge vertebrae and fusions. Scoliosis involves deviation and rotation of vertebral bodies and congenital scoliosis may be caused by hemivertebrae and wedge vertebrae and by vertebral bars. Hemivertebrae have an absence of one chondrification centre or possibly lateral deviation of the notochord. A vertebral bar is a localized failure of segmentation. Posterolaterally it will result in progressive combination of lordosis and scoliosis. Anteriorly it will cause progressive kyphosis. Butterfly vertebrae (sagittal cleft vertebrae) are perhaps due to an inadequate amount of sclerotome cells around the notochord or failure of fusion of bilateral chondrification centres. The spectrum of spina bifida ranges from myeloschisis to spina bifida occulta and is due to variably severe defects in neural tube closure. Normally, neurulation is completed by the end of the fourth week. Klippel–Feil sequence and fusion anomalies are a failure of primary segmentation.

Congenital scoliosis

Classification

Classification is an aid to both prognosis and treatment. The McMaster classification is widely acknowledged and based on untreated outcome. Like all classifications, it is idealized and there will always be patterns that do not fit neatly into the scheme. The McMaster system does not encompass the similar defects seen in congenital kyphosis, nor the developmental anomalies of the posterior elements which may be mistaken for idiopathic scoliosis.

The main types are summarized in Table 3.11.1 and illustrated in Figure 3.11.3. The expected degree of progression for the various types is shown in Figure 3.11.4.
### Table 3.11.1 Congenital scoliosis: main types of defect

#### Defects of segmentation
- **Bilateral**
- **Block vertebra**

#### Unilateral
- **Unilateral bar**
- **Unilateral bar and hemivertebra**

#### Defects of formation
- **Pseudarthrosis/agenesis**
- **Hemivertebra**
- **Unilateral complete failure of formation**
- **Fully segmented**
- **Semisegmented**
- **Incarcerated**
- **Unsegmented**
- **Wedge vertebra**
- **Unilateral partial failure of formation**

**Fig. 3.11.4**
Summary of the expected annual progression of the Cobb angle in patients with congenital scoliosis. (Data from McMaster and Ohtsuka (1982).)
Diagnosis

Prenatal ultrasound and postnatal radiographs are the main method of diagnosis. Spinal deformity may be visible from birth. In the absence of significant deformity, congenital anomalies may come to light at any age. It is important to pay particular attention to the spine of a child with lower-limb asymmetries or foot deformities. Congenital vertebral anomalies may be associated with myelodysplasia and lumbosacral agenesis. They are also seen in the VATER (vertebral–anal–cardiac–tracheo–(o)esophageal–renal) syndrome, the Freeman–Sheldon syndrome, and Larsen’s syndrome.

Box 3.11.1 Management of congenital spinal deformity

- Image the spine in two planes
- A dorsal hemivertebra may threaten the spinal cord as the kyphosis develops
- An unsegmented bar or asymmetry of growth plates can progress malignantly and require early surgery
- MRI is an essential investigation.

Natural history

The majority of malformations occur in the thoracic spine or thoracolumbar junction. Those involving failure of segmentation in the cervical spine are usually known as the Klippel–Feil syndrome (Figure 3.11.5). Affected individuals have a short neck, a low posterior hairline, and limited neck movement. The malformations are associated with a wide variety of anomalies including facial asymmetry, cleft palate, ptosis, facial nerve palsy, deafness, torticollis, webbing of the neck, thoracic scoliosis (both congenital and ‘idiopathic’ patterns), Sprengel’s shoulder, a variety of cardiac anomalies, respiratory problems due to chest deformity, and abnormalities of central control. Up to 20% demonstrate mirror movements of the hands (synkinesia), which may be due to spinal cord anomalies; voluntary movement of one hand is associated with involuntary movement of the other. Thirty per cent of affected individuals have genitourinary tract anomalies. A hemivertebra at the lumbosacral junction causes a particularly severe deformity and requires early surgical treatment. Vertebral anomalies at the cervicothoracic junction usually cannot be corrected surgically, and require early fusion in situ. Occasionally there are anomalies separated by apparently normal vertebrae. Cures may develop above and below congenital anomalies, as well as the more usual pattern with the anomaly at the apex of the curve. Neurological deficit is very unusual in scoliosis, unless there is spinal cord anomaly or diastematomyelia. It is common in congenital kyphosis.

Fig. 3.11.5
L5 hemivertebra.

Congenital kyphosis

This may occur through failure of formation, failure of segmentation, and rotatory dislocation of the spine. Failure of formation may occur, very rarely with, or without dislocation of the vertebral canal. A dorsal hemivertebra will cause a kyphosis. This will be more severe if the vertebral body does not form at all. These are dangerous deformities, and usually progress and may cause spinal cord compression. This produces an insidious myelopathy, which may not be recognized until the deficit is profound. If left untreated, these deformities eventually cause a complete paraplegia. Therefore they require early surgery. An unusual, but particularly dangerous, pattern is when a congenital scoliosis is combined with a kyphotic element and dislocation of the canal. This requires fusion in situ at diagnosis.

Natural history
McMaster and Singh have published a series of 112 patients with congenital kyphosis. They distinguished 68 patients with type I kyphosis (failure of anterior formation of a vertebral body), 24 with type II (failure of anterior segmentation), and 12 with type III (mixed type). Eight were unclassifiable (Type IV). These anomalies can occur at any level in the spine, but 66% of all types had an apex between T10 and L1. All progressed during adolescence, but certain patterns were particularly dangerous.

**Differential diagnosis**

Infantile idiopathic scoliosis is diagnosed in the absence of recognized congenital malformations. Congenital scoliosis is seen in some rare syndromes such as spondylothoracic dysplasia (Jacko-Levin syndrome), the VATER association, Goldenhar syndrome, Russell–Silver syndrome, Williams syndrome, and rarely in common syndromes such as Down syndrome. Freeman–Sheldon syndrome and Larsen’s syndrome may also have congenital spinal deformities.

**Presentation**

Cases may present throughout life, although the majority of severe cases will present in the first 2 years of life. Prenatal ultrasound identifies an increasing proportion of cases.

Cases are often spotted by the parents, and a low threshold for requesting spinal radiography is needed when there is clinical suspicion of spinal deformity. A common reason for referral to a spine surgeon is diagnosis from a chest radiograph taken during investigation of cardiac anomalies found at routine postnatal examination.

There may be anomalies of posterior elements that are undiagnosed. They may be found incidentally during surgery of ‘idiopathic’ scoliosis and risk surgical damage to the cord.

**Associated anomalies**

There is a high incidence of associated anomalies in children with congenital scoliosis, since this is a defect of development of both the mesoderm and the ectoderm. These include spinal, cardiac, and urogenital anomalies. Rib anomalies are commonly associated with the vertebral anomalies.

**Spinal canal**

Intraspinal anomalies include neurenteric and epidermoid cysts, lipomatoses, teratoma, absent or duplicated nerve roots, flum terminale thickening or tethering, bone or fibrous spurs (diastematomyelia), and diplomyelia. These are best identified by magnetic resonance imaging (MRI), which is an essential preoperative investigation.

**Skin**

Skin dimples, naevi, and hairy patches over the spine should be treated with suspicion. Masses due to lipomata or meningoceles, or the scars of closed meningoceles are also an indication for radiography. There is a probable relationship between spinal dysraphism and congenital scoliosis.

**Lower limb**

Any baby presenting with lower-limb anomalies or leg-length discrepancies should have the spine examined clinically, and probably radiologically. If a congenital scoliosis has been diagnosed, look for asymmetries of the legs and feet, and foot anomalies such as club-foot, vertical talus, cavus foot, etc. Neurological examination should include looking for wasting of muscles and reflex alteration or asymmetry. Unexplained trophic changes in the skin of the foot may be manifestations of spinal cord dysfunction.

**Cardiac anomalies**

Approximately 10% of patients with congenital scoliosis have cardiac anomalies which range from minor to severe.

**Urogenital anomalies**

Renal tract anomalies are seen in 25–40% of cases. These may be identified by ultrasound or contrast radiography. Some are identified from spinal MRI scans. Less commonly there may be uterine or vaginal anomalies.

**Prognosis**

Prognosis depends mainly on the degree of growth-plate asymmetry and growth potential. If a child has a significant curvature by the age of 10 years, there is likely to be a large curve by skeletal maturity. Associated anomalies of the neurological system, cerebral palsy, and other syndromes may also influence prognosis. Cardiac anomalies themselves may not influence curvature of the spine, but the thoracotomies needed to treat them can be detrimental to the spine. If a wide laminectomy is needed to treat intracanal lesions, kyphosis may develop in the presence of a neurological deficit. Generally, children with congenital scoliosis are shorter than average.

Prognosis is important in this condition and given in Figure 3.11.6.
## Management of congenital scoliosis

- Curves showing strong asymmetry of growth plates are likely to progress, particularly if there is an unsegmented bar.
- A majority of patients with congenital scoliosis tend to be short.
- Growth in an area of deformity tends to increase the deformity rather than increasing height.
- Associated anomalies may well affect prognosis.
- Lung development continues to the age of 7 years, so that severe chest deformities before this age are associated with reduced pulmonary development. Respiratory function is significantly diminished in curves with Cobb angles greater than 70 degrees.
- Congenital curves of less than 30 degrees by the age of 10 years are less likely to progress than those over 30 degrees.
- MRI is essential.

### Management (Box 3.11.1 and Box 3.11.2)

Plain radiography is essential for evaluating and monitoring the progress of the curve. Once the child can sit or stand, an erect whole-spine radiograph is best. In younger children, radiographs every 6 months are necessary to monitor the curve. Measurement of the Cobb angle is not very accurate (within 5 degrees at best), so that significant small changes may be missed. Close attention to the behaviour of the more aggressive patterns is essential, with regular and regularized radiographs. Older children can be monitored with surface topography where it is available. Plain radiography can usually be used to evaluate the bony anatomy and pedicle widening, and to identify ossified diastematomyelia.

MRI scanning of the spine, including the craniocervical junction, is essential in all patients with congenital scoliosis. If surgery is not contemplated, this investigation can wait until the child is old enough to cooperate with the investigation without a general anaesthetic. The object is to identify spinal anomalies. If any are found, the patient should be sent for advice from a neurosurgeon.

Controversy exists on the advisability of surgical resection of spurs, dividing the filum of tethered cords, and drainage of cysts. Generally the threshold for surgery is lower where there is an actual or progressive neurological deficit.

In general, bracing does not have much to offer patients with congenital scoliosis. It can be used to buy time when surgery is threatened in a small child. However a 'wait and see' policy is usually ill advised.

Surgery should be attempted sooner rather than later, particularly in the malignant patterns and in hemivertebrae at the lumbosacral junction.

### Surgical options

#### Fusion in situ

The simplest procedure is a posterior fusion in situ. Clearly, the earlier this is done, the smaller will be the curve and consequent deformity. Posterior fusion is usually appropriate for the cervicothoracic junction because the risk of obtaining anterior access at these levels is unjustified. Elsewhere in the spine this is usually combined with an anterior fusion. The posterior procedure alone does not prevent continuing anterior growth and the ‘crankshaft phenomenon’. However, it is the safest option in the presence of spinal cord anomalies. This type of surgery may prevent progression, but does nothing for present cosmesis except that the brace can be removed once the fusion is established.

#### Posterior fusion with correction

It is sometimes possible to correct mobile curves associated with a congenital malformation with modern instrumentation systems. It is important that congenital anomalies of the spinal cord are identified preoperatively, as correction of the curve may cause paraplegia.
Epiphysiodesis

A convex growth arrest involves a combined anterior and posterior ablation of growth plates. Normally rib graft is available from the anterior approach.

The best result is an improvement in the curve. Otherwise there should be stabilization of the curve. If the curve progresses, then instrumentation and an extended fusion is needed.

Osteotomy

This is an option where there is a block vertebra or where a previous fusion in situ has been performed.

Vertebrectomy

This is the procedure of choice for treating an isolated hemivertebra, particularly at the lumbosacral junction.

VEPTR or titanium rib

This technique depends on expanding the thoracic cavity unilaterally or bilaterally. Serial lengthening is needed, followed by definitive fusion.

Management of spinal cord abnormalities

This is outside the scope of this book. Neurosurgical advice is essential.

Neuromuscular scoliosis

Introduction

Neuromuscular scoliosis is the term given to that group of scoliotic deformities associated with muscle weakness of any origin (in the past, the term paralytic was used to describe this group of scoliosis). Neuromuscular scoliosis is usually classified into neuropathic and myopathic disease. Neuropathic disorders responsible for neuromuscular scoliosis include upper motor neuron conditions such as cerebral palsy, spino cerebellar degeneration, syringomyelia, spinal cord trauma, and spinal cord tumours. Lower motor neuron lesions include spinal muscular atrophy (SMA), poliomyelitis, other viral myelitides, myelomeningocele, and trauma. Neuropathic abnormalities also include dysautonomia. Myopathic pathology includes muscular dystrophy, particularly Duchenne muscular dystrophy, the congenital myopathies, congenital hypotonia, myotonia dystrophica, and arthrogryposis.

This classification does not indicate the relative frequency of neuromuscular scoliosis or the frequency of surgical intervention. More important, it does not indicate the type of scoliosis. The surgical treatment depends on the type of scoliosis and the underlying disease, rather than on whether the underlying lesion is neuropathic or myopathic.

In neuromuscular scoliosis, a child already hampered by an underlying and usually incurable condition is further disabled by progressive deformity that aggravates the functional deficit, compromises cardiorespiratory function, and transforms a normal-looking child into one twisted and perhaps crouched in a wheelchair. While it is not preventable by any currently available methods, it is a serious problem that is worth recognizing early so that prompt assessment can be made and an optimal management protocol adopted. Historically, many of the developments in this area were based on experiences with polio, which was complicated by progressive spinal deformity in some cases. This was partly but not wholly explained by asymmetry of muscle tone and strength and partly by severity and extent of involvement. Many of the implant systems now used date back to the polio era.

Presentation and natural history

Scoliosis presents as visible deformity of the trunk, and physicians and therapists should be aware of its increased incidence in children with mental or physical disability. The first indication may be shoulder or pelvic obliquity, rib hump, visible spinal curvature or, in the case of non-ambulant patients, loss of sitting balance. Initial assessment must include careful physical examination with recording of side and site of deformity, trunk balance, height of rib hump and shoulder inequality, pelvic obliquity, leg-length discrepancy, general mobility, and levels of intelligence (school grade), and social independence. The appearance of the deformity should be documented by clinical photography and surface topography, and the nature of structural bony deformity determined by radiography. Radiographs should include erect anteroposterior and lateral views of the spine, either standing or seated as appropriate, and left wrist for indication of bone age. Scoliosis measurements are best made by the Cobb method. More detailed analysis such as magnetic resonance imaging (MRI) and computed tomography (CT) may be indicated in particular cases or where surgery is contemplated. Because of the more severe effects of spinal deformity on children whose muscle function is already compromised, respiratory and cardiac assessment are essential, as well as complete neurological evaluation. Figure 3.12.1 shows the clinical and radiological appearance of scoliosis in a 16-year-old boy who had suffered a traumatic paraplegia at the age of 4.
Because children with neuromuscular scoliosis frequently have other significant problems, the effect of their deformity must always be seen in its complete context and not considered in isolation. Severe scoliosis is an ugly deformity, but to describe this as ‘cosmetic’ should not belittle the patient’s complaint. Other problems include cardiorespiratory restriction, secondary to the mechanical inefficiency of deformed chest cage working with inadequate nerve and muscle structures. Patients with restricted ambulation may have increased difficulty as trunk imbalance increases and pelvic obliquity causes hip problems and apparent leg-length inequality. Pain is sometimes an issue and can be helped by surgery.

Non-ambulant patients confined mostly or exclusively to a wheelchair show a very distinctive curve pattern with a thoracolumbar apex and a long swinging C shape that includes an oblique pelvis, almost as if it were the last vertebra in the curve (Figures 3.12.1B and 3.12.2). This pelvic obliquity is difficult to measure accurately but is the source of a significant proportion of the ill effects of spinal deformity in this group. In addition to cardiopulmonary compromise and cosmetic effect, wheelchair sitters will lose the ability to sit unsupported as the pelvis becomes more oblique (Figure 3.12.1A). Thus, needing one hand for support in their activities of daily living, they are reduced to single-handed function and further disability. This may be manifest in increased difficulty in all functions such as transfer from bed to chair, self-catheterization, or merely a simple two-handed task such as eating or dealing cards. Skin ulceration is another and potentially fatal complication. While neural deficit always carries the risk of pressure sores around the buttocks, sacrum, and hips, this may be complicated by pelvic obliquity as its progression presents new areas of skin with greater or lesser underlying bony points to do the damage. Pain or discomfort means that sitting times or tolerance may diminish.

Neuromuscular kyphosis is less common but carries the similar cardiopulmonary and cosmetic complications. In addition, severe kyphosis entails the strong possibility of spinal cord compression, which is not generally the case with lateral curvature of the spine.

Prognosis in neuromuscular scoliosis is generally of steady progression during growth, more rapid during phases of growth spurt, and significant slowdown but not complete arrest at skeletal maturity. Morbidity or mortality may result from the scoliosis itself or from the underlying condition, and neither should be considered in isolation. Management decisions must be based on present deformity, pain or discomfort, projected progression, the implications of increased functional deficit of any sort, and life expectancy. In the end, it is an individual judgement call that should take into account the views of the patient and of all the carers involved with the child.

Management

Exercises and other physical manoeuvres and orthotics are ineffectual in controlling progression in neuromuscular scoliosis, and it is fruitless to burden children already disabled with further invasion of their lives. Surgery, on the other hand, has a longer history for this type of scoliosis than any other varieties. Because surgery offers the only effective method of improving a scoliotic deformity, the indications and contraindications, advantages and risks, should be well understood and discussed before a decision is made. The aim of surgery is to reduce deformity, prevent progression, reduce pain and discomfort, preserve cardiorespiratory function, and maintain motor function and activities of daily living. Ten years ago, a child with severe mental and physical disability having little or no appreciation of their appearance, and mobility so limited that demands on respiration were minimal, will have had little to gain from surgery that was painful, major, and dangerous. This view has to be revisited in the face of other advances in medicine where these children are living longer and studies supporting intervention are published.

It should be remembered that scoliosis surgery is primarily a spinal fusion, the artificial stiffening of a spine that has been manually straightened to reduce the curve and its consequences. This is achieved by bone graft and metal implants. Improvements in posterior techniques have reduced the need for anterior procedures. An important objective is to prevent and treat pelvic obliquity. Bone grafting from the pelvis is much less needed as artificial agents to stimulate fusion become more widely available. Respiratory function improvement is not commonly found after these operations, but there may be reductions in respiratory...
Respiratory function improvement is not commonly found after these operations, but there may be reductions in respiratory infection rates. Ambulant patients may lose function after their spine is stiffened. The nature of this is not always easy to predict, but can include rolling on the floor, gait, transfers, self-catheterization, self-feeding, protecting pressure areas, and swimming (Figure 3.12.3).

**Duchenne muscular dystrophy and spinal muscle atrophy**

Severe curves in most types of scoliosis (e.g. idiopathic, congenital, and scolioses associated with cerebral palsy and spina bifida) are usually best treated by combined anterior and posterior surgery, but by the time patients with Duchenne muscular dystrophy (DMD) or SMA have developed severe curves, they are not fit for anterior spinal procedures. Progressive curves contribute to loss of forced vital capacity (FVC) (Figure 3.12.4). A 4–5% decrease in FVC occurs for every 10 degrees increase in curvature. In DMD progressive motor weakness accelerates FVC loss. There is some evidence that untreated scoliosis diminishes life expectancy. Progressive increase in pelvic obliquity often makes sitting uncomfortable and may make it impossible. Hips can dislocate or become painful.

**Box 3.12.1 Three types of scoliosis occur in patients with neuromuscular disease**

1. Collapsing curve that involves the entire spine and progressive pelvic obliquity
2. An idiopathic type curve
3. An idiopathic curve which subsequently develops into a collapsing curve.

Over 90% of patients with DMD develop a scoliosis when they become wheelchair bound at an average age of 9.5 years. Once the patient is in a wheelchair, the scoliosis progresses relentlessly to a C shape. This makes sitting uncomfortable and eventually results in loss of sitting balance. Activities of daily living, such as defecation, may become extremely difficult if a patient has a significant pelvic obliquity of 80 degrees or more (Figure 3.12.5). Delayed referral (or where the family will not accept surgery) will mean that a window of opportunity for surgical treatment is lost. Not all DMD cases get scoliosis and it may be that a lordotic spine is protective. There is accumulating evidence that corticosteroids can alter the natural history of DMD. Cardiomyopathy occurs especially in DMD and may restrict the treatment window for scoliosis surgery.
Patients with neuromuscular disease have multiple problems. A multidisciplinary team is essential (including, for example, paediatric neurologist, clinical geneticist, respiratory technician, paediatric cardiologist, paediatric anaesthetist, orthotist, physiotherapist, occupational therapist, and wheelchair and seating experts). From the spine point of view, 6-monthly erect radiographs and respiratory function tests are needed to monitor curve progression with expert input on cardiac function. If a curve starts to progress, then surgery should be considered sooner than later.

Scoliosis in Duchenne muscular dystrophy

DMD is the most rapidly progressive and the most common childhood neuromuscular disorder. It is an X-linked condition and affects only boys. The gene locus is on the short arm of the X chromosome and has been isolated and sequenced. Deficiency of its product dystrophin affects skeletal, cardiac, and smooth muscle. It is a large gene and may display genetic, and hence clinical, heterogeneity. Parents are usually unaware of any problem in the first year of life. About 50% of patients present in the second year with walking and speech delay. They may also present with abnormalities of gait such as toe-walking, a tendency to frequent falling, reluctance to walk, or ‘fainess’. The muscle weakness is relentlessly progressive. The ability to walk is lost on average at 9 years with a range from 6–12 years. Death usually occurs in the teens or early twenties, but life expectancy for some is slowly increasing with new methods of ventilatory support. It is characterized by progressive degeneration of skeletal muscle without an associated structural abnormality in the central nervous system.

Therapy through orthoses or seating

Attempts have been made to control the scoliosis by modifications of the wheelchair and the use of spinal orthoses. Although they may slow its progression, these measures do not prevent the development of a severe curve. Patients do not like orthoses as they lack the muscle power to pull away from any painful pressure area. Furthermore, the orthosis may diminish the already limited lung function in these patients. At best, spinal bracing only slows progression of the curve. Moulded seats can be useful for patients with cerebral palsy, particularly those with severe mental as well as physical disability, but patients with DMD and SMA find them too restrictive and prefer modular seating.

Therapy through standing and ambulation

It is possible to prolong ambulation in patients with DMD by the use of knee–ankle–foot orthoses (KAFOs). These are designed to hyperextend the hips, tightening the Y ligament to maintain the patient’s balance and promoting lumbar lordosis. Swivel walkers and standing frames may also postpone scoliosis and reduce loss of respiratory function.

Surgical stabilization

Scoliosis surgery is indicated in patients with DMD when they have lost independent ambulation, they have developed an early scoliosis, and they are still fit for surgery. Ideally, the surgery should be carried out when the curve is approximately 20 degrees, but often it is not carried out until the curve is more extensive. Fitness for surgery depends on both lung function and cardiac function. Provided that they do not have a cardiomyopathy, it is safe to operate on patients with a forced vital capacity of less than 35% if the anaesthetist is skilled in the management of these patients.

The main role of surgery is to stabilize the spine, improve the existing scoliosis, prevent a deterioration in the curve, and improve any pelvic obliquity. Spinal stabilization gives patients better sitting balance for the remainder of their lives and allows them to continue to sit comfortably in a wheelchair until they die, usually from a respiratory infection. Mobile arm supports may be needed as holding spine in extension makes self-feeding more difficult. One study suggests that life expectancy is increased in those choosing surgical treatment over those who rejected it.

Postoperatively, patients are mobilized early. They start to sit in wheelchairs 3–5 days after surgery. The spinal fixation must be sufficiently strong to obviate the necessity for any postoperative spinal orthoses (Figure 3.12.6).
Kaplan–Meier survival curve in patients with DMD. Both groups of patients were offered surgery. Time zero in the refused-surgery group was when they were offered surgery; in the spinal stabilization group it was when they underwent surgery. Patients who underwent surgery had a significantly longer survival than patients where surgery was declined (p <0.025).

Scoliosis in spinal muscle atrophy

The spinal muscle atrophies are a group of hereditary proximal and symmetrical muscular atrophies associated with degeneration of the anterior horn cells of the spinal cord and in severe cases of the bulbar motor neuron. Inheritance is autosomal recessive. The disorders are caused by an abnormal or missing gene (survival motor neuron gene, SMN1). 3 types are recognized, determined by the age of onset and the severity of symptoms. Type I (Werdnig–Hoffman) is evident at birth or within a few months. Type II (juvenile or intermediate SMA) starts at age 6–18 months, and Type III (Wolffart–Kugelberg–Welander or mild SMA) at ages 3–15 years.

Natural history of spinal muscle atrophy

There is usually a period of apparently normal development followed by an insidious or occasionally relatively acute onset of weakness, and then a plateau during which the weakness remains relatively static. The age of onset is variable and is not an absolute guide to classification. It is associated with weakness of the respiratory muscles, and children with Type I usually die from intercurrent infection before the age of 3 years.

Scoliosis can occur very early (Figure 3.12.7) and develops in the vast majority of patients. It is the most serious deformity occurring in these patients, but dislocation of the hip occurs more frequently than in DMD. Surgery can improve the scoliosis and prevent progression. The immediate impact on respiratory function is probably neutral but it may well prevent progression. Standing with appropriate support is probably beneficial in reducing progression.

Management of scoliosis in spinal muscle atrophy

Because the onset of scoliosis is much earlier, the treatment is slightly different. Once the diagnosis has been made, patients should be persuaded to stand. In the mild group, standing must be encouraged and, if the disease progresses to the extent that the child loses his or her independent mobilization, KAFOs, swivel walkers, or standing frames should be prescribed, depending on the ability of the child to cope with these aids. Once the diagnosis of intermediate SMA has been made, KAFOs or a swivel walker should be provided. In the severe form of the disease, the patient will only be able to stand in a standing frame with trunk support.

Once the child has developed scoliosis, spinal orthoses are indicated to minimize the progression of the curve until he or she is old enough for surgery. Patients as young as 15 months may present with curves of 50–60 degrees or more. Bracing should be continued until the child is old enough for spinal surgery, ideally at least 12 years of age. If bracing or serial plaster jackets cannot control the progression of the curve, earlier surgery may be required. The type of procedure is the same as for DMD with spinal stabilization.
stabilization and facet joint fusion from the upper dorsal spine to the sacrum, and fixation to the sacrum or pelvis. The youngest patient with SMA on whom the author has carried out this procedure was aged 6 years and 9 months at the time of surgery. By that time she had developed a curve of 95 degrees, despite bracing and standing treatment.

As with DMD, the main indication for spinal stabilization is to prevent the progressive deterioration of the scoliosis and the associated progressive pelvic obliquity which makes sitting uncomfortable, if not impossible (Figure 3.12.8). In addition, there may be a positive benefit on lung function, but this is not the indication for surgery.

Fig. 3.12.9
Scoliosis can occur very early in SMA. This 15-month-old boy with the intermediate form had a curve of 53 degrees with associated pelvic obliquity.

Fig. 3.12.10
A female patient with intermediate SMA who was referred when she was no longer fit for surgery. She has a typical C-shaped curve with marked pelvic obliquity and was unable to sit.
Fig. 3.12.8
Lateral radiograph following modified Luque spinal stabilization and fusion in a patient with DMD. A lumbar lordosis has been moulded into the rod. The rod used was an open rectangle, with the closed end wired to the sacrum and the open ends trimmed to length, depending on the height of the patient.

Summary
Neuromuscular scoliosis behaves differently from idiopathic scoliosis. It usually involves the entire spine and is associated with increasing pelvic obliquity that affects sitting balance, makes sitting uncomfortable, and may make sitting impossible. The increased pelvic obliquity may also predispose to dislocation of the hip. In DMD and SMA, the progressive scoliosis is associated with deterioration in lung function, in addition to the impaired lung function secondary to the disease process itself. The development of scoliosis is the most severe of the deformities that can occur in these patients because it has such a devastating effect upon their quality of life. Standing slows down the progression of the curve as well as the deterioration in lung function.

Notes:
* Based on chapters written for first edition by K.M. Dávid and H.A. Crockard.
Summary points

- Syndromes which affect bone and muscle may affect the ability of the spinal column to stay balanced and lead to scoliosis
- Scoliosis associated with syndromes behaves differently from idiopathic scoliosis
- Intervention in syndromic scoliosis may require more complex intervention and multiagency support.

Introduction

Some syndromes have a high incidence of scoliosis. This occurs due to poor neuromuscular control, deficient soft tissue restraints, or dystrophic bone. The intrinsic strength of the spinal column is reduced and deformities have a higher prevalence rate, present earlier in life, and tend to have more serious progression potential.

It is important in syndromal spinal deformities to understand the patient’s needs in a holistic way, and thus the spinal problems should not be divorced from the other, often much greater, needs of the child.

Early-onset progressive scoliosis

Although the development of all the conductive airways is complete at birth, only a relatively small number of respiratory bronchioles and alveoli exist. These multiply many times from the numbers present at birth to their full maturation by the age of 7 years. Restriction of the available space in the thoracic cavity can have a major effect on lung development. After birth until about the age of 7 years the effect is on the number of alveoli rather than the number of airways. Early-onset scoliosis under the age of 7 years, particularly in the first year or two of life, can result in serious future health problems.

Infantile progressive scoliosis

The great majority of infantile idiopathic scoliosis cases are benign and resolve without treatment. Twenty-five per cent do not resolve naturally; in most of these progression can be prevented by treatment or they can be made to resolve eventually. In 5% of infantile idiopathic cases the natural history is severe progression (Figure 3.13.1).

Parameters such as the size of the curve (Cobb angle) and the degree of transverse plane deformity (rib vertebra angle difference (RVAD)) are important criteria in distinguishing possibly progressive from possibly resolving deformities; clinical parameters are far more important. The overall child assessment is more important to assessing potential curve progression. The healthy well child with no significant comorbidities is likely to represent a fetal moulding that normally resolves when tone is fully developed. The neurologically challenged child with associated comorbidities is more likely to progress than the idiopathic scoliosis patient.

In addition to the geometric parameters measurable on a frontal spine film (Figure 3.13.2) (i.e. Cobb angle in excess of 30 degrees and RVAD in excess of 20 degrees), clinical assessment of curve stiffness is also important. The resolving curve tends to be flexible, but the progressive curve, particularly the malignant one, tends to be rigid. Resolving curves readily overcorrect, but
progressive curves hardly change at all.

Fig. 3.13.2
A) Measuring the RVAD at the apex of a curve and measuring Cobb angle: the RVAD is in excess of 20 degrees and Cobb angle is in excess of 30 degrees, indicating progression. (b) The same patient 5 years later after serial EDF casting, showing a much reduced Cobb angle and RVAD. The deformity is now clinically resolving.

Males are affected more than females in a ratio of 3:2. Thoracic curves are more common, but other patterns are not unusual. Most thoracic curves are convex to the left. Right thoracic curves in females and double-structural curves seem to have greater progression potential.

The condition is thought to be due initially to moulding of the malleable infantile skeleton. This is supported by the fact that plagiocephaly, plagiothorax, palgiopelvy, bat ear, and tight sternomastoid are all correlated with the convex side of the scoliosis. There is a higher incidence of mental retardation, congenital hip dislocation, congenital heart disease, and inguinal hernias, and there is a definite familial trend. These additional clinical features strongly support the notion that early-onset progressive scoliosis is syndromal rather than idiopathic. This is confirmed by the association with chromosomal abnormalities.

Treatment

Non-surgical treatment

If the child is diagnosed and referred within the first year of life, conservative treatment can be effective at promoting resolution or preventing progression. The older the presentation, the more difficult it is to achieve these goals. Once the child reaches the age of 4 or 5 years, non-operative treatment is probably of no avail. Serial elongation–derotation–flexion (EDF) casts are applied under a light general anaesthetic every 2 or 3 months, with the precise frequency being determined by growth, hygiene, and the state of the cast. As the plaster hardens, pressure moulding of the spine is carried out to exert an untwisting effect. Windows are then cut in the back and front of the cast to allow vests to be changed whenever required and thus promote hygiene. Once the child has reached the age of 4 or 5 years, the deformity becomes too rigid to be influenced by external cast pressure. The child is then observed at intervals of 6 months. Curves can resolve over several more years, with the rotational component being the last part to disappear. Curves that have been prevented from progressing should clearly be observed regularly throughout the adolescent growth period. There is no evidence that bracing favourably influences the natural history of any form of scoliosis, least of all the early-onset type.

Surgical treatment

Surgery is indicated for cases that have resisted serial cast treatment. It can potentially do more harm than good. As with all structural scolioses, the problem is one of relative anterior spinal overgrowth and therefore a posterior fusion is contraindicated as it will create a tether that may lead to a crankshaft deformity and a worse outcome.

An anterior epiphysiodesis to prevent the anterior growth is essential to prevent further curve progression. The treatment options are then to continue with external splintage or use a posterior growth system (Figure 3.13.3). Posterior growth systems just distract the spine and they require reoperation and lengthening every 6 months in order to gain maximal spinal length. Alternatively the Luque trolley technique implants rods that distract over wires as the spine grows. The disadvantage of the trolley systems is that the spine is opened at all levels whereas the growing rods can be passed submuscularly. Premature growth arrest is possible if the whole spine is opened by a growing pseudarthrosis controlled by the rods occurs in the majority and prevents patients have as many surgeries as with a growth rod. Which ever system is used they have a high complication and reoperation rate requiring intense follow-up and management.
Thoracic insufficiency syndrome

Thoracic insufficiency syndrome (TIS) is used to describe the inability of the thorax to satisfactorily support lung growth, respiratory function, or spine development due to congenital and acquired chest wall, spine, and other syndromic deformities. This is associated with Jeune syndrome (asphyxiating thoracic dysplasia) or Jarcho–Levin syndrome (multiple vertebral and rib fusion anomalies). Traditional spinal arthrodesis will only worsen the pulmonary compromise associated with these conditions and will not correct the thoracic deformity. The titanium rib project developed by Campbell and Smith is an expandable device attached to the ribs and spine. This device is associated with an opening thoracic osteotomy. This device is lengthened 6-monthly until skeletal maturity. These surgeries have allowed thoracic wall expansion to improve lung development.

Neurofibromatosis (see also Chapter 1.13)

There are two main sub-divisions, peripheral neurofibromatosis (NF-1) and central neurofibromatosis (NF-2). Spinal deformities are associated with NF-1 which is the common form of neurofibromatosis, with a prevalence rate of six per 1000. It has an autosomal dominant mode of inheritance with high penetrance but variable expressivity. There is a high mutation rate with many sporadic cases presenting as new mutations. The condition can affect all components of the musculoskeletal system, but the common clinical findings are: nerve sheath tumours; café-au-lait spots; diffuse, soft tissue hypertrophy; subcutaneous nodules; bone hypertrophy; vascular malformation; congenital tibial pseudarthrosis; congenital shortening; osseous cysts; melorheostosis; and neuroendocrine tumours. Any two of the following are considered diagnostic:

- Positive family history
- Positive nodule biopsy
- Six café-au-lait spots measuring at least 1.5cm
- The presence of multiple nodules.

Spinal deformity in NF-1

Those individuals who are minimally affected clinically have deformity patterns which are indistinguishable from their idiopathic counterparts. Patients present with late-onset idiopathic-type scolioses or with late-onset idiopathic-type hyperkyphosis (Scheuermann’s disease). Only careful clinical assessment of these criteria satisfies the diagnosis. These deformities can be managed in the same way as idiopathic deformities. Hyperkyphosis can be successfully treated orthotically.

The scoliosis affecting NF-1 patients is no different from idiopathic scoliosis itself; it is equally resistant to orthotic treatment. Only surgical treatment alters its natural history and the decision to treat is based on the same principles as idiopathic scoliosis. Preoperative magnetic resonance imaging (MRI) scanning is mandatory in order to detect any intracanal abnormalities which could produce neurological problems during surgery.

With NF-1 patients there is a tendency for deformities to reach unacceptable appearance earlier than with ordinary idiopathic scoliosis. The deformity is then at a higher risk of a crankshaft phenomenon if the deformity is only approached from posteriorly. Therefore it is appropriate to carry out an anterior discectomy and growth plate excision before posterior stabilization, in order to prevent late curve deterioration.

In severe NF-1 cases dystrophic bone changes may occur. In the axial skeleton, these include rib pencilling, enlarged intervertebral foraminae, and scalloped vertebral surfaces (Figure 3.13.4). The spinal deformities in severely expressed NF-1 are different. The curves tend to be short, sharp, and angular with a lot of rotation, while the kyphoses are also angular and tend to be in the thoracic or even cervical regions. The two often go together, with a lower thoracic lordoscoliosis and a high thoracic kyphosis above. These dystrophic types of deformity tend to develop at a much younger age and have much more progression potential. The degree of disfigurement produced by a deformity of considerable magnitude, often in association with short stature and other surface deformities, does provide indications for early surgical treatment. Because rapid progression of the dystrophic lordoscoliosis is...
inevitable, there is no sense in withholding surgical treatment. However, combined posterior and anterior surgery is essential, with the focus of attention on the front of the spine. Multiple discectomy with growth-plate ablation is a mandatory first stage (Figure 3.13.5). Definitive posterior instrumentation and fusion should be carried out in the older child, and some form of growing instrumentation should be provided for younger patients.

---

**Mesenchymal disorders**

**Osteogenesis imperfecta**

Represents a group of disorders which arise from primary inherited defects in collagen synthesis with the common feature of bone fragility. The most common biochemical abnormality is defective synthesis of sufficient type I collagen. The diagnosis is usually made on the basis of the presence of blue sclerae or a positive family history. Floppy mitral valves and aortic incompetence are important complications. The disease may be sufficiently mild to resemble those changes seen in idiopathic juvenile osteoporosis.

In severe osteogenesis imperfecta, repeated fracturing occurs which may start in utero, thus producing gross deformity and considerable ambulatory disability. Death is not uncommon either at birth owing to the soft deficient skull or in the first 2 years of life as a result of respiratory infection. Blue sclerae and deafness are less common in severe disease.

Lateral spinal radiographic appearances show multiple compression fractures and biconcave vertebrae. Spinal deformities are rare in mild disease, with a prevalence rate no greater than in idiopathic scoliosis, but patients with severe disease invariably have a spinal deformity (Figure 3.13.6). These are of the two primary types—lordoscoliosis and kyphosis. Bracing can be of some benefit in kyphotic situations, although soft ribs can easily be deformed by the brace. Progressive deformity is difficult to manage because of the soft bone. Some form of segmental instrumentation is required to dissipate loads along with a profuse amount of allograft bank bone to facilitate a solid fusion.
Fig. 3.13.6
A) Severe osteogenesis imperfecta with pelvic and leg deformity. B) These patients always have a scoliosis.

Marfan’s syndrome

A dominantly inherited disorder characterized by skeletal deformity, arachnodactyly, dislocated lenses, and aortic dilatation. Fibroblast-produced collagen is deficient and the soft tissue laxity thereby produced leads to joint hypermobility or dislocation, a tendency to hernias, aortic dilatation, and spinal deformity by increasing the intrinsic load on the spine consequent upon deficient soft tissue support.

Affected individuals are tall and thin, and the increase in stature is disproportionate. The fingers and toes are long and thin, and the palate is high and arched. Aortic incompetence, dissecting aneurysm, and mitral and tricuspid valve disease are the usual causes of death. The correct diagnosis is of extreme importance because many tall slim marfanoid patients present in scoliosis clinics and cardiology review is required after.

The prevalence rate of scoliosis in Marfan’s syndrome is about 50% and the nature of the deformity is very similar to idiopathic scoliosis. The prevalence rate of kyphosis seems to be very small. Double-structural curves are more common in Marfan’s syndrome. Treatment is along the same lines as that recommended for idiopathic scoliosis; for larger curves or earlier onset preliminary anterior discectomy should precede posterior segmental instrumentation and fusion (Figure 3.13.7).

Fig. 3.13.7
A) Severe lumbar scoliosis in a girl with Marfan’s syndrome treated 12 years previously by anterior Dwyer instrumentation. There is clearly a solid interbody fusion. B) Lateral radiographs showing that with time the fusion has bent into significant kyphosis. C) Sideways view of the patient showing a severe deformity which was also very painful. D) After two-stage spinal osteotomy and posterior instrumentation. E) Lateral radiograph 3 years postosteotomy showing an excellent correction of this difficult deformity. Her pain resolved.

Homocystinuria

The condition resembles Marfan’s syndrome but can be differentiated by the presence of widened epiphyses and metaphyses, frequent osteoporosis of the spine, and in particular an increased incidence of thromboembolism. It is due to a deficiency of the enzyme cystathionine synthase. Homocystinuria patients generally have some degree of mental retardation, a malar flush, fair hair, dental crowding, large skull sinuses, and a narrow high-arched palate. The most serious problem is a strong tendency to thrombosis of both arterial and venous systems; in one series, two out of five serious thromboses followed relatively unimportant
elective orthopaedic procedures.

There is platyspondyly on lateral spine radiographs and a 50% incidence of scoliosis on frontal radiographs, which appears to be similar to idiopathic scoliosis.

**Congenital contractural arachnodactyly**

This is an autosomal dominant condition characterized by contractures which are present at birth and tend to affect the proximal interphalangeal joints of the fingers, the elbows, the knees, and the ankles. Spontaneous improvement in these contractures always occurs. In addition, there is dolichostenomelia (long thin limbs), arachnodactyly, and abnormalities of the external ears. Scoliosis can occur; it is similar to idiopathic scoliosis and should be treated similarly.

**Ehlers–Danlos syndrome**

Excessively stretchable, fragile, and bruisable skin is also associated with loose-jointedness. A number of different types of Ehlers–Danlos syndrome have been described; in some there is excessive bruising and bleeding after minor trauma, and in others there is uncontrollable haemorrhage and even spontaneous bowel rupture. Type 6 is the ocular-scoliotic form due to a deficiency of lysyl hydroxylase and is associated with floppy joint hyperextensibility, vascular abnormalities, and an easily ruptured eye globe. Severe scoliosis has been described in several series, but inspection of the data suggests that these are, in fact, fairly mild curves, rather like late-onset idiopathic scoliosis.

**The mucopolysaccharidoses**

These disorders affect the skeleton through failure of normal breakdown of complex carbohydrates which accumulate in the tissues and appear in excess in the urine. As a result many different tissues can be affected, including cartilage, bone, liver, and central nervous system. There are several different types of mucopolysaccharidosis (MPS) but only three are particularly associated with spine problems.

**MPS 1H (Hurler’s syndrome)** produces severe mental and skeletal changes, and death usually occurs by the age of 10 years. The typical facial appearances of prominent eyes, frontal bossing, and coarse features with a flattened nasal bridge gave rise to the original description of gargoylism. There is abdominal enlargement due to hepatosplenomegaly. The fingers are stubby, the hands are broad, and the joints are stiff. There is an oblique acetabulum with subluxating hips. Death occurs from respiratory infection or coronary heart disease due to the accumulation of mucopolysaccharides. The spine is affected by a persistent infantile biconvex vertebral body shape and characteristic vertebral beaking due to failure of the anterosuperior corners of the vertebrae to form, making them hook-shaped. There is a characteristic kyphosis and the attached ribs are paddle shaped.

**MPS II (Hunter’s syndrome)** is less common and milder than Hurler’s syndrome, and affected individuals survive into the third decade. Only males are affected. Again, there is short stature with stubby fingers, stiffness, and contracture. The spinal changes are similar to Hurler’s syndrome but less obvious.

**MPS IV (Morquio’s syndrome)**. There is normal intelligence and variable physical disability, but the major problems are a short-trunked stature with a height of not more than 120cm. There is joint and skin laxity, genu valgum, and corneal clouding. The pelvis is hypoplastic and there is epiphyseal dysplasia. Death tends to occur as a result of either cardiorespiratory failure or spinal cord compression. As with MPS I and MPS II, there is a thoracolumbar kyphosis with platyspondyly and anterior vertebral breaking but there are two additional major spinal problems in Morquio’s syndrome: a thoracolumbar kyphosis (Figure 3.13.8) and atlantoaxial instability as a result of a deficient odontoid. The thoracolumbar kyphosis is associated with a barrel-shaped chest and prominent sternum to the point where premature fusion of the sternal segments with an immobile chest can lead to severe respiratory dysfunction.

![Fig. 3.13.8](https://example.com/image.png)

Typical appearances of platyspondyly and a bullet-shaped thoracolumbar vertebra in Morquio’s syndrome (MPS IV). There are similar lateral spinal appearances in spondyloepiphyseal dysplasia.
If the kyphosis is not severe it can be braced, but if neurological symptoms develop then it must be treated by anterior dural decompression, strut grafting, and posterior metalwork neutralization as with any kyphosis producing cord compression.

C1–2 instability is common and, while there may be clear physical evidence of myelopathy, the neurological signs are often atypical with tiredness, weakness, vague leg pains, paroxysmal tachypnoea, respiratory arrest, syncope, and gait abnormality. Although some of these signs can be bilateral, they are often expressed unilaterally.

The notoriety of C1–2 instability is such that C1–2 fusion should be carried out prophylactically in all cases, and this implies surgery before the age of 10 years.

The bone dysplasias

These are a group of conditions with the common factor that there is disordered development and growth of some part of the skeleton. There are many of these and, as they are not frequently encountered. The Skeletal Dysplasia Society provides guides on the diagnosis and prognosis for these rare conditions and should be consulted when the diagnosis is considered.

Multiple epiphyseal dysplasia is characterized by short stature with significant involvement of the epiphyses of hips and knees. The hands are characteristically short with stubby fingers. The problem here is of irregular epiphyseal growth without normal endochondral ossification while bone modelling is normal. The femoral capital epiphysis is always involved in a severe Perthes disease-like process. Secondary osteoarthritis is common in early adult life. The spine can be involved in a process similar to Scheuermann’s disease and responds to extension bracing. Significant scoliosis is not encountered.

Chondrodysplasia punctata (stippled epiphysis) is characterized by stippled epiphyses, extra-epiphyseal calcification, skin lesions, cataracts, mental retardation, short limbs, and short stature. The spinal stippling is caused by chalky deposits, and there are separate ossification centres for the body and posterior elements giving a characteristic separated appearance on a lateral radiograph (Figure 3.13.9). Spinal deformities, if present, are of the congenital variety with a recognizable anomaly at the curve apex.

Chondrodysplasia punctata. Note the separation of anterior and posterior elements and the chalky deposits.

Achondroplasia is a bone dysplasia with predominantly metaphyseal involvement and is an autosomal dominant condition with the great majority appearing as new mutations. The typical appearance is that of short limbs with short fingers on trident hands, a bulging cranium with a low nasal bridge, and characteristic pelvic changes with squaring of the iliac wings, more horizontal acetabulae, and widening of the upper femoral metaphysis with a short femoral neck.

There are two important effects on the spine in achondroplasia—spinal stenosis and a thoracolumbar kyphosis. Both can give rise to neurological problems. As with other dysplasias and the mucopolysaccharidoses, kyphosis is particularly prevalent and is due to a thoracolumbar anterior wedged bullet-shaped vertebra. This produces a local angular kyphosis (Figure 3.13.10) but, importantly, 90% of these kyphoses resolve spontaneously. Therefore the spine should be observed to allow the natural history to reveal itself. If the kyphosis persists and progresses to the point of neurological disability, anterior dural decompression and strut graft posterior metalwork is necessary.
A bullet-shaped thoracolumbar vertebra is common in skeletal dysplasias and is shown here in achondroplasia. Ninety per cent of these will correct spontaneously.

The most common sites for a stenosis in the achondroplastic subject are the thoracolumbar or upper lumbar regions. The anteroposterior diameter of the spinal canal is particularly reduced. Less than half of achondroplastic individuals have symptoms or signs of spinal stenosis, and less than 20% exhibit objective neurological findings. Preoperative imaging determines the levels that require being decompressed. In the achondroplastic adult, adequate decompression can be carried out by undercutting so as not to jeopardize posterior facet joint stability bilaterally. In the immature spine even this degree of decompression can give rise to a progressive kyphosis and thus concomitant fusion is necessary (Figure 3.13.11). Sometimes preoperative imaging demonstrates a prolapsed intervertebral disk rather than bony canal stenosis as the offending problem.

The upper cervical spine can also be the source of neurological problems because the occipitalization of C1 in association with stenosis of the foramen magnum can give rise to secondary atlantoaxial instability. Fusion from C2 to the occiput in extension is required.

Spondyloepiphyseal dysplasia tarda is associated with mild dysplasia of vertebrae and large joints, with the hips and shoulders particularly affected. It is often confused with Morquio’s syndrome. There is a small pelvis, a deep acetabulum, and a short femoral neck, but the distal epiphyses are not involved. The trunk is short with sternal protrusion and the vertebral changes are typical. There is platyspondyly, but the vertebral bodies are humped posteriorly, differentiating them from multiple epiphyseal dysplasia and MPS IV. Significant kyphosis is not the rule but may have to be dealt with by anterior decompression, strut grafting, and posterior metalwork. Mild kyphoses can benefit from extension bracing.

Spondyloepiphyseal dysplasia congenita is rare. The features of platyspondyly, Scheuermann-type changes of kyphosis, and bullet-shaped thoracolumbar vertebrae are more pronounced than in the tarda variety but can respond to extension bracing.

Diastrophic dysplasia is an autosomal recessive condition of short limbs, club-foot, joint contractures, and spinal deformity. A cystic swelling of the ear in the first few days of life later ossifies to produce the typical ‘cauliflower ear’ deformity. The first metacarpal is short, giving rise to the term ‘hitchhiker’s thumb’. There are dysplastic epiphyses and the hips are particularly severely involved. The club-foot deformity, like early-onset progressive malignant scoliosis, is particularly resistant to correction. Height seldom exceeds 1m.

There are a number of important spinal problems in diastrophic dysplasia. Odontoid hypoplasia can give rise to atlantoaxial instability which may require fusion. The cervical spine is particularly prone to the development of a kyphosis which can in its own right
produce neurological problems and even death. Sometimes the kyphosis can improve spontaneously, and therefore the neurological situation should be closely monitored before prescribing anterior and posterior fusion. Scoliosis is common in dystrophic dysplasia but curvature seldom becomes severe. Because of the relatively young age of patients, anterior and posterior fusion is required. Spina bifida occulta is a virtually constant finding in either the neck or lumbar region, and if instrumentation is to be used then the tethering effect must be preoperatively excluded by MRI scanning prior to the application of metalwork.

Summary points

- Brace treatment has best chance of success in younger children and those with smaller curves
- In most cases it can be expected to stop the curve becoming worse.

Introduction

To brace or not to brace is still a matter of debate. A large number of studies of this question are still being presented, with no less than 459 papers reported in Medline between 1966 and 1995. Most of these papers are retrospective and are open to criticism on various points. A meta-analysis has been published by Rowe and colleagues (1997). A recent Cochrane review states that there is very low quality evidence in favor of using braces, making generalization very difficult. It suggests further prospective studies following Scoliosis Research Society Guidelines.

History

The first effective brace module for idiopathic scoliosis was the Milwaukee brace (Figure 3.14.1). This was molded individually. Module braces, such as the Boston brace (Figure 3.14.2), which are made from prefabricated plastic were then developed. The module is trimmed to the needs of the individual patient and fitted with pads to correct the curvature.

Fig. 3.14.1
The Milwaukee brace.

Fig. 3.14.2
The Boston brace.
Indications

The indication for conservative treatment of idiopathic scoliosis is the possibility of influencing the natural history. This means that we must predict what will happen if the individual case is or is not treated. The natural development of idiopathic scoliosis is influenced by age, sex, stage of pubertal development, skeletal development (Risser sign), and the pattern and progression of the curves.

Bracing is ineffective in curves with a Cobb angle in excess of 50 degrees. To be effective, bracing should reduce the incidence of surgical treatment.

One study compared the effectiveness of brace treatment in adolescent idiopathic scoliosis with non-treated scoliosis cases, all with Cobb angles between 25–35 degrees. This supported the use of brace treatment in this subset of patients. Brace treatment is also supported by a meta-analysis which suggests that the 23-h regimen is better than shorter regimens.

The cosmetic appearance of the trunk is important. Another study showed a 41% improvement of the surface shape during brace treatment, although only a 9% improvement was seen radiographically. Brace treatment probably prevents progression of the Cobb angle, but some have reported improvement. Premenarchal children may have an increased risk of failure compared with older children.

Today, the indications generally suggested are as follows:

- A Cobb angle between 25–45 degrees
- A visible progression of 5 degrees observed during the previous 6 months
- At least 1 year of growth remaining
- Risser sign, 0–3.

Effectiveness depends on compliance; full parental support and cooperation with the orthopedic surgeon, the physiotherapist, and the orthotist is essential. A sufficient number of cases must be treated annually to obtain optimum results. Many new non-rigid braces have entered the market place but the results are no more or less encouraging at this stage than the more traditional rigid braces.

Results of brace treatment

Brace treatment should prevent further progression of the curvature. Usually an improvement of 10–20% is reported. In rare cases the curves are almost completely corrected. The Boston brace is more successful than the Milwaukee brace.

The best results are obtained when the initial correction of the scoliosis in the brace is at least 50%. The poorest results are obtained when there is a hypokyphosis of the thoracic area of less than 20 degrees. The brace must be used for at least 20h a day. It is taken off for sporting activities. Brace treatment must continue until skeletal maturity is reached (Risser 4).

Weaning from the brace treatment must be carried out slowly over a period of 4–6 months. A slow correction loss is often seen after cessation of treatment. The end result is usually a few degrees less than the degree of the scoliosis seen before the start of the treatment. The maximal correction loss is observed within 2 years of the end of the weaning. A follow-up of 2 years has been found to be enough to predict failure.

The failure rates ranges up to 30%. The reasons for these variations are mainly different indications for bracing.

Conclusion

Brace treatment of idiopathic scoliosis may influence the natural history in some individuals and may reduce the number of patients requiring surgical treatment. Close monitoring is required.

Iatrogenic spinal deformity

DOI: 10.1093/med/9780199550647.003.003015

Summary points

- Laminectomy, especially in the growing child can lead to late kyphosis
- Various strategies are available to prevent this.

Introduction

Iatrogenic spinal deformity is an abnormal alignment of the spine which is caused by medical treatment.

Aetiology

There are three main causes of iatrogenic deformity:

1) Postdecompressive surgery
2) Post-thoracic surgery
3) Postirradiation.

Teratogenic events can lead to spinal maldevelopment in utero.

Postdecompressive surgery deformity

Adults

This is a relatively common complication of spinal surgery in adults. It is caused by excessive removal of the posterior elements of the spine and/or a failure to recognize lesser spinal deformity in the coronal or sagittal plane prior to surgery because sole reliance has been placed upon magnetic resonance imaging for preoperative assessment. Spondylolisthesis due to excessive facet (zygapophysial) joint resection is the most common problem but lateral subluxation (especially at L4/5 and less so at L3/4). The integrity and orientation of the facet joints is critical to spinal stability. If more than 50% of the facet joint is excised, there is a significant risk of subluxation. This may precipitate spinal stenosis (see Chapter 3.8). The recognition of this complication by spinal surgeons has reduced the incidence of this complication. The identification of an underlying spinal deformity must be identified preoperatively so that the problem is not exacerbated by injudicious decompression.

Children

Multilevel laminectomies in children (usually for the treatment of spinal tumours) have a high incidence of late kyphosis. This occurs in up to 50% of children undergoing multilevel cervical laminectomy. The younger the child at the time of surgery, the more likely it is that deformity will occur. The facet joints are more horizontal in children than adults and therefore the risk of kyphosis is greater. In the young, the initial kyphosis may lead to anterior wedging of the vertebrae, resulting in further kyphosis. The posterior ligaments and the paraspinal musculature also play an important role in maintaining the sagittal profile of the spine. Disruption of these during major surgery may encourage kyphosis. Kyphosis is the most common deformity following multilevel laminectomy and is progressive with a risk of neurological deficit. The level of the surgery is important. The cervical spine is most at risk, followed by the thoracic spine (Figures 3.15.1 and 3.15.2). The lumbar spine is rarely affected.

Fig. 3.15.1
A) Preoperative MRI of a 4-year-old girl who presented with an intradural tumour. She subsequently underwent C3–7 laminectomy. B) The postoperative MRI which demonstrates the loss of normal cervical lordosis. The patient developed a
progressive cervicothoracic kyphosis which required correction and stabilization with ligament reconstruction.

Fig. 3.15.2
A lateral thoracic spinal radiograph of a boy who presented with a thoracic cord astrocytoma. He subsequently underwent T3–7 laminectomy followed by radiotherapy. The radiograph shows that, following surgery, the patient developed a progressive thoracic kyphosis measuring 90 degrees from T2 to T12.

Scoliosis rarely occurs following laminectomy and is usually caused by the pathology which precipitated the original surgery or its treatment. Scoliosis may be a presenting feature of a spinal tumour (Figure 3.15.3). Surgical excision of the tumour does not prevent progression of the curve.

Fig. 3.15.3
A progressive scoliosis developed in this boy who had undergone thoracic surgery followed by irradiation for an intrathoracic tumour.

Lordosis

Lordosis of the spine, producing a characteristic swan-neck deformity, may be seen following multilevel cervical laminectomy. Lordosis also occurs as a compensatory effect above an iatrogenic thoracic kyphosis and in the lumbar spine after extensive laminectomy.

Management

Prevention is the most effective method of treating this condition. Surgeons should try to preserve the posterior structures, especially the facet joints and ligaments. Liaison between the neurosurgeon and the orthopaedic spinal surgeon are important with prevention and appropriate primary surgery being preferable to revision surgery and stabilization. Laminoplasty (instead of laminectomy) has been shown to have a reduced incidence of kyphosis in the cervical spine in children. Instrumented spinal fusion at the time of surgery may be appropriate; for example, in spinal stenosis with coexistent degenerative spondylolisthesis.

Long-term postoperative follow-up is mandatory, especially in the young patient at risk. External support by bracing or a halo-jacket may be helpful in preventing progression. If the deformity is progressive, *in situ* fusion or correction and fusion are the best
approaches. A combined anterior and posterior approach will be necessary for correction of a kyphosis.

Ligament reconstruction has been described for postcervical laminectomy deformity. The theoretical advantage of this technique over fusion means that the growing child can gain some longitudinal growth and not be doomed to a shortened cervical spine. This may occur if the neck is fused at a young age, preventing further growth.

Post-thoracic surgery deformity

The removal of ribs in a growing child can destabilize the thoracic spine and lead to the development of scoliosis. The more ribs that are removed, and the closer the ribs are resected to the spine, the worse the resulting deformity. The curve deviates with the convex side to the side of the rib resection. In the developed world, the most common cause of thoracogenic deformity is the resection of multiple ribs for the treatment of malignancy. Elsewhere, tuberculosis is the main cause of this deformity.

Treatment

Conservative treatment is not usually possible. The absence of lateral ribs prevents the application of a brace to apply pressure to the spine. Instrumented correction and stabilization are required for progressive curves.

Postirradiation deformity

Radiotherapy is used as a treatment for childhood tumours, such as Wilms’ tumour and neuroblastomas. The normal growth of the spine may be affected, leading to spinal deformity. The epiphysis is particularly susceptible to radiation damage. The first case of scoliosis induced by radiation was described by Arkin and colleagues in 1950. Skeletally immature patients who receive more than 1000cGy are at risk. The risk of deformity increases with the amount of radiation absorbed. Asymmetric radiation is more likely to lead to scoliosis and symmetric radiation may lead to a kyphotic deformity. In another study, it was noted that 59 out of 81 patients who had radiotherapy for Wilms’ tumour developed a subsequent scoliosis.

The younger the patient at the time of exposure to radiation, the more risk there is of spinal deformity. Patients aged less than 2 years at the time of radiotherapy are particularly at risk.

Management

All paediatric patients undergoing spinal irradiation require follow-up by an orthopaedic surgeon or spine specialist until skeletal maturity. The principles for bracing or surgical management are the same as those for idiopathic deformity (Chapter 3.10). The risk of pseudarthrosis and infection is high, and healing may be prolonged if surgery is undertaken.

Conclusion

The importance of iatrogenic deformity lies in its recognition and prevention. This is certainly true for postlaminectomy deformity. Reducing the extent of surgery on the thoracic cage will decrease the risk of post-thoracotomy deformity. Radiation therapy is likely to generate spinal deformity, and these patients require vigilant follow-up. In adults, the most common deformity occurs as a result of a failure to fully appreciate the position of the spine preoperatively followed by injudicious decompressive surgery.
Summary points

- Kyphosis may be a focal deformity limited to a few spinal segments or a more global problem involving the thoraco-lumbar spine
- The causes are myriad and reflect all the disease processes that affect bone
- As well as producing pain from disturbed sagittal balance, neurological complications can occur infrequently
- Conservative treatment in established kyphotic deformity has a limited role
- The aims of surgery are to correct the deformity, restore sagittal alignment and decompress the neural elements as required.

Introduction

There are many causes of a kyphotic deformity of the spine, and the incidence and prevalence varies with the population studied. Postinfectious kyphosis is more common in developing countries, whereas post-traumatic, congenital, and degenerative deformities predominate in Western cultures.

The thoracic spine has a normal posterior convex angulation which usually measures 40 degrees. There is a wide physiological variation, and the mean figure alters with the age and sex of the individual. During adolescence, males have a greater kyphosis than females. The mean thoracic kyphosis increases with age in both sexes and is most pronounced at a mean age of 13.8 years. Importantly, unlike the coronal plane where we are all identical, our sagittal profile is like a fingerprint and very individual. When a sagittal deformity occurs it may be well tolerated or poorly tolerated depending on the individual normal profile including the pelvic position and lower limbs.

Classification of kyphosis is summarized in Table 3.16.1, and the management of each type is discussed in detail in the following sections.

**Congenital kyphosis**

Winter proposed a classification of congenital kyphotic deformities in 1977. In type I, normal vertebral segmentation is absent, resulting in an anterior bone block. Type II results from defects in formation of one or more vertebral bodies, and type III is a combination of types I and II.

In Type I deformities, the anterior bone acts as a tether and the angulation increases with continued posterior growth. The severity depends on the length of affected spine and the growth differential between the anterior and posterior elements of the spine. Type II deformities range from mild to severe. Mild cases show failure of formation of variable portions of a single vertebra. In severe types there may be total absence of a vertebral body and multiple defects. They occur most commonly at the thoracolumbar junction and, if asymmetric, a kyphoscoliosis results. The deformity increases significantly with growth and may lead to paraplegia, most commonly in adolescence.
The natural history of congenital kyphosis is poor and there is no successful non-operative treatment. The surgical treatment depends on the type of anomaly, the age of the patient, and the magnitude of the deformity.

If detected early, type I deformities can be treated by posterior fusion alone (extending one vertebra above and below the segmentation defect). Although the deformity is not corrected, it will prevent any deterioration in the curve. If a significant deformity exists, anterior osteotomies of the unsegmented bar combined with posterior instrumentation will be required to achieve correction and stabilization.

Type II deformities are best treated by posterior fusion (between the ages of 1–3 years). Resultant anterior growth reduces the deformity. Above the age of 5 years the same treatment can be applied if the kyphosis is less than 50 degrees. Deformities greater than this require both anterior and posterior surgery. The principles of surgery are to release the anterior tethers (anterior longitudinal ligament, annulus, and cartilaginous vertebral anlage) and insert bone grafts to achieve solid fusion. Correction of the deformity can be achieved at the time of anterior surgery or when posterior instrumentation is used. When the deformity is associated with a paraparesis, preoperative magnetic resonance imaging (MRI) is required to define the site of compression and exclude a tethered cord. In these cases, the anterior procedure should include partial vertebral resection to decompress the cord and to provide adequate space for the cord to move forward when correction is performed.

### Developmental kyphosis

#### Scheuermann’s disease

This condition of unknown cause is often associated with kyphosis. Avascular necrosis of the ring apophyses, disc herniations through the endplate (Schmorl’s nodes), excessive mechanical stress, and endocrine abnormalities have all been implicated in the pathogenesis.

The prevalence is approximately 1% of the general population and the female-to-male ratio is 2:1. The radiographic features of Scheuermann’s disease are rarely seen before the age of 10, but most are apparent by 13 years of age.

Pain is the most common complaint (50%); it is usually intermittent and located over the apex of the curvature. Long-term studies of this group confirm that pain remains a problem, and they continue to be employed in less physical jobs than controls. Greater deformity is associated with poor lung function. The deformity and its location are also frequent complaints. A typical Scheuermann kyphosis is shown in Figure 3.16.1 and the radiological criteria for its diagnosis are given in Table 3.16.2.

![Click to view larger](Fig. 3.16.1)  
Scheuermann’s kyphosis: typical radiographic features in an 18-year-old male with an 85-degree deformity.

<table>
<thead>
<tr>
<th>Table 3.16.2 Criteria for diagnosing Scheuermann’s kyphosis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Irregularity of the vertebral endplates</td>
</tr>
<tr>
<td>Narrowing of the intervertebral disk spaces</td>
</tr>
<tr>
<td>Three or more vertebrae with wedging of greater than 5°</td>
</tr>
<tr>
<td>A thoracic kyphosis exceeding 45°</td>
</tr>
</tbody>
</table>

There are atypical forms of Scheuermann’s disease. One form has endplate irregularity, Schmorl’s nodes, and disc-space narrowing without wedging or increased kyphosis. The other form has the clinical appearance of classic Scheuermann’s kyphosis but without the vertebral body changes.
An increased incidence (30%) of spondylolysis and spondylolisthesis has been noted in patients with Scheuermann's disease, possibly due to the increased posterior element loading and lumbar hyperlordosis. Neurological complications, although rare, are well recognized; spastic paraparesis may develop secondary to the angular deformity alone or as a result of a herniated thoracic disc.

Management

The main indications for treatment are pain and deformity, especially in the growing child. The objectives are correction of the deformity and reduction of the progression of the kyphosis. Orthotic treatment has consisted of hypertension casts and Milwaukee braces. Correction of the deformity is readily achieved using these methods; the smaller the deformity, the greater is the correction. There is some loss of correction after cessation of treatment, but 69% maintain a useful improvement. Brace treatment is not recommended in skeletally mature individuals (whose vertebrae have no remodelling potential). Surgery may be indicated in deformities greater than 70 degrees and where orthotic treatment is unacceptable or has failed. Posterior correction and fusion have been associated with a high pseudarthrosis rate, which prompted the development of anterior instrumentation and strut grafting techniques. However, with deformities that correct to less than 70 degrees on hyperextension radiographs, posterior fusion alone, combined with modern implants, will be sufficient in the adolescent with potential anterior growth. In deformities greater than 70 degrees, additional release of anterior tethers and fusion is required. The latter can be achieved by thoracotomy or by using the thoracoscope. Most recently, even large deformities have been treated by modern instrumentation systems using posterior approaches alone.

Postural round back

This can be distinguished from Scheuermann's disease by the modest kyphosis (40–60 degrees) and accentuated lumbar lordosis. The deformity is mobile, and is easily and voluntarily correctable with no associated muscle contractures. Radiographs show normal vertebral morphology without endplate irregularity. This condition should not be diagnosed until after 13 years of age as Scheuermann's disease may not manifest itself before then.

Treatment follows the same principles as outlined for Scheuermann's kyphosis. Postural exercises may be sufficient in preadolescent children. Brace treatment should be commenced with radiographic evidence of progression or endplate changes.

Inflammatory kyphosis

Pyogenic spondylodiscitis

This is a common problem in developing countries, and is becoming increasingly prevalent in Western societies with an aging population, intravenous drug abusers, and the increased longevity of high-risk groups such as diabetics. Staphylococcus aureus is the most common organism isolated (50–70%), and presenting symptoms may include fever, malaise, and back pain. There may be leucocytosis and raised erythrocyte sedimentation rate. However, atypical features are common and may include symptoms that lead to chest and abdominal investigations. In one series, the average period from first symptoms to diagnosis was 3 months. The radiographs may show intervertebral disc and adjacent endplate destruction (Figure 3.16.2).

Fig. 3.16.2
Pyogenic spondylodiscitis: lateral radiograph of localized kyphosis resulting from Staphylococcus aureus spondylodiscitis and vertebral collapse of T7–8 in a 62-year-old diabetic man.

In the absence of sepsicaemia, neurological deficit, or significant deformity, a tissue biopsy should be performed prior to antibiotic therapy. Tissue may be obtained by percutaneous methods or by transpedicular costotransversectomy or laminectomy. Surgery has a limited role and is indicated in the acute phase to decompress neural structures or for radical debridement in uncontrolled sepsis. In debilitated patients unfit for major surgery, drainage of a thoracic epidural abscess may be achieved via the thoracoscope. A less invasive approach may be adopted in the lumbar spine with minimal kyphosis. This involves application of a...
spinal external fixator to stabilize the adjacent motion segments and the installation of a suction-irrigation system in the intervertebral disc.

Cervical spine involvement is uncommon. Kyphosis may progress in the absence of pain. Surgical stabilization may be required with anterior and posterior surgery. Kyphosis may result from collapse of the disc space and vertebral destruction. Pain and progressive deformity are common sequelae. The principles of surgery in these cases are anterior radical debridement of all infected material, decompression of the dura, and bone grafting of the anterior column defect. During the latter process the sagittal contour of the spinal column is restored. Collapse of the graft may be prevented by wearing an orthosis, but modern pedicular-hook implant systems allow posterior stabilization without the need for postoperative bracing.

**Tuberculous spondylitis**

Tuberculosis remains a major health problem worldwide and a significant cause of acquired kyphosis (Figure 3.16.3). Its management is described in detail in Chapter 3.18.

![Click to view larger](Fig. 3.16.3)

**Post-traumatic kyphosis.** A) Lateral radiograph of a T7 vertebral fracture in a 57-year-old woman treated conservatively 18 months previously. B) T2-weighted MRI scan demonstrating cord compression.

**Ankylosing spondylitis**

This is a chronic inflammatory disease of unknown aetiology. It affects 0.02–2% of the general population, and is more common in males (2.4:1). Ankylosing spondylitis can be classified as an enthesopathy, i.e. inflammatory focus at the site of ligament or capsule insertion that produces reactive bone formation. Progressive endochondral ossification occurs which produces stiffness and ankylosis of the joints.

In the spine, ankylosis of the sacroiliac joints is followed by ossification of the interspinous and interlaminar ligaments, ankylosis of the facet joints, ossification of the annulus fibrosus, and syndesmophyte formation. This proceeds in a cranial direction and may involve the whole axial skeleton to produce characteristic radiographic appearances (bamboo spine). During the inflammatory episodes, pain is reduced by a flexed posture (which reduces facet joint pressure). This predisposes to development of kyphotic deformities in the cervicothoracic, thoracic, and lumbar spine. In severe cases, individuals are unable to stand upright, lose horizontal gaze, and develop a ‘chin-on-chest’ deformity. The functional limitations are exacerbated by flexion contractures or ankylosis of the hips.

**Management**

Modern conservative treatment emphasizes non-steroidal anti-inflammatory medication combined with regular exercise to maintain spinal mobility. Sleep in the supine position and on pillows is necessary to try to prevent kyphosis.

In most cases the problematic kyphotic deformity is located in the lumbar spine. It may be corrected by a lumbar osteotomy, first described by Smith-Peterson and colleagues in 1945. Other techniques have been described, but the general principle is acute angular correction of the spinal deformity below the conus medullaris thereby reducing the risk of neurological damage. The aim is to restore horizontal gaze and sagittal alignment of the spine so that C7 is centred over the sacrum. We currently favour the technique described by Thomasen in 1985. The lamina and pedicles of L3 are removed and the vertebral body is decancellized. Finally, an osteotomy of the posterior vertebral cortex is performed. Extension of the spine closes the osteotomy and creates an extension-compression fracture. The correction is held with pedicle screw instrumentation and the spine is formally arthrodesed. The screws should be inserted before the osteotomy is made. The advantages of this technique are that by shortening the spine, neural tension is avoided and the risks of aortic rupture reduced. Typical corrections of 30–40 degrees are achieved with this technique.

In severe thoracic kyphosis (with normal or increased lumbar lordosis and normal cervicothoracic alignment), multiple anteroposterior thoracic osteotomies are used to correct the deformity. In cases where the primary deformity is at the cervicothoracic junction, an extension osteotomy is performed. This is carried out at the C7–T1 level (below the entrance of the
vertebral arteries in the transverse processes of C6) and uses the relatively capacious spinal canal at that level to obtain correction safely.

The final correction should achieve a balanced spine in the sagittal plane with the centre of gravity passing through the sacrum. Failure to do so risks the development of pseudarthrosis (due to tensile stress on the fusion mass) and progressive kyphosis above the stiff instrumented section (J.K. Webb, unpublished data).

**Metabolic kyphosis**

**Osteoporosis and osteomalacia**

Longitudinal studies demonstrate that kyphosis increases with advancing age. The kyphosis is more severe in women and is negatively correlated with bone mineral density.

The kyphotic deformity may be severe and result in sternal stress fractures and impingement of the costal margin on the iliac crest. Pulmonary complications are rare; an age-related decrease in vital capacity, especially when combined with a past history of cigarette smoking, is the usual cause of lung dysfunction in this group.

With rapidly progressive deformities it is important to exclude other conditions that mimic postmenopausal osteoporosis, such as spinal metastases, multiple myeloma, and endocrine disorders. A bone biopsy and quantitative histomorphometry is indicated in cases where osteomalacia is suspected.

The majority of affected individuals are asymptomatic, but some may complain of increasing deformity and back pain.

**Management**

Conservative treatment should be tried first; analgesics, anti-inflammatory agents, and extension exercises are prescribed. These measures may be supplemented with underarm orthoses.

Surgery may be indicated when there is incapacitating pain unresponsive to non-operative treatment, progressive deformity, and in the rare instance where paraparesis results from retropulsed bone from compression fractures. Technical problems arise from the porotic bone that provides poor fixation for implants. Additional problems are posed by the coincident chronic medical conditions that increase postoperative morbidity. An anterior release and thoracotomy are often poorly tolerated. The laminae maintain their strength longer than the vertebral bodies, and an alternative approach is shortening of the posterior column of the spine (by osteotomies and facetectomies) combined with multisegmental stabilization with alternate sublaminar wires and Mersilene tapes attached to Luque rods. Correction may be achieved, but the pseudarthrosis rate is greater than in cases of idiopathic juvenile kyphosis treated surgically.

**Post-traumatic kyphosis**

Kyphosis is a recognized common complication after thoracolumbar and lumbar fractures (Figure 3.16.3). Considerable controversy surrounds the treatment of these injuries, particularly burst fractures. The posterior column of the spine is a biomechanical concept that includes the bone and ligamentous structures dorsal to the posterior longitudinal ligament. It functions as a tension band; progressive kyphosis results from its damage when associated with anterior column injury (i.e. compression fractures). Identifying injury to the posterior column is often difficult; a widened interspinous gap or dorsal haematoma should be sought in the physical examination. Plain radiographs may show interspinous widening or laminar fractures. Posterior column injury may be inferred from the amount of damaged vertebral body, the spread of the fractured fragments, and the degree of corrected traumatic kyphosis. Soft tissue damage may be better visualized with modern MR sequences.

A kyphotic deformity of 30 degrees is associated with an increased incidence of back pain. Progressive deformity may also result in late-onset paraparesis but as stated earlier in some individuals this may be well tolerated whereas in others it is not.

**Management**

The treatment of post-traumatic kyphosis is initially symptomatic; surgery is indicated where conservative treatment has failed or where there is neurological deficit. The goals of surgery are decompression of the spinal cord, correction of the deformity, and establishing spinal stability.

Posterior approaches (without transpedicular osteotomy) fail in the majority of cases; the bone graft is under tension, and pseudarthrosis and implant failure are common occurrences. Anterior approaches permit cord decompression and restoration of a solid anterior column to the spine. The correct sagittal alignment must also be obtained postoperatively. In moderate kyphosis this can be achieved in one procedure. In more severe deformities the anterior procedure may need to be combined with shortening of the posterior column by Smith-Peterson osteotomies and pedicle screw instrumentation.

**Iatrogenic kyphosis**

**Postlaminectomy kyphosis**

Laminectomies are less commonly performed during discectomies and nerve root canal decompression; deformities after these laminectomies are rare in adults where there is no pre-existing spinal deformity.
The incidence of deformity rises with multilevel laminectomies (Figure 3.16.4); one study reported an incidence of 46% in patients under 25 years of age who underwent laminectomy. Where laminectomies were performed in patients aged less than 15 years, the incidence of deformity was 46%; all laminectomies in the cervical spine or cervicothoracic junction and 36% of thoracic laminectomies were followed by kyphoses.

Fig. 3.16.4
Postlaminectomy kyphosis resulting 5 years after multilevel laminectomies for a spinal intramedullary tumour.

Removal of the tension band effect of the posterior ligamentous structures results in unopposed flexion moment of the spine at that level. When total facetectomies are combined with laminectomies in adults, it results in subluxation and an angular kyphosis. In children the increased bending moment increases pressure on the cartilaginous portion of the anterior vertebral body. There is decreased growth in this area and wedging of the vertebra occurs. This results in a long gradual kyphotic deformity.

Management

Treatment of the deformity depends on the pathology necessitating the laminectomies. The child should be carefully monitored and when kyphosis develops, a brace should be applied to control the deforming forces temporarily. Where the original diagnosis was a malignant tumour with poor prognosis, this should be the only treatment. If the prognosis is good, surgery should be recommended as prolonged brace treatment is ineffective.

Technical problems result from the deficient bone stock posteriorly, and isolated fusion in this area has a high pseudarthrosis rate. Continued posterior growth will cause further progression of the deformity. A combined approach is necessary. Anterior discectomies, correction of the deformity with strut grafting, and arthrodesis should be followed by posterior fusion carried into the normal lordotic segments. This may be performed as a single operation or as a staged procedure. Instrumentation may not be possible in these children, especially in the upper thoracic spine. A halo-cast should then be worn for 4 months.

Postradiation kyphosis

Radiotherapy for childhood malignancies (Wilms’ tumour and neuroblastoma) may include the spine in the irradiated field. Radiation affects the epiphyseal plate of long bones and vertebrae, resulting in disturbance of metaphyseal remodelling and reduced longitudinal growth. Spinal deformity occurs with differential growth of the affected vertebrae. Vertebral endplate irregularities (‘bone within bone’ appearance) are common radiological features.

The threshold radiation dose for producing spinal deformity is 1000cGy; no spinal deformity has occurred with radiation below this level. Symmetric portals for irradiation produce a pure kyphosis; asymmetric fields produce either a scoliosis or a kyphoscoliosis. The younger the patient at the time of exposure, the greater is the risk; this is most marked in children aged less than 2 years. In one study of 81 patients who had received radiotherapy for Wilms’ tumours, all but one subsequently developed a spinal deformity. Nineteen developed a kyphoscoliosis and two a kyphosis.

Management

Significant deformity is rare before the age of 10 years; curves may deteriorate during the pubertal growth spurt. There is no evidence for delayed skeletal maturation in these children. Orthotic treatment may be used for curves between 20–40 degrees, although there is no good evidence that orthoses produce permanent improvement.

Surgery is indicated for curves greater than 40 degrees or where a kyphotic deformity of more than 20 degrees exists at the thoracolumbar junction. The principles of fusion and the selection of fusion levels are the same as those for idiopathic scoliosis. Pseudarthroses and infections are more common in the irradiated spine; repeat bone grafting may be necessary at 6 months.

Neoplastic kyphosis
Skeletal metastases are present in 70% of patients with terminal cancer, and half of these have demonstrable spinal lesions. Most are asymptomatic, but progressive tumour infiltration of the vertebra may lead to collapse, kyphotic deformity, and pain. Up to 5% of these patients will also develop neurological deficits from compression by tumour or retropulsed bone or disc. In these instances radiotherapy is less effective and surgery may be indicated.

Decompression of the spinal cord, reconstruction of the anterior column, and restoration of sagittal alignment may all be achieved via an anterior approach. These patients are often cachectic and in poor general condition; using the earlier discussed principles, perioperative mortality rates of 30% have been reported.

In the past, surgical treatment for metastatic cord compression involved laminectomies. This approach was abandoned as the clinical results were poor. Adequate neural decompression was not achieved, and further cord damage occurred through the resultant spinal instability. A better appreciation of the need to restore the normal sagittal contour, more radical posterolateral decompression, and modern pedicle instrumentation have led to a resurgence of posterior surgery in spinal metastatic disease. This surgery is better tolerated, and the neurological and functional outcomes are comparable with the best reports of anterior decompression.

Spondylolisthesis and spondylolysis

**Summary points**

- Spondylolysis is a stress fracture of the vertebral arch. It may lead to vertebral slipping, spondylolisthesis.
- Spondylolysis is commonly lytic, isthmic, or degenerative.
- Spondylolysis and Spondylolisthesis can affect both children and adults.
- Most common symptoms are low-back pain and/or radiating pain. True neurologic deficit is rare.
- Treating clinicians should be aware of the processes involved and the common consequences.
- The majority of symptomatic patients are treated nonoperatively.
- Operation is indicated in rare cases with neurologic deficit and in children or adolescents with a slip of 50 per cent or more.
- Most common complications of surgery are nerve root compromise (especially in connection with slip reduction) and non-union.

**Classification**

Spondylolisthesis is the forward slip of a vertebra on another. The most common cause is degenerative spondylolisthesis which is seen in the older population as a result of disc and facet joint degeneration. In the young, the majority of vertebral slips are of the isthmic type in which an interruption (spondylolysis) or elongation of the pars interarticularis (isthmus) of the vertebral arch is present (Figures 3.17.1–3.17.3). Dysplastic spondylolisthesis develops because of congenital changes in the upper part of the sacrum and the vertebral arch of L5. Subluxation of the facet joints is always present in this form. True dysplastic spondylolisthesis is extremely rare. According to the classification of Newman and Wiltse (Table 3.17.1), additional types of spondylolisthesis are traumatic spondylolisthesis in acute fractures and pathological spondylolisthesis caused by infection or tumour destruction of parts of the vertebral arch. Iatrogenic spondylolisthesis after excessive resection of posterior vertebral elements should be added. The Wiltse classification has been criticised rightly for being inconsistent and mixing aetiologic (e.g. dysplastic) and anatomic (e.g. isthmic) terms. As its inventors already realised, the distinction between isthmic and dysplastic forms is not always possible. And no specific treatment guidelines are derived. To overcome these shortcomings, improved classification systems have been proposed by Marchetti and Bartolozzi (1997) and Mac-Thiong and Labelle (2006). They are rather complex and do still not yet allow a clear scientifically based distinction between dysplastic and isthmic slips. Furthermore, their treatment recommendations are not validated in clinical series so far. For clinical decision making at present, the essential factors are the degree of slip, the sagittal alignment (lordosis/kyphosis) at the level of the slip, patient’s age, and symptoms. In this context, it is of secondary interest whether a slip is to classify e.g. as dysplastic or not.

Spondylolysis is a fatigue fracture of the isthmus of the vertebral arch with the histological characteristics of a fibrocartilaginous pseudarthrosis. The lysis may heal, resulting in a normal or elongated isthmus (Figure 3.17.4).

Fig. 3.17.4
Spontaneous healing of a spondylolysis. A) Symptomatic L4 lysis in a 12-year-old girl. B) One year later a mild slip is present and the patient is symptom free. C) After 3 years the lysis has healed, the isthmus is elongated, and the patient is symptom free.

Spondylolisthesis affects only humans. It has never been described in animals except in an experimental study.

Spondylolysis has never been found in a newborn. The youngest reported patient with spondylolysis was a 3.5-month-old girl, and a case reported of unilateral spondylolysis with 4-mm slip in a 10-month-old girl. In Caucasians the prevalence of spondylolysis is 4.4–5% at early school age. It increases during growth, and is 6–7.2% in adults. In some ethnic groups the prevalence is much higher (Alaskan Inuit, 32.9%; Japanese Ainu, 41%). Isthmic spondylolysis is more common in males, but severe slips occur more frequently in females. Lumbar spondylolysis affects the fifth lumbar vertebra in 90% of cases, the fourth in 5%, and the third in 3%. Symptomatic spondylolysis is more likely if it occurs in the segments above L5. Spondylolysis may be present without vertebral slip. In most cases, however, it leads to spondylolisthesis. In the majority of individuals the slip is mild (10–20% of vertebral body length). The slipping occurs during the growth period, and slip progression is rare after growth is complete.
Risk factors for the progression of spondylolisthesis in young individuals are a high degree of slip and age before growth spurt. The trapezoidal shape of the slipped vertebral body and rounding of the upper endplate of the sacrum are secondary changes.

According to Laurent and Einola (1961), slip is measured as the ratio of the sagittal slip to the sagittal length of the slipped vertebral body expressed as a percentage (Figure 3.17.5A). The lumbosacral kyphosis seen in more severe slip is assessed from the same radiograph and measured as the angle between the posterior border of the first sacral vertebral body and the anterior or posterior border of the fifth vertebral body (Figures 3.17.5B and 3.17.6A).

---

**Aetiology**
Spondylolysis is related to the erect posture of humans and to lumbar lordosis. A higher incidence has been found in individuals practising sporting activities with repeated hyperextension movements of the lumbar spine and/or lifting (e.g. gymnasts, divers, javelin throwers, weight lifters, ballet dancers). The possible role of particular sagittal profiles and pelvic parameters (including elevated pelvic incidence) is emerging.

Marty et al (2002) found that individuals with spondylolisthesis have a higher pelvic incidence, a steeper sacral slope and a greater sacral kyphosis than control persons. The concept of abnormal pelvic morphology and disturbed spino-pelvic balance in spondylolisthesis is supported also by other authors. However, Huang et al (2003) could not confirm increased pelvic incidence as a predictor of slip progression. Based on an anthropological study, Whitesides et al. (2005) stated that increased pelvic incidence in spondylolisthesis appears to be secondary to changes in the sacral table angle (i.e. the angle between the superior endplate and the posterior wall of S1) caused by the slip.

The condition can also be inherited. The primary site of the inborn error has not yet been identified. It may in the bony structures (isthmus dysplasia), or in the soft tissues (intervertebral disc, ligaments), or in both leading to a particular sagittal profile with a high pelvic incidence and a high lumbar lordosis.

### Disc degeneration

The disc below the slipped vertebra is pathological even in young individuals whether or not they have pain. Degeneration of the adjacent disc above the slipped vertebra is common in symptomatic patients. Symptomatic disc hernia at the level of the slip is rare in patients with isthmic spondylolisthesis.

### Lumbar scoliosis

Lumbar scoliosis is seen as a secondary phenomenon to spondylolisthesis. ‘Sciatic’ scoliosis is due to pain and muscle spasm, and usually disappears after relief of symptoms. Structural (‘olisthetic’) curves are caused by rotational displacement of the slipped vertebra. Lumbosacral fusion is indicated if progression occurs (Figure 3.17.7).

### Natural history

The natural history of isthmic spondylolisthesis is benign in the majority of cases. The affected segment stabilizes itself. Even so, isthmic spondylolisthesis is the most important cause of low back pain and radiating leg pain in children and adolescents. The prognosis of back pain and working ability of adults with isthmic spondylolisthesis is no different from the rest of the population. Back pain symptoms in adults are related to the following:

- Slip of more than 25%
- Spondylolysis at L4
- Early disc degeneration
- Low socioeconomic status
- High occupational loading of the back
- Severe psychosomatic stress symptoms.

There is no explanation yet as to why some people with spondylolysis or isthmic spondylolisthesis become symptomatic while the majority remain symptom free. It is also unknown why slips above L5 seem to cause relatively more pain symptoms than L5 slips.
The proposed sources of the pain include the lytic defect itself, the intervertebral disc, and the ligaments. This is not yet resolved.

### Presentation

The onset of the symptoms is often spontaneous. In young patients there is often a history of sports activities. Sometimes acute trauma is reported.

The main symptoms are as follows:

- Low back pain during physical activities while standing and/or sitting
- The pain radiates to the buttocks, to the posterior or lateral aspect of the thigh, and, rarely, more distally to the lower limb, ankle, or foot.

In severe slip (>50%) symptoms may include:

- Gait disturbances
- Numbness
- Muscle weakness
- Symptoms of cauda equina compression.

There is no direct relationship between severity of subjective symptoms and the amount of slip.

Gait and posture are normal unless radicular symptoms are present or the slip is severe. The mobility of the lumbar spine is free or decreased due to muscle spasm and pain. There is local tenderness during palpation and in most cases a step can be felt between the spinous processes at the level of the slip. Hamstring tightness is common in younger patients. The Lasègue test is usually negative. Muscle power, reflexes, and skin sensation of the lower extremities are normal in the majority of patients.

In severe slips, the posture of the patient is abnormal (Figure 3.17.8). The sacrum is in a vertical position due to retroversion of the pelvis. There is a short kyphosis at the lumbosacral junction and a compensatory hyperlordosis of the lumbar spine, usually reaching up into the thoracic region. The spine is scoliotic and often out of balance. The patient is unable to extend hips and knees fully during standing and he or she walks with a typical pelvic waddle. The hamstrings are extremely tight and signs of neural impairment (muscle weakness, disturbances of skin sensation, incontinence) may be present. Astonishingly, even in very severe slips, neurological findings are rare and many patients are often free of pain despite significant posture changes and hamstring tightness.

### Investigation

The vertebral slip is diagnosed from a plain lateral radiograph of the lumbar spine taken in standing position and centred on the lumbosacral junction. In most cases the lysis can be seen from the lateral radiograph. If there is doubt, oblique radiographs will show the defect (Figure 3.17.9). A computed tomography (CT) scan with tilted gantry is the most reliable imaging mode for demonstrating the spondylolysis (Figure 3.17.10).
Magnetic resonance imaging (MRI) demonstrates the shape of the spinal canal and possible compression of neural structures (Figure 3.17.11) and shows degenerative disc changes in and above theolisthetic segment (Figure 3.17.12). However, the clinical relevance of disc degeneration seen on MRI is unclear and therefore in this respect MRI is uncertain.

A) MRI of a 10-year-old girl with spondyloptosis. B) MRI of a 34-year-old female with mild isthmic L5 slip and severe radiating pain. Lateral disk hernia compressing the L5 root against the pedicle.
Fig. 3.17.12
Disc degeneration on MRI of a 20-year-old female 56 months after direct repair of a symptomatic L5 lysis. The patient has only mild low-back symptoms.

Technetium scintigraphy is used in patients where fresh (traumatic) spondylolysis is suspected with normal radiographs. The impending lysis may be seen in the scintigram (Figure 3.17.13). It also helps to judge the possible healing of the defect.

Fig. 3.17.13
Scintigraphy showing fresh traumatic spondylolysis in a 15-year-old boy.

Electroneuromyography may be indicated in cases with clinical neurological signs. Discography can be used for preoperative assessment of the condition of the disc(s) above the slipped vertebra.

Management in children and adolescents

Symptomatic spondylolysis or mild spondylolisthesis (up to 25% slip) is treated non-operatively by decreasing the level of physical activities, strengthening of back and abdominal muscles, and sometimes a brace or plaster of Paris jacket.

At this stage it is very important to explain to the patient and his or her parents that the natural course of the condition is benign and that the symptoms resolve, usually after several months, without any special treatment. Sports players are advised to modify their training program to avoid pain-causing exercises. There is no reason to stop all physical activities. Younger patients before or during the growth spurt should be followed up with radiographs at 6- to 12-month intervals because of the risk of progression at this age.

Indications for operation in children and adolescents are:

- Pain unresponsive to non-operative measures
- A slip of more than 25% in a very young patient (even with minor symptoms) to prevent further slip progression
- Significant posture changes
- Gait disturbances
Possible neurological changes in the severe slip.

The choice of operative procedure depends on the amount of slip and on the personal experience and preferences of the surgeon. Table 3.17.2 represents the author’s policy and is used as a guideline for decision-making. The final decision is an individual one depending on the patient’s skeletal maturity, gender, anatomical features of the slip, ability to cooperate, and the aspirations of the patient and his or her parents.

LS, lumbosacral

Uninstrumented segmental posterolateral fusion in situ using autogenous bone from the posterior iliac crest is the method of choice for cases with a slip up to 50% (Figure 3.17.14). The segment above the slipped vertebra is not usually included in the fusion in young patients even if it shows signs of degeneration in discography or on MRI. The patient is mobilized 2 or 3 days after the operation wearing a soft brace for 3 months. Sports activities are forbidden for about a year. There are no restrictions on physical activities after solid healing of the fusion. This method is safe and effective, and there are no specific complications. In this young age group, bony fusion is achieved in almost 90% of cases, and subjective results are good or satisfactory in 82–96%. Symptoms disappear in most cases even when solid fusion is not achieved.

![Click to view larger](Fig. 3.17.14)

A) Posterolateral fusion. B) Anteroposterior radiograph shows a bilaterally strong fusion mass 3 years after operation.

If there is a lysis without a slip or a very mild slip, direct repair of the isthmic defect is recommended. Different methods of internal fixation (screws, cerclage wires, butterfly plates, hook plates) have been described. The author prefers Scott’s wiring technique (Figure 3.17.15). Postoperative immobilization with a plastic thoracolumbosacral orthosis is recommended for 3–6 months. Equivalent results to the results of posterolateral fusion can be expected in the mid-term. Schlenzka et al (2006) were not able to prove the benefit of direct repair in comparison to segmental fusion in a long-term study.
If the slip exceeds 50%, the physiological lumbosacral lordosis decreases and a progressive kyphotic deformity develops. For biomechanical reasons, posterior or posterolateral fusion is not sufficient to prevent progression without anterior support. Anterior interbody fusion through a transperitoneal approach using autogenous tricortical iliac crest grafts is preferred (Figure 3.17.16).

Combined anterior and posterolateral (circumferential) fusion is necessary to stop progression in slips with significant lumbosacral kyphosis (more than 10–20 degrees) (Figure 3.17.17). There is no need to include more than the olisthetic segment into the fusion. After anterior or combined procedures the patient is mobilized at the second or third postoperative day and wears a plastic thoracolumbosacral orthosis for 3–6 months. The clinical results of anterior and combined fusion in severe slip are comparable to the results of posterior or posterolateral fusion. The risk of complications is obviously higher in anterior fusion. Massive intraoperative bleeding, postoperative thrombosis, and retrograde ejaculation in male patients may occur. However, in experienced hands these complications are rare.
degrees). C) Two years after combined fusion there is solid bony healing and improvement of the deformity (slip, 52%; lumbosacral lordosis, 4 degrees).

Reduction of the slipped vertebra is technically possible. So far no benefit has been shown for reduction procedures compared with fusion in situ. There is a high risk of complications related to these procedures. At this stage of knowledge, the author would consider slip reduction in children and adolescents only for cases of spondyloptosis (slip of 100% or more).

Decompressive laminectomy is indicated in young patients only in rare cases where there is true impingement of neural structures. If decompression is performed during growth, segmental fusion always has to be added to prevent subsequent progression of the slip.

**Management in adults**

The primary treatment of a symptomatic spondylosis or isthmic spondylolithsis is non-operative. Load reduction, stabilizing exercises of abdominal and back muscles, local injections of steroids/local anaesthetics, physiotherapy, a soft brace, and pain-relieving drugs should be tried first. In some cases changes to the working environment of the patient may be necessary. It is very important to give the patient objective understandable information. One should not underestimate the psychological effect on a non-medical person of being told that a vertebral arch in his or her back has ‘broken’ and has caused ‘slipping’ of the vertebra. The natural history of this condition has to be explained to the patient with special emphasis on the benign course and the tendency of the process to self-stabilize in the long term.

Indication for operation is severe low back and/or radiating pain which does not respond to the measures described earlier and interferes significantly with the patient’s daily activities.

Decision-making is much more difficult than in the treatment of young patients. The older the patient, the more likely it is that changes outside the lytic/olisthetic segment are responsible for the symptoms, i.e. one has to clarify whether the radiological finding of spondylosis or isthmic spondylolithsis is really the sole cause of the patient’s symptoms. In addition to the patient’s history and physical examination, a thorough analysis of all aspects of the individual case is mandatory. Pain analysis (pain drawing, visual analogue scale, Oswestry Questionnaire) and assessment of the patient’s psychosocial situation are performed. Radiological investigations include flexion-extension views and discography to identify the actual source of pain. Diagnostic pars blocks can be very useful and may identify the spondylolisthesis as an isolated source of pain and pars repair could be considered.

The choice of the operative procedure depends on the results of the preoperative work-up. Posterolateral fusion augmented with transpedicular instrumentation (Figure 3.17.18) is performed in patients who suffer mainly from low back pain. If root symptoms are predominant, decompression (Gill’s operation) is indicated. During this procedure the loose lamina and the pseudarthrotic tissue of the lysis are carefully removed bilaterally. The nerve roots have to be totally free after this resection. In some patients the roots are caught under the pedicle. Additional resection of the medial and inferior parts of the pedicle is necessary to achieve complete nerve root decompression. Gill’s operation alone is sufficient only if the olisthetic disc is severely degenerated and the segment is stable. Otherwise, instrumented posterolateral fusion is added.

The extension of the fusion proximally (one or more segments) depends on the condition of the segment(s) above the slipped vertebra.

Direct repair of the spondylolysis may be performed in young adults with symptomatic spondylolysis or mild slip if the condition of the disc is satisfactory on MRI investigation. The author uses this procedure in adults mainly at the L4 level because in the L5 slip the disc below is almost invariably abnormal.

Slip reduction is not usually indicated in adult patients. Adult patients with a severe slip (>50%) should be treated by decompression and instrumented fusion in situ to the sacrum. Sometimes the fusion will need to extend to L4 depending on the slip angle, the disc/facet status, and the slip angle.

In cases of spondyloptosis with severe symptoms and impairment of patient’s posture, L5 vertebra resection and fusion of L4 onto the sacrum may be considered. This is a high-risk procedure and should be performed only by very experienced spine surgeons.
The results of operative treatment of isthmic spondylolisthesis in adult patients are as unpredictable as all low back pain operations. The literature is unhelpful because of different approaches to patient selection and the influence of the specific socioeconomic environment in different countries. One study reported a fusion rate of 88% after uninstrumented posterolateral in situ fusion and a clinical success rate of 65% in 45 adult patients. Risk factors for a poor outcome were compensation cases and pseudarthrosis. A trend towards unsatisfactory result was seen in males, middle-aged individuals, smokers, and patients with preoperative radicular symptoms. Another study used transpedicular fixation and achieved a 94% fusion rate. They reported numerous instrumentation-related complications (malposition of screws with and without neurological damage, screw loosening, and breakage). There is no evidence that the addition of interbody spacers would improve patients’ outcome. Most of the complications were of no clinical importance, but the potential danger of implants is obvious. They should be used only by well-trained spine surgeons.

Conclusion

Spondylolysis occurs in 4.4% of children and about 6% in the adult population. In general it is a benign condition. The majority of individuals that develop mild or moderate isthmic vertebral slip remain free of symptoms for their whole life or show only mild symptoms.

In children and adolescents with mild slip, primary treatment of pain symptoms is non-operative. Young children before growth spurt need radiographic follow-up to check for progression. If the slip exceeds 25% in a child, segmental fusion should be considered. Uninstrumented posterolateral fusion is the method of choice for treatment of pain symptoms not responding to conservative measures in slips up to 50%. In severe slips (>50%) anterior or combined fusion is necessary to prevent further progression of lumbar sacral kyphosis. The clinical results of in situ fusion in this age group are satisfactory in 80–90%. Slip reduction has not yet been shown to be superior to in situ fusion. It may be performed in cases with spondyloptosis and severe impairment of neurological function and sagittal malalignment of the spine.

In adults, careful analysis of the patient’s problems is crucial to identify the source of pain and the importance of non-organic factors and the environment. If pain is moderate, non-operative treatment is indicated. If symptoms persist and interfere with daily activities, operation may be necessary. Decompression (Gill’s operation) is indicated if radicular symptoms are dominant. Posterior spondylodesis augmented by transpedicular fixation leads to solid fusion in over 90% of patients. Subjective outcome depends very much on patient selection. Slip reduction is not indicated in adult patients. Vertebra resection may be considered in adult patients with severe subjective and objective symptoms due to spondyloptosis.

The infected spine

Summary points

♦ TB is the most common spine infection worldwide
♦ In the developed world, staphylococcal infections are more frequent
♦ Untreated these infections can cause paralysis or even death.

Introduction

It is known that spinal infections have afflicted humans since early times. Osteomyelitic changes affecting the spine have been demonstrated in skeletons from 4000 bc found in the Nile Valley and in Egyptian mummies.

Pathology

Classification is normally by the causative organism. Infective organisms may be pyogenic, granulomatous, or parasitic. Infection is usually either by direct implantation or secondary to a septic focus elsewhere in the body with spread into the vertebrae through Batson's plexus of veins or the segmental arteries. Infection may affect the vertebral body, the intervertebral disc, the epidural space, and the posterior elements, but most commonly involves the anterior and middle columns.

Pyogenic spinal infections

Pyogenic infections may present acutely or chronically. The presentation depends on the age of the patient, the immune response, and the infecting organism. Almost any infective organism can cause vertebral infection under suitable conditions. The most common by far is Staphylococcus aureus, but in a significant minority of cases there is Escherichia coli, Proteus, and streptococcal involvement. The mode of spread is usually from other septic foci via the vascular system. The most common site is in the lumbar spine and multiple vertebral involvement is usual. Infection may track along tissue planes, and without early control will cause secondary abscess formation and pointing at distant sites. The vertebral canal may be invaded by pus and granulation tissue either directly from the disc space or through the exit foraminae causing meningitis or transverse myelitis. If this occurs, recovery is uncommon. Retropulsion of bone or disc causes neural compromise, and destruction of vertebral body and discs causes local instability and deformity. However, with effective control, healing occurs with fusion of adjacent vertebrae.

Epidemiology

The incidence of pyogenic spinal infection is almost certainly increasing because of increased awareness, diagnostic improvements, and enlargement of the ‘at-risk’ group (HIV/AIDS, poor nutrition, the elderly, diabetes, and other comorbidity) Spinal infection represents 3–4% of all osteomyelitises, but the figure has been quoted as high as 16%. The population incidence is about 1 in 250 000. Spinal infection is involved in 10–11 per 10 000 hospital admissions for back pain. Epidural abscess is thankfully rare and represents about 1.2 per 10 000 hospital admissions.

Box 3.18.1 Populations particularly at risk include the following

♦ The elderly
♦ Intravenous drug users
♦ Immune deficiency states, including AIDS
♦ Rheumatoid arthritis
♦ Malignancy
♦ Spinal fractures and paraplegia
♦ Infective endocarditis
♦ Renal failure
♦ Sickle cell disease
♦ Chronic alcoholics.

The presence of associated ‘conditions’ tends to delay diagnosis and there is a higher risk of neurological compromise. Direct spread of infection also occurs with stab wounds, gunshot wounds, and surgical trauma to the spine.
Clinical signs include the following:

- Localized tenderness
- Muscle spasm and limitation of movement
- Local or distant fluctuant mass
- Sinus formation
- Occasional angular defect.

Clinical features

Localized constant pain, often at an unusual site and exacerbated by movement and percussion, is the most common feature, and there is associated muscle spasm. Most patients do not present with acute pyogenic signs. Fever is present in only about a third of cases.

Neurological deficits may be present and careful evaluation is vital, especially where there is pre-existing pathology. Neurological signs, which will depend upon the nature and site of the spinal infection, will be present in 15% of patients. Quadriplegia is a presenting feature in cervical spine involvement, and paraplegia in the thoracic spine. Lumbosacral involvement is more likely to produce single or multiple root deficits.

Primary extradural abscesses have a predilection for the thoracic spine. The usual presentation is a history of severe local unremitting pain with single root symptoms. There is a tendency for the epidural abscess to spread throughout the epidural space causing rapid onset of neurological deterioration and paraplegia.

Investigations

Laboratory investigations

The erythrocyte sedimentation ratio (ESR) is usually above 50mm/h, and C-reactive protein (CRP) and alkaline phosphatase may be raised. These tests are non-specific and may be difficult to evaluate, particularly in children and patients with rheumatoid arthritis. CRP is best for postoperative infection. The white cell count is raised in less than half of cases. Blood cultures when the patient is febrile are more reliable. Urine culture may be valuable if urethral manipulation is considered to be causative.

Imaging

Although plain radiography is imperative, it is of little value in early cases. Disc-space narrowing and occasionally paraspinal widening occurs after 2–3 weeks, and secondary bone changes may take up to 3 months to occur. The earliest changes are of loss of delineation of subchondral bone. Radiographic changes are progressive with time but may remain limited to the disc complex (Figure 3.18.1). Plain radiographs are not very useful in assessing response to treatment.

Fig. 3.18.1
A) Plain lateral radiograph of a 42-year-old drug abuser presenting with increasing pain and deformity in the thoracic spine. B) MRI showing typical vertebral destruction from Staphylococcus aureus. There is clearly cord compression. C) Anteroposterior and D) lateral radiographs following debridement, grafting, and internal fixation.

Nuclear studies

Technetium-99m bone scans can be positive as early as 2 days from the onset of symptoms; they have a high sensitivity (95%) but a lower specificity (75%). Positron emission tomography (PET) scanning is helpful but not widely available. Indium and gallium scans have proved less useful.
Computed tomography scanning

Computed tomography (CT) scanning (Figure 3.18.2) is useful for assessing the degree of bone destruction and examining the surrounding soft tissues.

![Image](https://example.com/image1)

**Fig. 3.18.2**
A CT scan in a child with sickle cell disease reveals the infected site which had been missed at surgical exploration. The infecting organism was *Salmonella*.

Magnetic resonance imaging scanning

Magnetic resonance imaging (MRI) scanning has become the most important investigation. It has a sensitivity of 96%, about the same as radionuclear scanning, but has a higher specificity (up to 95%) (Figure 3.18.3).

![Image](https://example.com/image2)

**Fig. 3.18.3**
MRI of a 9-month-old child with a pyrexial illness. The MRI shows bony destruction of the left pedicle of L5, with a soft-tissue extension. The organism was *Escherichia coli*.

Microbiology

The diagnostic ‘yield’ from needle biopsy is disappointingly low. A histological diagnosis is almost invariably positive, but less than 50% produce a positive culture, particularly when antibiotics have been used. Pus from needle biopsy of the primary focus or from more distant abscess cavities gives 80–90% successful culture.

Histology

Needle biopsy can provide confirmatory material especially when culture is negative.

Differential diagnosis

The most common differential is between infection and tumour. Haematomas may mimic epidural infection. Diagnosis of pyogenic infection within either the disc or the bony canal can be difficult after recent spinal surgery.

Non-operative treatment

The principles of non-operative treatment are rest and appropriate antibiotics. When the diagnosis is certain, the organism is known, and there are no progressive neurological features, non-operative treatment is indicated. Bed rest and intravenous antibiotics may be required initially with the acute presentation, and this should be continued until pain reduces and a response can be confirmed. The patient may then be mobilized in a brace and continue on oral antibiotics.
The length of time required on antibiotics is arbitrary and depends on the organism, its sensitivity, and the patient’s clinical response. As a guide, intravenous antibiotics should be used for a period of 6–8 weeks followed by a similar period of treatment with oral antibiotics. Some recommend indefinite antibiotics to suppress infection. Serial ESR/CRP examination is usually of value and antibiotics should continue for a month after both symptoms and ESR have returned to normal. Radiographic and MRI evaluation is useful, but there is a distinct lag-time before healing can be confirmed.

**Surgical management**

Surgical management is indicated if there is a failure of conservative treatment, or the diagnosis and organism cannot be confirmed, or there is a significant neurological deficit, particularly when there is epidural spread. Mechanical instability may also be an indication for surgical management. The aims of surgery are to drain the abscess, make a definitive diagnosis, and decompress the neural tissue, either root or cord. Following this, it is necessary to achieve stability and rapid healing of the lesion by bone grafting and internal fixation. Surgery should always be directed to the area of pathology. Usually this involves an anterior approach to the spine. There is no place for decompressive laminectomy alone, which almost invariably produces instability, except in the rare cases of epidural abscess or where there is primary posterior involvement.

In the debilitated patient it is possible to drain an abscess by the posterolateral approach. It is difficult to achieve spinal stability by this approach, particularly if there has been significant vertebral destruction.

There is a significant mortality following surgery in the high-risk groups, where diagnosis has been delayed and destruction of soft tissue is extensive. Neurological recovery occurs in more than 80% of cases, particularly where there is neurological sparing preoperatively. Recovery may be delayed for many weeks, particularly in elderly patients.

Late deformity following pyogenic infection can present a formidable challenge. The neurological deficit which often accompanies severe deformity adds to the difficulty. Scarring in the neural canal and almost certainly long-standing vascular inadequacy makes correction and stabilization a high-risk procedure.

**Discitis and postoperative infection**

Although the term discitis was originally used solely for infection in children it has now come to describe any primary disc-space infection. There are two types of discitis, one occurring in children and the other occurring following endplate closure. In adults, haematogenous spread probably cannot occur through the intact endplate. Either an intradiscal procedure has been undertaken or there is a defect in the endplate.

**Disc-space infection in children**

Discitis in children is characterized by severe localized back pain and spasm, loss of disc-space height, and a raised ESR. In the pre-antibiotic era this condition was known as benign osteomyelitis, because discitis is usually self-limiting and heals without antibiotics to a bony ankylosis.

Children present with only mild toxemia but with a constant well-localized back pain, muscle spasm, and stiffness. The child will often not weight-bear. Pain may be referred to the hips and upper thigh, particularly when the infection is in a lumbar disc. Delay in diagnosis is not uncommon. The white cell count is usually normal, but with a raised ESR or CRP. Blood cultures are usually negative. Initially there are no radiographic changes. After 2 weeks there is a progressive disc-space narrowing, and at about 2–3 months some endplate irregularity is apparent. Quite marked central erosions into the endplate may be produced.

MRI is usually diagnostic. Disc biopsy for culture and histology is usually unnecessary.

The mainstay of treatment is rest, initially strict bed rest, followed by mobilization in a well-fitting cast or brace as soon as the pain reduces, often after 2 or 3 days. Broad-spectrum intravenous antibiotics are usually given initially before progressing to oral treatment. This is despite the fact that it has been shown that this condition is usually self-limiting, even without antibiotics.

Surgery has a place only when pain persists, and in these cases there is often marked endplate destruction and sclerosis. Following curettage and grafting, healing is often rapid.

It is notable that late kyphosis rarely occurs in childhood discitis. However, in babies who develop vertebral infection in the first few months of life, vertebral destruction is rapid and is followed by the development of kyphosis (Figure 3.18.4).
Disc-space infection in adults

Disc-space infection can occur following any invasive procedure on the disc. The avascular disc is prone to low-grade infection with only a small innoculum but can almost certainly be minimized by prophylactic antibiotics.

Postdiscectomy discitis is characterized by the onset of severe back pain a few days after an invasive procedure. The pain is continuous and may be referred to the hips. Tenderness is well localized and there is considerable spasm of the back muscles. The white cell count is often normal but the ESR and CRP is raised. MRI is usually positive. Rest and broad-spectrum antibiotics may be required even if the condition cannot be confirmed with certainty. Late erosive changes in the endplate are seen on both MRI scans and radiography.

The natural history is of resolution over a period of weeks and occasionally months. About 50% fuse spontaneously within 2 years.

Postoperative infection

Spinal surgery involving implants carries an infection risk of 3–4%. We found 95% involved either Propionibacteria or Staphylococcus aureus. The remainder involve Gram negative organisms. Prophylactic antibiotics should always be used when implanting metal. Effective treatment implies early diagnosis and drainage. As with implants elsewhere, the wound is opened thoroughly, debrided, and thoroughly irrigated, and the metal is left in place until fusion has occurred. Intravenous antibiotics may be required for 6–12 weeks followed by oral therapy. Cure can only be obtained with removal of the implants.

Granulomatous infections of the spine

Granulomatous lesions are caused by organisms typified by the formation of a granuloma. The most common of these are tuberculosis and brucellosis, but fungi can also be a cause.

Tuberculosis

More than 30 million patients suffer from overt tuberculosis in the world today, of whom 2–3% have involvement of the skeletal system. Spinal tuberculosis accounts for roughly 50% of all cases. There are an estimated two million patients with active spinal tuberculosis in the world, and the numbers are likely to increase due to the poor economy and living standards of the developing nations, the increasing incidence of HIV-infected patients, and emergence of multidrug-resistant strains.

Pathology

The organism usually responsible for spinal tuberculosis is Mycobacterium tuberculosis. Pulmonary tuberculosis is found in less than 10% of patients (Figure 3.18.5A). The spread of infection is mainly via the arterial vascular channels and Batson’s plexus. More than 50% of lesions occur in the dorsolumbar region. Children show a higher incidence of cervical involvement than adults. About 5% of patients have skip lesions, which are separated by two or three normal vertebrae (Figure 3.18.5B).
Fig. 3.18.5
A) MRI of an adolescent girl showing a tuberculous focus of infection at the mid-dorsal level together with a pulmonary lesion. B) Skip lesions are seen in about 5% of patients investigated using plain radiography and in about 15% when MRI is used.

The vertebral bodies are affected in the majority of the patients, but the appendices (pedicle, laminas, transverse process, or spinous process) are involved in less than 10%. Many types of body involvement are observed (Figure 3.18.6). Paradiscal infection is the most common type, especially in adolescents and young adults. The infection spreads through the epiphyseal arteries and there is narrowing of the disc space with involvement of the adjacent bodies. Disc-space narrowing is observed 2–3 months before any osseous changes are seen (Figure 3.18.6A).

Fig. 3.18.6
The various types of body lesions seen commonly. A) Reduction of disc space with marginal erosions is the first sign of paradiscal lesion. B) Complete destruction of vertebral bodies can be seen, especially in children, and severe deformities occur. C) Body lesions with reduction in the body height and normal disc spaces can cause difficulty in differential diagnosis with metastasis and other neoplastic conditions. D) Anterior lesions show notching in the anterior margin without involvement of the whole body or the disc.

Tuberculosis in children

Complete destruction of one or two vertebrae is more common in children below the age of 10 years. The anterior column deficit is enormous, and these children are specifically prone to severe deformity and late-onset paraplegia (Figure 3.18.6B). Posterior or the appendicular lesions may affect the pedicle, transverse process, laminas, or spinous process (Figures 3.18.7 and 3.18.8).
In the anteroposterior radiograph of the spine a normal vertebra has two pedicles and a spinous process resembling the eyes and the beak of an owl. Destruction of a pedicle as shown in the figure leads to loss of a pedicle, resulting in the 'winking owl' sign.

The natural history of untreated spinal tuberculosis is one of continued destruction of the vertebral bodies and progressive deformity with potential for neurological deficit due to compression of the neural structures by caseous and infective granulation tissue. Specific antituberculous chemotherapy can arrest the progress of the disease at any stage and hasten the healing and consolidation of the focus.

The disc is destroyed early in the course of the disease. The rate of bony fusion in spinal tuberculosis is high. In patients with severe disease, many vertebral bodies are destroyed and there is usually a severe collapse before contact of healthy bone can take place (Figure 3.18.9B). Deformity may progress to more than 60 degrees in about 5% of the patients, and there may be some neurological symptoms or signs in about 15–20%. Children who have a severe collapse of more than 90 degrees in the dorsal and the dorsolumbar vertebra are also prone to late-onset paraplegia in their second or third decade.

Clinical features

There is usually insidious, but sometimes acute onset of weight loss, loss of appetite, malaise, and evening rise of temperature, pain, and restriction of movement localized to the site of the lesion but soon becomes referred and aggravated with spinal movements. Tenderness to pressure over the involved vertebra is always present, and tapping on the spinous process causes referred pain. Deformity occurs as the involved vertebrae are softened. A retropharyngeal abscess causes difficulty in deglutition and phonation (Figure 3.18.10A). A cold abscess is present in more than half of patients (Figures 3.18.11 and 3.18.12).
A 4-year-old child with extensive involvement of the mid-dorsal region with spinal instability. There was severe pain even on minimal movement and the child had to support the trunk with both upper limbs to adopt a sitting posture.

Fig. 3.18.11
A) Lateral radiograph of the cervical spine showing abnormal kyphosis of the cervical vertebra due to the tuberculous focus at C1–2. Note the large prevertebral soft-tissue shadow indicating a large retropharyngeal cold abscess. This patient presented with dysphagia and had difficulty in breathing, requiring immediate intervention. The normal prevertebral shadow does not exceed more than 2–3mm and an increase must raise suspicion of retropharyngeal abscess. B) A cold abscess in dorsal lesions usually collects in the paravertebral space and appears as a fusiform paravertebral shadow on anteroposterior radiographs.

Fig. 3.18.12
A) Cold abscess in lumbar lesions can travel along the lumbodorsal fascia and present in the Petit’s triangle. B) However, the abscess usually collects in the psoas sheath and huge collections of more than 1L are commonly seen.

Thoracic paravertebral abscesses may spread into the extrapleural space or may rupture into the pleura, resulting in empyema or track backwards along the intercostal vessels and nerves onto the chest wall. In lumbar lesions, the majority of cold abscesses enter the psoas sheath and form a psoas mass in the groin, the pelvis, the gluteal region, or the posterior aspect of the thigh or the popliteal region.

Diagnosis

MRI is very useful for delineating the soft tissue masses in both the sagittal and coronal planes and for indicating the extent of the disease and the spread of the tuberculous debris (Figure 3.18.13). A relative lymphocytosis, an elevated ESR, and a positive
tuberculin skin test are not infallible; skin test and ESR may be normal in more than 10% of patients. ESR may provide a rough guide for assessing response to therapy. Enzyme-linked immunosorbent assay (ELISA) for antibody to mycobacterial antigen-6 is also used in diagnosis and in differential diagnosis from other diseases such as brucellosis, typhoid, and syphilitic infections. CT is better for assessing bony destruction (Figure 3.18.14).

MRI is superior to all other forms of investigations in demonstrating the anatomy of the spinal canal and the extent and cause of pressure over the neural structures. It demonstrates clearly whether compression is due to an abscess or to sequestration of the disc and necrotic bone into the spinal canal. Subligamentous spread of a paraspinal mass with involvement of contiguous vertebra strongly suggests a tubercular infection.

A CT scan is very useful for the accurate assessment of the extent of bony destruction and the early identification of lesions where the pedicle or the posterior structures are involved. Injection of contrast leads to enhancement of the border of the paraspinal mass (rim-enhancement sign).

Treatment of uncomplicated spinal tuberculosis

Chemotherapy using antituberculous drugs is the mainstay of treatment. Chemotherapy has also made surgery more successful by drastically improving wound healing and reducing secondary wound infections. Surgery is helpful in managing deformity, neurological involvement, and non-response to chemotherapy (Figure 3.18.15). Unless there is an emergency, it is safer to perform a definite surgical procedure after chemotherapy for 3–4 weeks and adequate improvement of the nutritional status of the patient. Treatment is summarized in Table 3.18.1.

Inclusion criteria: patients with clinical and radiologic evidence of tuberculosis involving any vertebra from the first dorsal to the first sacrum and without neurologic involvement.

Exclusion criteria: presence of severe extraspinal disease (tuberculous or nontuberculous) or a previous history of antituberculous chemotherapy or surgical intervention.

Favorable status: no residual neurologic impairment, sinuses, clinically evident abscess, or impairment of physical activities due to the spinal lesion, and with radiologically quiescent disease. (NB Bony fusion and the severity of deformity were not considered in the assessment for favorable status.)

The current recommended daily dosage for the treatment of adults, with or without HIV infection, is 300mg isoniazid, 600mg rifampin (rifampicin), and 20–30mg/kg pyrazinamide. In this intensive phase, which lasts for 2 months, ethambutol (or streptomycin for children who are too young to be monitored for visual acuity) should be included when the severity of the lesion is extensive and there are complicating factors like neurological involvement, in patients from a population where there is a high primary resistance to isoniazid, and if there is a suspicion of drug resistance. After the intensive phase of 2 months, with either the triple-drug or the four-drug regimen, a continuation phase using isoniazid and rifampin can be continued for a period of 9–12 months.

Late deformity can occur in two distinct phases: the active phase, which includes the changes in the first 18 months when the disease is still active, and the healed phase, which includes all changes in deformity after cure has been achieved. The extent of
the collapse and its progress during a long-term follow-up has been found to depend on the age of the individual, the level of the lesion, and the presence of spinal instability. Paraplegia due to tuberculosis has traditionally been divided into two groups: **early-onset paraplegia**, which occurs within the first 2 years of the onset of the disease, and **late-onset paraplegia**, which usually occurs after many years.

**Brucellar spondylitis**

*Brucella* is endemic in agricultural areas of the world, particularly where goats are common. *Brucella melitensis* is found in goat’s milk, although other milk-producing animals can act as a reservoir. *Brucella abortus* and *B. suis* are present in about 30% of the cattle in the United Kingdom but rarely cause disease. Brucellar infections present in a similar way to tuberculosis. Spinal *Brucella* is mainly found in the lumbar region and multiple sites are common. Presentation may be relatively acute, particularly if *Brucella* causes a meningitis. *Brucella* can also cause a local sacral ileitis. Diagnosis depends on considering the possibility of brucellosis and on bacterial culture and serology. The usual treatment is chemotherapy with a range of antibiotics (tetracycline, streptomycin, and rifampin (rifampicin)). Chemotherapy should be maintained for at least 3 months and possibly longer, and even then the recurrence rate is high. Surgical management is limited to patients who fail to resolve, particularly if there is neurological compromise.

**Fungal infections**

Fungi may cause granulomatous lesions in the spine. Fungal infections include coccidioidomycosis, blastomycosis, histoplasmosis, cryptococcosis, and aspergillosis. They all occur in endemic regions and are rarely seen in the United Kingdom except in cases of immunodeficiency. They are all difficult to identify and to treat.

**Parasitic infections**

*Echinococcus* is a very rare cause of spinal infection which presents with large expansile lytic lesions (hydatid cysts). Diagnosis is made by a positive complement fixation test as well as the typical radiological changes. Treatment is by radical surgery combined with mebendazole. Results are very poor with a high rate of recurrence and also a high rate of paraplegia.

**Minimally infective organisms causing spinal infection**

*Salmonella typhimurium* can cause spinal infection in endemic areas and typically in patients with concomitant sickle cell disease. Other *Salmonella* species can cause spinal infection in the immunosuppressed. Commensals such as *Serratia marcescens* and *Nocardia* have been reported as causing spinal infection. These organisms have little relevance except in the immunocompromised.

**Notes:**

1
Disc Degeneration

- **DDD** - Multifactorial disease
- MRI is key imaging technique but cannot differentiate painful from painless degenerate disc
- Normal disc on T2W MRI has outer black annulus fibrosus and inner bright nucleus pulposus
- On T2W MRI DDD is dark and discitis is bright but occasionally disc may be bright in DDD due to liquefied nucleus.

Degenerative disc disease

Disc degeneration is a multifactorial disease. There is a general misconception to consider degeneration as a part of the normal ageing process but many factors including mechanical, genetic, nutritional, and traumatic causes have all been implicated in its aetiology. Similar changes have been described in asymptomatic young individuals, further evidence that genetic factors play a significant role (Figure 3.19.1).

Click to view larger

Fig. 3.19.1
Normal T1W (A) and T2W (B) sagittal images for lumbar spine. Short arrow shows annulus fibrosus and longer arrow points to the nucleus pulposus.

A wide spectrum of imaging techniques has been used to image low back pain. Plain film changes of degenerative disc disease (DDD) are a late finding. Computed tomography (CT) changes can be appreciated earlier, but only when the disc has bulged beyond its normal margins or when intradiscal gas or osteophytes have developed. Due to its ability to detect changes in the water content of the disc, magnetic resonance imaging (MRI) plays a principal role in identifying the degenerate disc and in differentiating other causes of pain; however, there are no reliable findings that help to differentiate the painful from the painless degenerate disc. Recent advances in MRI like functional $T_2$ mapping can also evaluate disc function.

The adolescent disc demonstrates three different anatomical areas on $T_2$-weighted (T2W) water-sensitive MRIs. There is a black outer zone of annulus fibrosus, a bright inner zone of the nucleus pulposus, and an intermediate zone, histologically representing a transition between the regular lamellae of the annulus and the more loosely packed nucleus. With increasing age, the ability of the nucleus to imbibe water decreases and there is a gradual loss of its bright signal. The early changes of disc degeneration parallel this change, but occur at a faster rate. Lumbar disc degeneration assessment is graded on the basis of MRI signal intensity on T2W midsagittal fast spin echo images, and distinction between nucleus and annulus, disc structure, and height. A grade 1 disc is homogenous, hypointense, with normal height with a clear distinction between nucleus and annulus. A grade 5 disc is inhomogenous, hypointense, with a collapsed disc space with loss of distinction between nucleus and annulus.

Cadaveric studies have shown that annular disruption is the decisive factor in disc degeneration. Annular tears, particularly radial tears are not necessarily a consequence of ageing. Annular tears can be radial, concentric, or transverse. A specific type, with a hyperintense round lesion surrounded by a black annulus has been called a high signal zone (HSZ) (Figure 3.19.2). There is some evidence that discs with HSZs are more likely to be symptomatic at discography. Other authors however, disagree. Annular tears are more conspicuous following gadolinium enhancement. On serial MRI of annular tears in lumbar discs, it has been suggested that hyperintensity on T2W MRIs and enhancement of annular tears do not indicate that the tear is acute in nature. With
progressive DDD there is loss of vertical height, disc material bulges in all directions, and the facet joints sublux. The combination of these changes can narrow the spinal canal, lateral recesses, or exit foramina and cause nerve root compression.

Fig. 3.19.2
Focal high signal (HIZ) in the posterior L4/L5 annulus (arrow) represents an annular tear.

The adjacent vertebral bodies also show changes in form of signal alteration (Table 3.19.1).

Type 3 endplate changes can be seen on plain films. Type 1 changes are non-specific and simply indicate marrow oedema (Figure 3.19.3). When present on both sides of a disc, which demonstrates low signal on T2W images, increased marrow water can usually be attributed to disc degeneration rather than tumour or infection. Discitis is also associated with peri discal marrow oedema however, in contradistinction to DDD, the infected disc has high signal on T2W images (Figure 3.19.4). In some cases of severe disc degeneration, the nucleus can become liquefied, and also return high signal on T2. In these cases, differentiation from discitis can be more difficult. As many of the infections are low grade and inflammatory indices are often normal or only minimally elevated, enhancement of the vertebral body endplates following administration of gadolinium-labelled diamino-tetraethyl-pentaacetic acid (Gd-DTPA) may assist, but it is non-specific and can also occur after uncomplicated surgery. Simultaneous enhancement within the endplate, posterior annulus, and vertebral body itself is more specific for infection. The pattern of endplate changes may provide a clue, in that fatty type 2 changes are unlikely to persist adjacent to an actively infected disc. In other cases, biopsy may be required to exclude infection (Figure 3.19.5).

Fig. 3.19.3

Disc prolapse

Annular disc degeneration may lead to annular tear and disc herniation. Disc herniation is most common at the L4/5 and L5/S1 levels. Plain radiographs have no role in the investigation of a patient with sciatica. Increasing use of non-ferromagnetic metalwork has improved the diagnostic capability of MRI after surgery as well. In the postfusion patient with radiculopathy, where implanted metal may interfere with both CT and MR interpretation, CT myelography may still have a role.

On MRI, disc prolapse is classified as disc herniation or disc bulge. If disc displacement in axial plane beyond the edges of the ring apophysis is less than 50% it is disc herniation and if more it is termed as disc bulge. Disc bulge is regarded as a degenerative process distinct from disc herniation.

Disc herniation is further subdivided on the basis of circumference, shape, and location. On the circumferential basis, localized displacement in axial plane beyond the edges of the ring apophysis is of two types: focal, if it is less than 25% and broad based, when the displacement is 25–50%.

On the basis of the shape it is classified as: protrusion, if the greatest distance in any plane, between the edges of the disc material beyond the disc space is less than the distance between the edges of the base of the herniated disc in the same plane (Figure 3.19.6); otherwise it is termed as extrusion. Extrusion can be referred to as sequestration if the displaced disc material has no continuity with the parent disc. Migration is a term used when the disc material is displaced away from the site of extrusion, irrespective of sequestration (Figure 3.19.7).
Fig. 3.19.6
Broad based L5/S1 disc protrusion: A) T2W sagittal; B) T1W axial. Left paracentral disc protrusion (arrows). The left S1 nerve root is not visible in the lateral recess. The right S1 nerve root is well visualized.

Fig. 3.19.7
Disc extrusion. A) T2W sagittal and B) T2W axial MRI demonstrate large L5/S1 disc extrusion (white arrow) elevating the PLL (black arrow). On axial image through the S1 vertebral body, disc appears to be sequestrated. C) Sequestered disc. Disc fragment (arrow) is noted posterior to the L4 vertebral body. It lacks continuity with the parent disc.

On the basis location, in the axial plane, it is classified as: central, subarticular (lateral recess region), foraminal (pedicle), and extra foraminal (far lateral). In sagittal plane it is categorized as discal, pedicular, supra- and infrapedicular. Nerve sheath tumours and facet synovial cysts can occasionally mimic disc extrusion or sequestration on MRI and may pose a diagnostic challenge.

A number of studies have emphasized that disc prolapse as revealed by MRI have been noted in asymptomatic individuals. In addition, the grade of disc degeneration or prolapse does not predict the clinical outcome. Furthermore, histologically proven degenerate discs with substantially decreased amount of nuclear material can still produce normal images on MRI.

Disc prolapse

- Plain radiograph has no role in patient with sciatica.
- MRI changes do not always correlate with symptoms.
- Disc prolapse nomenclature
- On MRI, nerve sheath tumours and facet joint cyst can occasionally mimic a sequestered disc
- Spinal cord compression and spinal canal stenosis should be excluded on axial MRI images

Imaging the postoperative spine

The patients with new or persistent symptoms following surgery (failed back syndrome) pose a difficult diagnostic dilemma. If symptoms persist or recur then images should be inspected to confirm that surgery was undertaken at the correct level and side. Thus, identification of lumbosacral transitional vertebra (LSTV) on MRI is very important. Disc bulge, protrusion, and spinal canal stenosis is nine times more common at the interspace immediately above LSTV. L5 can be readily identified on axial MRI as iliolumbar ligament always arises from the transverse processes of L5. If these points have been confirmed, persistent or new low back pain or recurrent sciatica following discectomy can be attributed to recurrent or residual disc material, epidural fibrosis or haematoma, discitis, arachnoiditis, or abscess (Figures 3.19.8 and 3.19.9).
Plain films are still used to assess spinal fusion, especially to assess metal discontinuity or fracture and displacement. Flexion and extension views can be used to assess vertebral stability. Cross-sectional CT imaging has largely superseded plain radiography as it can provide more detailed information. Implanted metal is not a contraindication to MRI or CT per se; however, depending on the metal used, paramagnetic artefacts, distortion, and beam hardening can obscure anatomic detail. In comparison to the steel implants, titanium metal implants cause fewer artefacts on CT as they have a low x-ray attenuation coefficient and also have less ferromagnetic affect and cause less susceptibility artefact on MRI. Ultrasound is utilized to diagnose, delineate the size and location of postoperative collections, and aspirate superficial collections. Where there is clinical suspicion of postoperative discitis, contrast-enhanced MRI is the imaging investigation of choice; however, in the early stages it may be difficult to discriminate between septic and aseptic discitis. Imaging findings must be correlated with the clinical picture and biochemical markers.

In persistent or recurrent radicular symptoms, the differential diagnosis is between recurrent disc material, neural irritation from epidural granulation tissue, and, rarely, residual disc material. It has been proposed that contrast-enhanced MRI is superior to MRI, CT, and myelography in discriminating recurrent disc from scar tissue. Where enhancement is used, it has been suggested that ionic MR contrast media, in comparison to non-ionic media, diffuses less readily into disc material and provides greater contrast with scar. The addition of fat-suppressed T1 images and obtaining images immediately after the contrast injection may improve scar visualization. Residual disc may only show rim enhancement due to surrounding granulation tissue. The degree of enhancement of scar tissue is also dependent on its age and reaches a maximum by the first year. Disc enhancement may also be seen if imaging is delayed.

Gadolinium should not be regarded as mandatory to diagnose recurrent disc material. In equivocal cases, gadolinium enhancement does help, although it is important to appreciate that vascularized discs may enhance and dense fibrosis may not. The presence of epidural scar tissue on MRI does not necessarily indicate a poor outcome. Disc degeneration is a risk factor for recurrent herniation irrespective of its volume.

The MRI appearance of epidural haematoma depends on its age. In the early phase, the signal characteristic is that of fluid—low on T1 and high on T2. As it begins to deteriorate, methaemoglobin release causes the signal on T1 to increase. Finally, haemosiderin deposition causes the signal on T2 to become low. In most cases, haematoma comprises several of these stages.

Other potential MRI findings in the failed back syndrome include arachnoiditis, seroma, and, rarely, pseudomeningocele.
Arachnoiditis is diagnosed by the identification of one of several patterns. The most specific is clumping and agglutination of multiple nerve roots. Another pattern, termed the ‘empty sac’, occurs when the nerve roots adhere to the thecal sac itself, leaving an apparently empty cerebrospinal fluid space. This pattern can be seen in asymptomatic individuals, emphasizing the importance of clinical correlation.

Other conditions

The most common tumour encountered is the vertebral haemangioma. As these lesions contain both fat and fluid elements, its MRI appearances are usually typical; the lesion is bright on both T1 and T2 images (Figure 3.19.10). Metastases and myeloma may have variegated marrow appearance on MRI (Figure 3.19.11) (Table 3.19.2).

Spondylolisthesis is classified as degenerative, isthmus (spondylolytic) and dysplastic, traumatic, and pathological. Degenerative spondylolisthesis is commonly noted at L4/5 and isthmic is more often at L5/S1 (Figure 3.19.13). Axial loaded MRI may show dynamic degenerative spondylolisthesis, which may be missed on plain radiography or conventional MRI. A facet joint effusion of 1.5mm or more at L4/5 is suggestive of degenerative spondylolisthesis even if anterior translation is not noted on supine lumbar spine MRI. On MRI, indirect features of pars spondylolysis are widening of the canal size and posterior vertebral wedging and are helpful in diagnosing pars defect in absence of spondylolisthesis. A full discussion of infection, tumour, ankylosing spondylitis, and spondylolisthesis is beyond the scope of this chapter.

---

**Interventional techniques in spinal disease**

**Vertebral biopsy**

Vertebral body biopsy is a safe procedure when carried out with appropriate care. Coagulopathy should be excluded prior to the procedure. CT or fluoroscopic guided biopsy can be performed. Fluoroscopic procedures are quicker than CT guided procedures, but CT provides more accurate needle placement for smaller lesions (Figure 3.19.14).
CT-guided core biopsy was found to be 93.3% accurate with highest accuracy rates for malignant lesions and false negative for benign, inflammatory, pseudotumoural and systemic pathologies. A negative biopsy in neoplastic lesions must be further confirmed with an open biopsy. Reported complications including infection, haematoma, and self-limiting neurapraxia are rare.

**Intradiscal interventional procedures**

Percutaneous access to the lumbar and thoracic discs is readily achieved via posterolateral and cervical discs via an anterolateral route under fluoroscopic control.

**Discography**

Statistics on lost man-hours and health costs in the patients with chronic disabling back pain show no evidence of abating despite a proliferation of surgical procedures and fusion devices. Part of the difficulty is patient selection, as routine imaging cannot confirm an abnormality as the definitive source of pain. This is where discography has a role. Discography can provide both anatomical and more importantly ‘physiological’ information on the source of pain, though false negatives and positives are the subject of much controversy (Figure 3.19.15).

**Discography** is most useful at differentiating painful from non-painful discs and should be regarded as a preoperative examination. Discography is valuable in selected patients with moderate loss of nuclear signal intensity and no other MRI features of DDD. Lesser roles include differentiating scar tissue from recurrent disc and confirming disc containment prior to percutaneous surgery. Pressure-controlled manometric discography can distinguish asymptomatic discs with grade 3 (Dallas Discogram Scale) annular tear.
Percutaneous intradiscal therapy

It is of two types, intradiscal electrothermal therapy (IDET) and percutaneous intradiscal radio frequency thermocoagulation (PIRFT). In the former, heat is generated electrically and in the latter through radiofrequency. These modalities are used in treatment of painful annular tears by coagulating the inflammatory tissue and the nerve endings, thus ablating pain. The treatment, however, is not permanent and, if successful, has to be repeated. In IDET a catheter is passed into the nucleus pulposus such that it lies along the inner margin of the annulus whereas in PIRFT the catheter is placed into the centre of the disc. Initial non-randomized studies suggested a favourable outcome for IDET but not for PIRFT. Various randomized controlled trials (RCTs) have suggested both favourable and unequivocal outcomes. A recent study, however, has shown that with application of strict selection criteria (patients with mild disc degeneration, annular tear proven on imaging, and pain on low-pressure discography), superior outcomes can be achieved with IDET.

Prolapsed discs that have failed to respond to conservative measures can be treated by a variety of intra- and extradiscal measures. Intradiscal treatment includes chemonucleolysis, percutaneous nucleotomy, and laser nucleotomy. All involve instrumentation of the nucleus pulposus and its removal by chemical dissolution, suction, or heat.

Chemonucleolysis helps in reducing turgidity in the nucleus and decreasing pressure on the nerve root. Significant improvement of outcome and reduction in recurrence rate has been demonstrated with an addition of 1000U of an intradiscal chymopapain following transforaminal endoscopic discectomy. Percutaneous laser disc decompression has made vaporization of a small area of the nucleus pulposus possible.

An alternative means of percutaneous disc excision is automated percutaneous lumbar discectomy. Dynamic stabilization system is useful to prevent progression of initial lumbar degenerative disc disease after nucleotomy for symptomatic prolapsed disc. According to NICE guidance (2006), the potential candidates for disc decompression using coblation are patients with contained disc leading to back and leg pain. Percutaneous endoscopic transforaminal lumbar discectomy (PELD) are also being performed for the herniated discs and foraminal PLED is considered to be an efficacious treatment option for soft migrated disc herniation.

Percutaneous facet joint injection

Facet joint arthritis is easily seen on axial CT or MRI sections. The appearances mimic changes of osteoarthritis elsewhere, with joint-space irregularity, osteophytes, and subarticular sclerosis. It is frequently identified in the asymptomatic population. There are no firm clinical signs confirming the facet as the source of the patient’s symptoms. Injection of local anaesthetic and steroid into the facet has been used as both a diagnostic test and a therapeutic measure (Figure 3.19.16). There is moderate evidence of long- and short-term relief of lumbar facet joint pain by use of an intra-articular facet joint injection, medial nerve blockade, and neurectomy or rhizotomy. Occasionally, small synovial cysts can be identified arising from the facet joint. These can be intra- or extraspinal. Intraspinal lesions may present with neural compression (Figure 3.19.17). Imaging-guided cyst aspiration can be performed under fluoroscopic, CT, and MRI guidance. An interlaminar approach under fluoroscopic guidance has been used to puncture an intraspinal zygapophyseal cyst to alleviate the radicular symptoms.
Fig. 3.19.17
Left L3/L4 intraspinal facet joint cyst (arrows). T2W (A) and T1W (B) axial MRIs show bright signal in the facet joint cyst suggesting presence of internal haemorrhage.

Each facet receives dual innervations from the median branches above and below. Median branch blockade is an alternative to facet blockade provided that both branches are injected. The target point is the elbow between the transverse and the superior articular process. Functional status improvement was noted in 82% of the patients with local anaesthetic nerve root block of the lumbar facet joint irrespective of steroid use. Rhizolysis (radiofrequency neurotomy) is similar to medial branch blockade but achieves more long-lasting results. Like IDET, this treatment is not permanent. If a satisfactory response to intra-articular facet injection is achieved, more long-term pain relief is gained by medial nerve neurotomy by radiofrequency ablation or cryoneurolysis.

Selective nerve root blockade

Multilevel disc degeneration and multiple root symptoms are common in older age groups. Images obtained in the recumbent position may underestimate the presence or degree of root impingement. Selective root blockade provides a means whereby an individual root can be anaesthetized and the subsequent effect on symptoms determined (Figure 3.19.18).

Vertebroplasty/kyphoplasty

Percutaneous vertebroplasty involves the injection of cement into a collapsed vertebral body, mainly for pain relief. Patient selection for both procedures should be performed with a multidisciplinary approach including spinal surgeon and radiologist. The principal indication is painful osteoporotic collapse. Indications also include malignant collapse and expansive intravertebral haemangioma. Vertebroplasty can be considered in patients with intractable pain due to vertebral fractures. It is contraindicated in coagulopathy. VERTOS and INVEST are two current multicentre RCTs that have yet to confirm a more favourable outcome with percutaneous vertebroplasty than conservative treatment.

The technique involves the injection of polymethylmethacrylate (PMMA) into collapsed vertebral bodies. The vertebral body is cannulated either by a direct posteroanalateral approach or via the transpedicular route. Once needles are positioned, cement is injected under pressure to support the vertebral body. Complications include extravasation of cement, which may lead to nerve or thecal compression (Figure 3.19.19).
A) Lateral fluoroscopic view demonstrates 11G vertebroplasty cannula (arrow) with cement filling the D12 vertebral body. B) Shows an excellent filling of the vertebral body and minor extravasation into the prevertebral vein (arrow).

A variation on this procedure is balloon kyphoplasty. This procedure is used to correct an angular deformity resulting from vertebral collapse. Following vertebral cannulation, a Teflon balloon is dilated under pressure within the vertebral body. Once the deformity has been corrected, the balloon is deflated and removed and the cavity is filled with cement.

Out of the two percutaneous vertebral augmentation techniques, vertebroplasty offers comparable pain relief but is safer as often only a unilateral approach is utilized, with fewer requirements of PMMA and without risk of adjacent level fracture.

Summary points

♦ History: onset event, radiation, exacerbation, night pain, functional deficit
♦ Examination: active and passive movement, impingement signs, instability tests
♦ Investigation: x-rays, ultrasound, CT and MR.

Clinical assessment

Diagnosis depends upon three lines of enquiry, all of which should concur for the case to be proven. The first line of enquiry is the history. Using questions and answers we develop a short list of two or three possible pathologies. This is then subject to rigorous analysis against known facts. Occasionally the inquisition will trigger a red flag (the crescendo pain of calcific tendinitis), or it leads into an area where mistakes in diagnosis can lead to tragic events (the missed secondary tumour in the humeral metaphysis). However, we must remember that patients are human, they forget, dissemble, and sometimes lie. So ask the same question in two different ways (for instance, "have you had any illnesses?" followed by "what tablets are you on?") and if the answers don’t match you discard them or dig deeper.

The second line of enquiry is to examine the shoulder in a logical stepwise manner. But remember:

♦ That examination techniques may be 75% accurate, or less
♦ Tests can be confounded (for instance, stiffness renders the impingement tests null and void)
♦ Some conditions can have a very similar examination profile to others, they mimic the other condition.

Fortunately pathology from the shoulder tends to fall into one of four areas: the stiff shoulder, the wobbly shoulder, pain on reach (the painful arc), and the remnants. Examination will at least get you into one of these four areas, and the first three have a specific forensic investigation that will prove the case.

So we come to the third line of investigation, and the most powerful, the forensics. In our case, radiology, ultrasound, magnetic resonance imaging (MRI), and arthroscopy. Rarely blood tests will be required. Stiff shoulders merit a radiograph; wobbly shoulders merit examination under anaesthetic and arthroscopy; and pain on reach merits an ultrasound. Forensics trumps the history and the examination.

Our problem is that we do not have unlimited time in outpatients. For this reason the hip surgeon goes to the forensics first, the radiograph of the hip, and then asks the patient about their symptoms. The shoulder surgeon has been hampered by the lack of forensics, but portable ultrasound can be performed rapidly in the clinic, and can give a firm diagnosis on those with pain on reach, and radiographs will sort out the stiff shoulders. Finally shoulder arthroscopy has come of age so that most shoulder conditions cannot only be identified but can also be treated arthroscopically.

Age is key to shoulder pathology. A useful aphorism is that ‘all patients below the age of 40 have instability until proven otherwise’, for instability is a condition of teens to thirties. Rotator cuff disease is a degenerative disease that starts to give pain on reach in the forties, tears of the cuff in the late fifties to sixties, and cuff arthropathy in the eighties (thus the aphorism ‘Grey hair equals cuff tear’). The Japanese call contracture (frozen shoulder) ‘50-year-old shoulder’ for a reason, and if the letter states that the patient is 70 and has had a hip replacement then it is more likely that they have arthritis in the shoulder rather than a contracted (frozen) shoulder.

Observation

Dr Watson was a poor doctor for Holmes had to admonish him: ‘Observe my dear Watson, don’t just look!’ Facts can be deduced as the patient enters the room, before a word is said or a hand shaken. Do they look biologically the same age as their chronology, younger or older? How are they dressed, for patients with stiffness or loss of reach can’t pull sweaters over their heads, so will have clothes that button or zip up? How are they holding the shoulder? How protective are they? Is their neck held stiffly or moving normally? Remember the aphorism ‘Grey hair equals cuff tear’. With increasing experience you may note subtle signs such as the oven burns from syringomyelia, the bossed clavicles of glenoid dysplasia, or the absent facial expression of the patient with fascioscapulohumeral dystrophy.

Introduce yourself whilst cautiously shaking their hand, and at the same time note whether they have the shoulder shrug of the patient with a massive cuff tear, the stiff shoulder of arthritis, Dupuytren’s palmar contracture so often associated with contracted (frozen) shoulder, the engulfing hand of acromegaly, the rheumatoid hand of the rheumatoid shoulder, a weak grip, a strong grip, a tentative protective grip, a stiff shoulder, or a mobile shoulder.

The history

The problem with shoulders is that a history of true shoulder pain (pain felt over deltoid insertion), that has come on insidiously, is...
made worse by shoulder movement, that radiates down the radial border of the forearm, and that awakens the patient at night could come from virtually any patient with any disorder of the shoulder. Such a history would fit with a rotator cuff problem, a contracture (frozen shoulder), a calcific deposit, arthritis, or even instability. Even worse, since the majority of these problems are soft tissue problems, they won’t show up on a radiograph. Quiel homere, what can we do? The answer is that the shoulder surgeon relies more upon the objective physical signs and provocative tests of the examination, and these guide him to the correct investigation. The history should not be dismissed, but it can be performed rapidly. As Cyrtax said ‘with the shoulder the history matters little, it is the examination that counts’.

**Referred pain**

The first purpose of the interview is to ascertain whether the pain is from the shoulder or referred from another source. True shoulder pain originates from the shoulder and radiates to the muscles of the arm, around the insertion of deltoid. Indeed many patients will say, ‘It’s not my shoulder doctor, it’s my arm’, and will vigorously rub the deltoid insertion when asked to show where the pain is. When severe, the pain will radiate down the radial border of the forearm to the wrist, occasionally to the thenar eminence. The pain may radiate into the supraspinatus fossa, beneath trapezius, but pain more central to this, or along the medial border of the scapula is far more likely to be referred from the neck. Shoulder pain is made worse by shoulder movement. 

Alarm bells should ring in patients whose pain radiates into the hand, for this is the pattern of referred pain from the C6 and C7 nerve roots. Similarly, beware of the patient whose pain radiates to the ulnar side of the forearm, the axilla or the chest, for this is the radiation from the thoracic outlet, the lower trunks of the brachial plexus (C8, T1), or the C8 and T1 roots. In patients with such radiation, always suspect a neurological cause for their pain and perform a careful neurological examination.

Referred pain from the viscera (gall bladder to right shoulder and myocardium to left shoulder) is mentioned in every textbook, but search as I may I have yet to see such a case in a shoulder clinic, despite being responsible for the secondary care of 400 000 patients and the tertiary care of 3 million people for the last two decades.

Pain coming from the acromioclavicular joint and the sternoclavicular joints are better localized than glenohumeral joint pain. Patients will point to the acromioclavicular joint when that is the cause. Pain from the sternoclavicular joint is well localized and radiates out along the subcutaneous border of the clavicle.

**True shoulder pain**

Enquiries should be made into the generic qualities of the pain: the onset event, duration, severity, radiation, exacerbating features, and what treatments have been attempted so far and to what effect? But lots of pathologies share the same features of pain in the shoulder, so it is only really worth seeking those factors that are specific to certain pathologies. The nature of pain is rarely discriminatory in the shoulder.

- **The onset event**: note the date of onset and calculate the duration. Is the condition acute or chronic? Often shoulder pain comes on insidiously, but if there was an initiating event this is an important clue. How much energy was involved in the event? Enough to tear a degenerate cuff? Enough to cause a transient dislocation? Enough to cause a fracture? There are some pathologies that have a distinct onset. Acute calcific tendinitis has a sudden onset with such severity of pain that the patient takes themselves to the emergency department in the middle of the night. The patient with neuralgic amyotrophy awakens with severe burning pain in the arm, followed by weakness in various muscles around the shoulder. The rotator cuff tear has a sudden severe pain followed by a window of relief lasting some hours (the lucid interval), then severe pain from that night onwards

- **Night pain** is a common feature of shoulder disorders. This may vary from difficulty settling, to occasional awakening, to awakening every night, to arising at four in the morning as further attempts at sleep are impossible to the final stage of being exiled to the spare room for keeping their partner awake all night. These latter stages should trigger alarm bells, a radiograph should always be taken to exclude a metastatic deposit in the humeral neck or a calcific deposit. Analgesic consumption is important, the amount of consumption and need for opiates. Night pain will not give you a specific diagnosis but it will influence your priority to treat. For instance, the patient with a contracted (frozen) shoulder who has no night pain can be treated conservatively, but if the patient arises at four every morning as further sleep is impossible, consideration should be given to performing an arthroscopic capsular release

- **Pain on reach**: a functioning rotator cuff is essential to reach. Pain and weakness on reaching forward, upward, outward, or backward, in a mobile shoulder, is specific to rotator cuff disease. This pain is made worse with load such as lifting a kettle, or even a cup of tea, and the shoulder will fatigue with prolonged reach such as driving

- **Jerk pain**: a sudden minor wrench on the contracted capsule (frozen shoulder) brings disproportionate pain and tears to the eyes in contracted (frozen) shoulder. This is never mentioned in any textbook, but is a solid fact

- **Previous treatment**: previous steroid or local anaesthetic injection, administered to a specific site (cuff, acromioclavicular joint, or glenohumeral joint), may have alleviated their pain for a duration. This allows you to pinpoint the specific area of pathology.

The majority of patients will present with pain and can then be placed into one of three categories: stiff shoulders (arthritis and contracted (frozen) shoulder), wobbly shoulders (instability), and loss of reach (pinching, partial and full thickness tears of the rotator cuff), so we need two additional lines of questioning about stiffness and instability.

**Stiffness**

Stiffness limits function. Yet it is extraordinary how patients can adapt to stiffness in one shoulder. Neer showed how most activities can be performed as long as you have 150 degrees of flexion, 40 degrees of external rotation, and internal rotation to L2. The Stanmore functional triangle has been described as the ability to reach the mouth, the opposite axilla, and wipe the bottom. Less movement than this severely compromises the ability to maintain independent living. There are five main causes of stiffness.
Weakness from tendon rupture

Weakness from a rotator cuff tear is common. The patient complains of inability to reach and will often say that they have to assist the arm, by holding the forearm with the opposite unaffected hand. Commonly the patient will have to assist to brush the hair, to wash, to brush the teeth, and to reach forwards. They will adapt and use tricks such as holding the elbow to the side whilst lifting, and will lean right forwards almost touching the floor to dress and undress. Wasting will be apparent. Usually the weakness is accompanied by pain.

The isolated rupture of long head of biceps occurs with a sudden painful event, is associated with bruising down the course of biceps (rotator cuff tears rarely bruise), and the patient notices a change in shape of biceps to the ‘Popeye muscle’. This is painful accompanied by pain.

Weakness can only come from three things: rupture of a tendon (common), muscle weakness (myopathy, extremely rare), or failure of motor enervation (nerve palsy, rare).

As you can see all you need to make the accurate diagnosis in stiffness is a radiograph, in two planes, and to interpret it correctly.

Instability

At last we come to an area where the history is discriminatory. If the patient says their shoulder came out, it came out. This history can be pursued vigorously. Describe the first dislocation, how and when? Was this traumatic or atraumatic? Was it transient or locked out? Did it go back spontaneously, with a little help from bystanders, at hospital, under sedation, or under general anaesthetic? Was it secure afterwards, were they protective, did it redislocate, how, when, how many times, how was it then put back in?

Strangely, patients have little concept of the direction of dislocation, to be honest it is so painful they don’t care, but if radiographs were taken with it dislocated this is helpful, as is the presence of a Hill–Sachs or reversed Hill–Sachs lesion at the time of the consultation.

Of course there is a group of patients with symptomatic subluxation, and atraumatic transient dislocation, for whom diagnosis can be difficult. Always suspect this as a cause of shoulder pain in anyone less than 40 years of age.

Some patients will helpfully show you they can dislocate the shoulder. Beware; this is a red flag situation. They may just have marked joint laxity with posterior positional dislocation, in which case they gently sublux on raising the internally rotated adducted shoulder and then get a clunk of relocation as the shoulder is abducted. But if they dislocate with the elbow at the side and a huge grin on the face, beware—this is a Polar III, muscle-induced dislocation that will be resistant to any surgical adventure. The history and examination for muscle patterning and Polar III instability is complex and will be described in detail in Chapter 4.7.

Neurological and other conditions

Finally, one of the joys of being a shoulder specialist is that patients will turn up outside the three boxes of stiff shoulders, wobbly shoulders, and loss of reach. These are the remnants, but no less important for being so. These cases are the neurological conditions: the winging scapulae, thoracic outlet syndromes, neuralgic amyotrophy, and a variety of nene palsies. Then the curios: the Sprengel’s shoulder, obstetric plexus palsies, glenoid dysplasias, muscular dystrophies, as well as disorders of the acromioclavicular and sternoclavicular joints. Finally come the nasties, for tumours do occur around the shoulder, primary tumours being rare, but the proximal humerus is a common site for secondary tumours. Thus the patient may present with weakness, loss of function, swelling, wasting, noises, and winging.

Weakness

Weakness can only come from three things: rupture of a tendon (common), muscle weakness (myopathy, extremely rare), or failure of motor enervation (nerve palsy, rare).
when it occurs, but the pain settles within a few days, so the patient may present with weakness of elbow flexion and supination (using a screwdriver), although this is uncommon because the short head of biceps is intact. Weakness is more commonly seen in the rarer rupture of the distal tendon of insertion into the radial tuberosity.

Isolated ruptures of pectoralis major are subtler. There is a painful event in a 20-year-old man, who is a weightlifter or frequent gym user, who may or may not be on ‘health food supplements’ that may or may not contain nandrolone or some other androgenic steroid. There is a change of shape of the anterior axillary fold accompanied by bruising. There is weakness of pectoralis major.

Weakness from nerve palsy

Axillary nerve palsy is rare. It occurs after anteroinferior and inferior dislocations of the shoulder. There is decreased sensibility of the badge area of skin and weakness and wasting of deltoid. Muscle fasciculation may be seen. The injury is often a neurapraxia, but the nerve can be completely ruptured and require grafting.

Suprascapular nerve palsy is usually insidious in onset, presenting as a severe burning pain over the upper scapula accompanied by rapid wasting of infraspinatus (and supraspinatus although that is less obvious as it is covered by the healthy trapezius). It mimics cuff tear but the wasting is much more severe than seen with rotator cuff tears and has a more rapid onset. There is weakness and fatigue on reach.

Injuries to the long thoracic nerve and to the spinal accessory nerve lead to loss of scapula control and winging. Patients often complain that the ‘shoulder blade sticks out’. It may press awkwardly against the seatback when seated on a chair. Partners and family members note the cosmetic asymmetry of the shoulder blade. There is a loss of the shoulder fulcrum and lifting is weak and limited.

Weakness from muscle dystrophy

Fascioscapulohumeral dystrophy (FSHD) is the rarest of the causes of shoulder weakness. Patients usually present from late teens through to late twenties with shoulder girdle weakness particularly in abduction and flexion. The facial muscles are weak leading to a loss of facial expression, and that weird symptom, inability to whistle! Strangely the deltoid muscle is often preserved leading to a ‘Superman’ appearance. The key to diagnosis lies in the affected chromosome 4q35.

Swelling and deformity

Occasionally patients complain of swelling. A swollen sternoclavicular joint is often noted by a perimenopausal female looking in the mirror. Swelling of the medial clavicle can occur in SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome or Garre’s sclerosing osteomyelitis. The patient may notice a swelling over the acromioclavicular joint with the ‘Geyser’ sign where fluid herniates out of the top of the joint from a communication with a massive cuff tear. The massive bursal fluid swelling of cuff tear arthropathy disturbs the patient with this condition. Remember that tumours both benign and malignant occur around the shoulder.

Deformity may be a presenting complaint, usually in children and adolescents. The deformity of congenital pseudarthrosis of the clavicle, the bossed clavicle of primary glenoid dysplasia, the elevated scapula of Sprengel’s shoulder, the ‘waiter’s tip position’ of Erb’s palsy. The absent pectorals of Poland’s anomaly and the dimples of posterior positional dislocation are all infrequent findings in the shoulder clinic.

Examination

The examination is more revealing than the history. Most pathology will fall into one of three boxes: the stiff shoulder, the wobbly shoulder, and pain on reach (the cuff). Examination should be tailored to the pathology suggested by the history. For instance, if the history points towards a wobbly shoulder then the time available to you should be used for instability tests, rather than the more esoteric eponymous tests of the rotator cuff. In the real world time is limited.

A plethora of eponymous clinical signs have sprung up over the last two decades. However, few have weathered the tests of specificity and sensitivity to gain mandatory use in the examination. Beware that clinical signs can be confounded, particularly by stiffness. Thus the belly press sign, an enormously important sign of subscapularis dysfunction, can be confounded by stiffness into internal rotation, producing a false positive belly press sign. Inspection and palpation are common to all stems, but should not take long.

Inspection

Stand back and look at the profile of both shoulder girdles from the front. Is there asymmetry? Is one shoulder lower than the other? Is the posture slouched (common with thoracic outlet problems), are the scapulae protracted (gunslingers posture)? Is there asymmetry of deltoid bulk that is more pronounced than dominance should allow? Look from the side. Is the biceps’ shape altered? Look from the back. Is there wasting of infraspinatus (rotator cuff tear or suprascapular nerve entrapment)? Is there any winging? Pay attention to old surgical scars. Are the scars stretched as occurs with instability, or are there any striiae on the skin?

Pay careful attention to the humeral head. Is it elevated or more prominent than it should be, for this will suggest a tear of the cuff? If, like Sherlock Holmes, you are observing rather than just looking, inspection will take a matter of seconds.

Palpation

The sternoclavicular and acromioclavicular joints are subcutaneous, and if the history has suggested that they are culpable, then they are easy to palpate. However, the glenohumeral joint line cannot be reached because the acromion covers the posterosuperior
aspect, the coracoacromial ligament covers the anterosuperior aspect, and the conjoined tendon covers the anterior joint line. This only leaves the posterior joint line that lies beneath both deltoid and infraspinatus rendering palpation of the joint line impractical. Yet the greater tuberosity can be palpated easily. Since this is the site of most cuff pathology you may detect tenderness and even a ‘sulcus and eminence’ of the tear itself. Unless there is a lump or bump don’t spend too much time palpating. But do place a hand on the shoulder as you move it for soft crepitus and catching may be felt from the cuff, squeaking from an arthritic joint surface, or even a clunk of subluxation or relocation in unstable shoulders.

**Examination for stiffness**

The examination for stiffness precedes all else, for if the joint is stiff no further examination is required—the patient needs a radiograph of the shoulder. Stiffness confounds the tests of rotator cuff dysfunction and so must precede them. Finally if the opposite of stiffness, excessive motion, is discovered then more attention must be placed on instability testing.

**Active movement**

Ask the patient to move the shoulder himself or herself—this is active motion. Using a single finger to guide and nudge the patient’s arm into flexion will save you a great deal of time with verbal instruction. Patients do not understand instructions such as ‘flex or abduct your shoulder’. Place your other hand over the shoulder as the patient moves so that you will detect the rhythm between scapulothoracic and glenohumeral motion, detect translation of the humeral head, and finally detect crepitus, creaking and clunking. *This means you have to examine one shoulder at a time, starting obviously with the normal side.*

See if there is a restriction in active movement (that is, the range that the patient can comfortably initiate and sustain), and then the passive movement (the limit to which you can move the shoulder when pain is abolished). Four movements will be assessed, forward elevation, external rotation, internal rotation, and cross body adduction. By convention zero degrees is the anatomical position with the arm to the side and the antecubital fossa pointing forwards.

Note the level at which active movement ceases. Now rather than cause the patient increasing pain by forcing the shoulder passively further up, ask the patient to stoop forward *(the bow test of Kolbel)* for this often eases their pain and allows you to assess their passive range without hurting them *(Figure 4.1.1)*. With the arm supported by you in this position of maximum elevation, ask them to stand, and finally now ask them to lower the arm, whilst you pay particular attention to how the scapula moves. You will see, in patients with rotator cuff disease, that they lock the glenohumeral joint during descent through their painful arc, leading to pseudo-winging.

**Passive movement**

If despite stooping the patient forward the shoulder will not move further, then we have a block to passive motion, true stiffness. Always note the quality of the end point of this movement. A leathery block to movement suggests a contracture. A firm bony end point is caused by osteophyte impingement in arthritis. An open end point—in other words, you know that the joint will move further but you dare not move it any more because of inordinate pain—is a red flag, it means either that there is a tumour or that the patient is exaggerating their symptoms.

Assess rotation both actively and passively. Beware for the shoulder is designed to position the hand accurately in space. Patients with little external rotation will cheat and abduct the arm in order to get the hand into position. *(Remember that in every good detective story a few false clues are thrown in to see how clever you really are.) Keep the patient’s elbow locked to the side when testing external rotation *(Figure 4.1.2)*. Patients with rotator cuff disease have near normal external rotation, but painful restriction of internal rotation. Patients with frozen shoulder and arthritis have passive restriction of both external rotation and internal rotation. Internal rotation is measured by the vertebral level at which the thumb rests at maximum internal rotation reach. If the patient has
marked restriction of elbow flexion (for instance, in rheumatoid disease) then vertebral level is not an accurate method of measurement.

Fig. 4.1.2
Keep the patient’s elbow locked to the side when testing external rotation.

If significant passive stiffness is discovered then no further examination is required. A radiograph is mandatory and this will be normal in contracture and abnormal in arthritis, massive end-stage cuff tear, and locked posterior dislocation. Remember that stiffness may nullify further testing by producing false positive results.

Examination of the rotator cuff

To understand the clinical signs associated with rotator cuff disease you must first understand the anatomy and pathology of the rotator cuff. Most important is Professor Olivier Gagey’s concept of the fibrous skeleton of the cuff. The supraspinatus tendon comes from the centre of its muscle belly and migrates to the anterior edge of the tendon footprint of insertion. This central oblique tendon is extremely strong and acts as a ‘firebreak’ to tears. The majority of tears start just behind this tendon insertion leading to the typical posterosuperior cuff tear. This concept is expanded in Chapters 4.2 and 4.3.

The posterior superior cuff

Neer’s sign

This is the classic painful arc (Figure 4.1.3). Movement into the first 70 degrees of flexion is easy and pain free, but then as the footprint of the supraspinatus passes under the acromion, from 70–120 degrees, there is impingement between the surfaces and pain, and motion slows. As the footprint clears the under surface of the acromion, from 120 degrees to top pain eases and motion speeds up once more (Table 4.1.1).

Fig. 4.1.3
Neer’s sign. The first 70° of movement are normal and rapid. Above 70° the patient winces, slows down, and becomes protective.

ER, external rotation; IR, internal rotation; SLAP, superior labrum anteroposterior.

Neer's test is to inject some local anaesthetic into the bursa, bathing the bursal side of the footprint of cuff insertion. This abolishes the impingement and the normal patism of movement is restored.

Hawkins's sign

The arm is elevated in the scapula plane to 90 degrees. Now the elbow is flexed to a right angle and the arm is internally, and then externally rotated (Figure 4.1.4). Pain is seen to occur on internal rotation as the footprint of supraspinatus impinges against the anterior acromion. The sensitivity and specificity for Hawkins sign is 75%. It is one of the most useful tests of the posterosuperior cuff. Beware that passive limitation of internal rotation nullifies this test.

Jobe's sign

The arm is brought up in the scapula plane with the elbow extended and the arm fully internally rotated such that the thumb points to the ground (the Australians call this the 'empty tinny test' for it is the position in which you test that your can of beer is finally empty) (Figure 4.1.5). The patient is asked to hold this position against resistance from the examiner. If there is damage to the
supraspinatus insertion then pain will register with the patient. If there is a tear of supraspinatus the arm will be weak. The accuracy of Jobe’s sign is 58%. It is another good test.

![Image](87x621 to 259x751)

**Fig. 4.1.5**
Jobe’s sign. The arm is brought up in the scapula plane with the elbow extended and the arm fully internally rotated such that the thumb points to the ground. (The Australians call this the ‘empty tinny test’ for it is the position in which you test that your can of beer is finally empty.) The patient is asked to hold this position against resistance from the examiner.

If either Neer’s, Hawkins’s or Jobe’s signs are positive then you should move straight to the ultrasound examination (Figure 4.1.6). The ultrasound will show you whether there is a tear, give you its exact position, and a measure of its dimension, it is worth a thousand eponymous tests. However, there are many other tests of the posterolateral cuff and it is pertinent that you have heard of them.

![Image](87x316 to 216x489)

**Fig. 4.1.6**
Point-of-care ultrasound can be performed by the surgeon in the clinic.

**Lag signs**

These depend on weakness of a segment of the cuff. They are the modern equivalent of the ‘drop arm sign’. The drop arm sign was a particularly barbaric way of looking at a patient with a massive supraspinatus tear. The examiner elevated the arm to 120 degrees in the full knowledge that, without a functioning cuff, the patient will find it impossible to maintain this position. The examiner then let go and the arm dropped to the side! Patients were not as amused by this test as their examiners!

**The external rotation lag sign**

This demonstrates that there is a significant tear in supraspinatus. Like the drop arm sign this depends on placing the arm into a position that needs a strong supraspinatus and then letting go. The examiner takes the affected elbow and supports the weight of the upper arm with the shoulder in 90 degrees of scapular elevation. Now, using their other arm, the examiner externally rotates the forearm into full external rotation. Maintaining this position against gravity depends upon an intact supraspinatus. Now the examiner lets go of the forearm. If the cuff is intact this position can be maintained by the patient, but if the cuff is torn then the forearm will drop by about 30 degrees, the external rotation lag. In real life there are problems with the test. The examiner must understand exactly what they are doing, as must the patient. Pain may interfere with the test. Stiffness will render it null and void. There is difficulty between assessing how much movement is recoil and how much is lag. It is poorly reproducible. It has a specificity of 63% and a sensitivity of 80%. It has been superseded by portable ultrasound.
Hornblower’s sign

This is another lag sign. All military hornblowers must assume an identical position when blowing their horns. Otherwise they would look a mess! This position is with the hand at the lips and the elbow as high as it will go so that the arm, and forearm are parallel to the ground. This position can be maintained in the face of a torn rotator cuff. However, if the examiner now takes the hand, and fully externally rotates the forearm so that the forearm is now perpendicular to the ground we now have a position that can only be maintained with an intact cuff. Let go of the hand now and the forearm will drop, or lag, by 30 degrees. This test suffers from the same problems as the external rotation lag sign. It has been superseded by portable ultrasound.

The subscapularis

Tears of the anterosuperior cuff (subscapularis and biceps) are less common than those of the posterosuperior cuff. These tears start around the biceps pulley and the superior part of the insertion of subscapularis into the lesser tuberosity. Subscapularis has a multipennate tendon of insertion into the lesser tuberosity.

The belly press sign (Napoleon’s sign)

This is the single most useful test of subscapularis function. The patient is asked to place the palm of the hand upon their abdomen. Now they are asked to keep the hand where it is and bring the elbow forward as far as it will go. If there is a complete tear of the subscapularis they will not be able to bring the elbow forwards. If they can pull the elbow forwards they are then asked to press the hand hard into the belly. If there is a partial tear of subscapularis they elbow will drop back (a lag sign) (Figure 4.1.7). Beware—if the shoulder is still a false belly press sign occurs, for instance, in patients with limited internal rotation from arthritis. Beware patients can cheat; in this case they flex the wrist pulling the elbow forwards, producing a false negative belly press sign. They must keep the wrist in a neutral position or the test is null and void. Finally, biceps problems can mimic subscapularis problems confounding the belly press sign.

The lift off test

This test is similar to the belly press sign, but is performed in more internal rotation. This means that the wrist must be placed on the small of the back, rather than on the abdomen. Now the patient is asked to actively increase the internal rotation by lifting the wrist away from the skin. The problem with this test is pain. Patients with cuff problems do not like placing the hand into internal rotation, and pain nullifies the test. Stiffness will also nullify the test.

Internal rotation lag sign

This is a modification of the lift off test. The arm is placed with the wrist on the small of the back. The examiner now takes the wrist and pulls it 5 cm away from the skin. With an intact subscapularis, and no pain or stiffness, the patient should be able to maintain this position. However, if subscapularis is torn then the wrist will drop (lag) back onto the skin of the small of the back. Once again it is difficult to discriminate between recoil and lag, and has the same problems of pain and stiffness.

The biceps

There is not a good test for biceps! Biceps shape is important. All medical students know the ‘Popeye sign’ of a ruptured long head of biceps. However, you can have a complete intra-articular rupture of long head of biceps without a Popeye sign when the hypertrophied tendon jams in the sulcus, like a cork in a bottleneck. Between these two extremes the biceps can adopt subtle changes in shape.

Lafosse sign
This test is designed to isolate biceps by asking the patient to supinate the forearm against resistance. The examiner cradles the elbow with the shoulder held at about 40 degrees of scapular elevation. The examiner grips the patient’s wrist and pronates the forearm, asking the patient to resist (supinate) this force.

O’Brien’s test

This is designed to detect a SLAP (superior labrum anteroposterior) tear. It is performed similarly to the Jobe test, but with the arm held at 20 degrees inside the neutral position (across the body) and at 90-degree elevation, and full internal rotation. The patient is then asked to resist the attempts of the examiner to push the arm towards the ground.

Yergason only described his test in one patient, yet this test has been copied from textbook to textbook. Speed’s test also has a low sensitivity and specificity. These tests are fully covered in Chapter 4.4.

Examination for instability

First some definitions are needed. Laxity is defined as ‘asymptomatic excessive translation’. This is to be differentiated from instability, which is defined as ‘excessive translation that causes symptoms in the conscious patient’.

Start with some general observations. Does the patient, like Abraham Lincoln, have the appearance of Marfan’s syndrome? Are they tall, thin, and have arachnodactyly? Do they have the rubbery skin of Ehlers–Danlos? More to the point, and more commonly, do they have striae, one of the commonest markers of laxity? Do they have surgical scars that have stretched, another marker of laxity? A peculiar pit, or dimple, on the posterior aspect of the shoulder has recently been described as an association with posterior positional instability.

One of the dilemmas with examination of the unstable shoulder is that the patient will not let you! The art of examining the unstable shoulder is akin to horse whispering, you must first gain the trust of the patient. Like the abused horse the patient will have come across doctors before who have tried to dislocate their shoulder (the apprehension sign), have caused undue pain to their shoulder, and this shows in their eyes. Like the scared horse the whites of the patient’s eyes will be showing, never releasing their laser-like concentration on what nasty trick you are about to do to them. Moreover they will be resistant to any movement of their shoulder, for they know that they live on the knife-edge of dislocation, one of the most painful conditions that can occur to the human frame. Why else do you think that the inquisitors used the rack to torture confessions from their victims? This resistance to examination leads to another chicken-and–egg conundrum for any examination is greeted by intense protective muscle spasm. This complicates any examination for abnormal muscle couples around the shoulder.

The examination starts by gaining the patients trust, and you do this by examining the good shoulder first, and gently. More can be gained by looking at the asymptomatic shoulder than the protected shoulder. Most patients with dislocation have a pair of loose shoulders already. This is true even of most traumatic dislocations (as has been shown by Cheng Wallace (2007) in a study of 215 professional rugby players), but more so for atraumatic and posterior positional dislocation. So the first thing to look for is excessive mobility, and the second thing excessive translation and finally provocative testing (Box 4.1.1).

Box 4.1.1 Examination for instability

- Excess laxity:
  - Hyperlaxity (external rotation greater than 80 degrees)
  - Internal rotation (internal rotation above T5)
  - Beighton’s score
  - Striae
  - Gagey’s sign (lax inferior capsule)

- Excess translation:
  - Rowe forward
  - Rowe backward
  - Sulcus
  - Drawer tests

- Provocative:
  - Posterior jerk: posterior subluxation
  - Apprehension sign: anterior subluxation
  - Crank test: anterior subluxation
  - Jobe relocation test: anterior subluxation.

Excess movement

Hyperlaxity
Laxity is a feature of youth! Stiffness is a feature of ageing. Children have been shown to have marked shoulder laxity. However, by the age of 18 (the commonest age for first-time dislocation) the extreme laxity of youth will have passed. The normal end point for external rotation is about 70 degrees. However external rotation of 85–95 degrees is clearly abnormal and this is termed ‘hyperlaxity’. It is a clear sign of shoulder laxity. The normal shoulder will internally rotate to T7 (the lower border of the scapula); anything more is a sign of laxity.

**Brighton score**

The Brighton score is a useful objective guide to laxity. Wrist hyperflexion counts for two points, little finger hyperextension at the metacarpophalangeal joint a further two, elbow recurvatum another two, knee recurvatum a further two, and the final two come from the ability to stoop forward so as to place the palms of the hands flat on the floor. This gives a total out of ten points.

**Gagey’s sign**

This is a sign of excessive capacity or laxity of the inferior capsule. With the arm abducted to 90 degrees, the elbow fully flexed and the hand captured and not allowed to move from that position, the elbow is pushed upwards, abducting the arm as fully as it can go. The looser the inferior capsule, the higher the elbow will go (Figure 4.1.8).

**Excess translation**

Now is the time to stress the joint and see if translation is excessive. Of course this depends on what is normal and the examiner can only gain an appreciation of that with experience. Massive muscular men may show no apparent translation, whereas tiny, size zero girls may demonstrate a fair degree of translation for the same applied force. The amount of translation is graded by convention as 0 for nil, 1 for normal translation, 2 for translation to the glenoid rim, 3 for subluxation, and 4 for dislocation. We will try to translate the joint forwards (Rowe test), downwards (sulcus sign), and backwards (posterior jerk test).

**Rowe test**

This is the single most useful test of the unstable shoulder. The key is to unpack the capsule of the joint so that it is at its very loosest, for in that state abnormal translation can be shown, that can never be revealed when the capsule is in its tightest configuration. This means getting the standing patient to lean forwards some 40 degrees. Then the patient lets the arm hang down limply. In this unpacked position the surgeon grips the humeral head in one hand and steadies the socket by firmly holding the scapula and clavicle in the other hand. Now the surgeon applies forward (Figure 4.1.9) and then backward translation to the joint. The degree of translation is graded 0–4. Clearly the asymptomatic side must be tested first.
Rowe test. This is the single most useful test of the unstable shoulder. The key is to unpack the capsule of the joint so that it is at its very loosest, for in that state abnormal translation can be shown, that can never be revealed when the capsule is in its tightest configuration. This means getting the standing patient to lean forwards some forty degrees. Then the patient lets the arm hang down limply. In this unpacked position the surgeon grips the humeral head in one hand and steadies the socket by firmly holding the scapula and clavicle in the other hand and then pushes the head forwards assessing the degree of abnormal translation.

Anterior drawer test

This test is analogous to the anterior drawer test of the knee. The test was first described by Gerber and Ganz in 1984; their description of the test is precise, but has been incorrectly copied into major textbooks. Like the Rowe test, the anterior drawer depends upon unpacking the capsule, positioning the shoulder with the capsule in its loosest configuration. The patient lies supine on the couch and the shoulder is held in the unpacked position of 70-degree flexion in the scapular plane, and neutral rotation. The patient’s forearm is gripped in the examiner’s axilla. One of the examiner’s arms stabilizes the scapula whilst the other drives the humeral head forward and backwards (posterior drawer test). This is a good test but the examiner needs three hands and the patient has to lie down. The Rowe test is easier and quicker. Many textbook editors describe the test being done with the patient seated, and the arm at the side. In this position the capsule is firmly packed and translation will be markedly inhibited confounding the test.

Sulcus sign

Some patients have really loose shoulders. These patients will dislocate in one direction and sublux in the opposite direction; they are thus classified as having multidirectional instability. These patients can be seen to sublux inferiorly by pulling down on the arm, when a dimple will appear between the acromion and the top of the humeral head, the so-called ‘sulcus sign’ (Figure 4.1.10).
Provocative tests

Posterior jerk test

Posterior instability is tested with the ‘posterior jerk test’. This test is poorly described in standard textbooks. The arm is elevated in adduction and internal rotation, and the humeral head will gradually slip off the back of the glenoid; this is usually pain free. With the shoulder thus dislocated the arm is taken from adduction to abduction and the humeral head will suddenly relocate with a jerk; this is usually associated with pain (Figure 4.1.11).

The apprehension test

This is a crude test that mimics an anterior dislocation whilst the inquisitor observes the patient’s psychological resistance and physical protective instincts towards the thing they most dread, dislocation of their shoulder. By the twenty-first century doctors should use such barbaric tests sparingly! The diagnosis should already be clear from the history, or emergency department records, or radiographs. The diagnosis of recurrent anterior dislocation is seldom difficult (unlike posterior positional dislocation). If there is some difficulty then the Rowe test is far more revealing and does not hurt. For the sake of completeness we will describe the test. The shoulder is brought up into 90 degrees of abduction and then progressively externally rotated. The normal shoulder can be fully externally rotated until a firm passive end point is reached, and it will cause no pain. However, this same manoeuvre in a patient who has recurrent instability will cause extreme apprehension, then pain, and will finally dislocate. Clearly if examining the patient awake, in the clinic, the examiner should stop at the stage of apprehension but there are two further extensions of this test. If the patient is not looking sufficiently apprehensive then the shoulder is cranked into more external rotation, the crank test. If the patient is looking sufficiently apprehensive then pressure is applied to the humeral head to translate it back into socket, and the flood of relief visible on the patient’s face gives a positive relocation test, eponymously named after that kind Dr Jobe, the Jobe relocation test.

Neurological examination

If examination has revealed that the shoulder is not stiff, that the tests of the rotator cuff are normal, and that there is no evidence of instability, radiographs and POC ultrasound are normal then you have a problem; you are also going to run over the twenty minutes allotted to each patient. Turn to the chapter on examination of the cervical spine for further details.

The acromioclavicular joint

The acromioclavicular joint (ACJ) is subcutaneous, and therefore much easier to examine than the shoulder joint itself. It is rare for the ACJ to be the culprit if it is not tender along its anterior, superior, or posterior joint line. Instability can be seen if gross and the joint translates abnormally if it is unstable. Finally the joint can be stressed by torsion, elevating the shoulder into the high painful arc, or by compression (the scarf test), or ‘cross-over test’, or extension and adduction with resistance ‘the half nelson or resisted extension test’. O’Brien’s test described an active compression test with the upper limb flexed to horizontal at the shoulder with a little adduction. If the origin of the pain is in doubt, a small amount of lignocaine (1–2mL) can be injected directly into the ACJ and the tests repeated. The cross-over test and resisted extension test are most sensitive (77% and 72% respectively). O’Brien’s test was found to have low sensitivity (41%) but high specificity (95%). A positive finding on all three tests, however, conferred an accuracy of 93% and probably renders a diagnostic injection test unnecessary.

Investigation, the forensics

Plain radiographs

In the twenty-first-century rush to get scans, plain radiographs are often forgotten. This is a mistake. There are many things that
are best seen on plain old-fashioned radiographs and these are fractures, calcific deposits, arthritis, tumours, and locked dislocations. All right you can see these on an MRI scan, but who has instant access to an MRI scanner in clinic? Besides, calcific deposits are far more difficult to see on MRI than on plain radiographs. A radiograph is the mandatory investigation for the stiff shoulder, and mandatory in any patient with a history of cancer (Box 4.1.2). The radiograph should be taken in the plane of the glenoid, which is 30 degrees to the sagittal plane of the body; this is the true AP of the shoulder.

Box 4.1.2 Investigations

- Stiff shoulder: plain radiograph
- Wobbly shoulder: examination under anesthesia, arthroscopy
- Pain on reach: ultrasound.

Although cuff disease and instability are soft tissue diseases they may lead to secondary bone changes that can be seen on radiographs. Radiographs may show changes in the greater tuberosity in rotator cuff disease. These will range from irregularity of the bony footprint, sclerosis, pseudocysts, and eventually flattening of the tuberosity.

Changes may also occur at the anteroinferior acromion with sclerosis (sourcil sign) and spur formation within the footprint of the coracoacromial ligament. Less accurate is a reduction in the acromiohumeral distance, or a break in Shenton’s line of the shoulder.

Secondary changes in instability are the Hill–Sachs lesion (best seen on a Stryker notch view or West Point view) and bony Bankart lesions (best seen on an axillary or Bernageau view).

ACJ arthropathy is most readily confirmed with a plain radiograph of the joint. This requires the x-ray beam to be tilted 20–30 degrees in a caudal direction and the voltage reduced to ensure that the ACJ is not obscured by the base of the acromion or over-exposed (Zanca view).

Computed tomography scanning and computed tomography arthrography

Computed tomography (CT) scans are useful for surgical planning, particularly prior to fracture fixation and complex primary shoulder replacements. In continental Europe, CT is commonly used in the assessment of rotator cuff tears, particularly to assess fatty infiltration of the muscle belly (using the Goutallier classification) prior to surgery. CT arthrography can be used for rotator cuff disease and instability, but has been mainly superseded by MR arthrography (MRA).

CT is a useful modality for examining the sternoclavicular joint.

Ultrasound

In the clinic time is of the essence, so an abbreviated study is permitted, scanning in only three planes, as opposed to the 12 planes recommended in most radiological texts. An axial scan is first used to demonstrate the lesser tuberosity, subscapularis, biceps sulcus, and long head of biceps tendon. Secondly, an oblique coronal (or longitudinal) view is used to show the greater tuberosity and the supraspinatus. Finally, a sagittal oblique (transverse) view is used, demonstrating the greater tuberosity and supraspinatus tendon, rotator interval, and biceps. All findings are recorded in detail at the time. In each of the three planes a record is made of the articular appearance (normal, positive cartilage reflection sign, osteophytes), the bone (normal, irregular, calcification, fracture line), the collagen (normal, heterogeneous, hypertrophic), presence of a defect (rim-rent, cleft, delamination, focal absence, absent cuff), and the presence of an effusion (nil, effusion, flattening of bursa, bursal concavity). A firm diagnosis of the state of the rotator cuff and biceps is then recorded. A full thickness tear is diagnosed on sonography if the tendon is absent, or if there is a focal deficit. A combination of one or more indirect signs such as a bursal concavity, an effusion around the biceps, bony irregularity, or a positive cartilage reflection sign allow a judgement to be made by the surgeon of the presence of a supraspinatus tear.

Magnetic resonance imaging and magnetic resonance arthrography

MRI has revolutionized the field of imaging in the shoulder, because it can image the soft tissues. Unlike ultrasound, MRI can image through the bone, and it can image the bone, and it can image to depths of tissue that cannot be reached by high frequency ultrasound. It is therefore the imaging modality of choice for instability, as it will demonstrate labral abnormalities. Visualization of SLAP tears and Bankart tears are improved by MRA using gadolinium enhancement.

MRI is the imaging modality of choice for large rotator cuff tears where the degree of retraction under the acromion, and the degree of wasting and fatty infiltration of the muscle belly will determine whether the tear should be repaired, or whether repair is a forlorn hope. MRI is useful in demonstrating articular side partial tears.

MRI is not as good as CT for looking at bone yet it is the investigation of choice for avascular necrosis. MRI is the investigation of choice for lumps, masses, and tumours around the shoulder. MRI will demonstrate pathology that cannot be seen by ultrasound, such as labral cysts and ganglia.

However MRI is not without problems. The equipment is extremely expensive and far from portable! Patients do not like MRI. It is claustrophobic, noisy, and patient unfriendly. One-third of patients will not have a second MRI scan. It will demonstrate morphology, but not histology. It suffers from a phenomenon called the ‘magic angle effect’ that can produce false positive results. MRI is very
bad at showing calcific deposits as these are dark, as is the tendon, so there is no contrast difference between the calcium and the tendon.

MRA suffers from the problem that it is invasive. Intra-articular injection of gadolinium is usually done under image intensifier control and local anaesthetic. This ramps up the degree of difficulty, often needing two radiology suites, careful timing, transfer from room to room, and the time of a skilled radiologist. On top of this patients do not like invasive diagnostic procedures.

**Arthroscopy**

Shoulder arthroscopy remains the gold standard forensic investigation for the shoulder. Not only can the inside of the glenohumeral joint be appreciated, but also the outside view of the rotator cuff from within the subacromial bursa. An essential preamble to arthroscopy is examination under anaesthetic.

**The load and shift test**

This is a provocative test, being the shoulder equivalent of the Barlow and Ortolani tests of the hip, or the pivot shift in the knee. The arm is cradled by the examiner and brought into the unpacked position of 70-degree flexion in the scapula plain. The joint surfaces are compressed (loaded) and then a conscious effort is made to dislocate the shoulder, then to reduce it. The clunk of dislocation and relocation is quite distinctive.

The arthroscope is now introduced into the joint and a standard 12-point examination is conducted.

1. The primary landmark of shoulder arthroscopy is the long head of biceps, and this is a good place to start the examination (Figure 4.1.12). Examine the anchor (SLAP tears), the tendon (vinculae, mesentery, ensheathed biceps, hourglass biceps), the pulley (pulley failure, partial tearing, subluxation, dislocation), and finally the tendon may have ruptured
2. Move back to the supraspinatus tendon. This may show a rim-rent lesion, PASTA lesions (partial articular surface tendon avulsion), and small, moderate, large, or massive rotator cuff tears
3. Next examine the rotator interval for angiogenesis and granulation tissue (contracted [frozen] shoulder), or widening (instability), the bumper sign (coracoid impingement), the comma sign (subscapularis rupture), and as a hiding place for loose bodies
4. Examine the middle gleno-humeral ligament. It can be variable in thickness or exhibit a Buford complex (cord-like with a high origin)
5. Examine the subscapularis for partial tears, HAGL (humeral avulsion of the glenohumeral ligaments) lesions, pulley lesions, or complete tears
6. Examine the labrum. This can show evidence of PSI (posterosuperior internal impingement), SLAP tears, ASI (anterosuperior internal impingement), Detrisac type 2 lesion, Bankart tear, Perthes lesion, ALPSA lesion (anterior labrum periosteal sleeve avulsion), bony Bankart lesion, inferior fibrillation, posterior fibrillation, and posterior Bankart lesion
7. Examine the glenoid surface with its central grey spot. There may be arthritic damage, anterior cavinwaxing or crating (instability), or a bony Bankart (reverse pear-shaped glenoid)
8. Come to the inferior glenohumeral ligament that may be stretched or torn. There may be a positive see through sign or a positive drive through sign (associated with instability). The inferior recess may be contracted or loose and is a favourite hiding place for loose bodies
9. Return to your starting point either taking the high road where you see the bare area, Hill–Sachs lesions, and the state of the articular surface, or the low road where you see the posterior labrum and posterior gutter
10. Now exit the glenohumeral joint and enter the loft-space of the subacromial bursa. Examine the roof for impingement signs, firstly scuffing of the coracocromial footprint (Copeland–Levy A1); gross fibrillation (A2); loss of footprint and sclerosis (A3)
11. Examine the floor of the loft-space, the bursal surface of the rotator cuff. Is it normal? Examine for scuffing (B1), fibrillation and partial tearing (B2), or a full thickness rotator cuff tear (B3). Is there a plica?
12. Finally examine, ballotte, and palpate the under surface of the acromioclavicular joint and expose it if necessary.

**Fig. 4.1.12**

Long head of biceps, the primary landmark of shoulder arthroscopy.
The 12-point examination is thorough and should confirm the diagnosis. More detail can be sought from textbooks such as Shoulder Arthroscopy by Bunker and Wallace, which is available free on the Internet at sites such as http://www.shoulderdoc.co.uk. These days arthroscopy is rarely used for diagnosis alone, it is used for treatment, releasing contracted shoulders, decompressing impinging shoulders, repairing rotator cuff tears, and stabilizing the unstable joint. All of these will be covered in the ensuing chapters in this section.

Summary

Surgeons only need to know two things: when to operate and how to operate. When to operate is what this chapter has been about. Knowing when to operate involves establishing the diagnosis and the severity of the disease. However, despite the advances in clinical examination and the profusion of forensic examinations (radiographs, CT, ultrasound, MRI, MRA, and arthroscopy) that are now available to us, the diagnosis can remain elusive. The surgeon must take in a vast amount of information, solve several simultaneous equations at once, discard the dissembling and lies, assemble the truths, seek concordance, check with forensics, and come to a solution. Nobody said this was easy; it is why surgeons are carefully chosen, continuously examined, trained for 20 years, and prefer coastal navigation to football. Higher-level reasoning has always, and will always be the most important distinctive characteristic of the consultant surgeon.

As to how to operate, that will be covered in the following chapters.

Further reading

Pathology of cuff tears

Summary points

♦ Rotator cuff tears are common
♦ Aetiology complex and multifactorial
♦ Tendons deteriorate with age
♦ Posterosuperior tears are more common
♦ They evolve in a typical fashion
♦ Anterosuperior tears are less common.

Introduction

Rotator cuff pathology accounts for one-third of all shoulder referrals. Theories on aetiology are broadly divided into two camps: intrinsic (related to the tendons themselves) and extrinsic (related to factors external to the tendon). The relative significance of each of these factors has stimulated much debate and zealots defend their views with fervour! The aim of this chapter is to give a balanced review of the relevant literature, concluding that many factors are at work and the end result is tendon pathology.

Macroscopic structure

Structurally and functionally the rotator cuff should be considered as a complex of four muscles arising from the scapula whose tendons blend as they insert onto the humerus (Figure 4.2.1).

The supraspinatus inserts onto the superior facet of the greater tuberosity of the humerus. The greater supraspinatus muscle bulk anteriorly is reflected in an increased tendon thickness. Laterally the supraspinatus tendon passes under the acromioclavicular joint and the coracoacromial arch. The arch is formed by the anterior undersurface of the acromion and the coracoacromial ligament (CAL). The subacromial bursa reduces friction as the humeral head and supraspinatus tendon move relative to the arch.

The infraspinatus inserts onto the middle facet of the greater tuberosity. The teres minor is the smallest of the rotator cuff muscles, and attaches to the lowest facet of the greater tuberosity.

Posteriorly the supraspinatus tendon blends with the infraspinatus about 15mm proximal to the insertion and from this point cannot be separated by blunt dissection. The infraspinatus and teres minor merge proximal to the musculotendinous junction.

The subscapularis is a large triangular muscle, which originates from the subscapular fossa. The subscapularis tendon is visible inside the shoulder joint as it passes laterally through the oval foramen of Weitbrecht to insert onto the lesser tuberosity.

The long head of biceps lies in the interval between the subscapularis and supraspinatus tendons, passing through the glenohumeral joint from its origin, the supraglenoid tubercle, to the bicipital groove. Its synovial sheath is an extension of the articular capsule.
**Microscopic structure**

Clark and Harryman examined the detailed structure of 32 intact rotator cuffs. A five-layer structure to the supraspinatus and infraspinatus tendons was reported as follows: (superficial to deep) obliquely orientated fibres of the coracohumeral ligament (1mm thickness); parallel tendon fibres (3mm thickness); the tendinous fascicles then become smaller and less uniformly orientated (3mm thickness); loose connective tissue with some thick collagen fibres; and a thin continuous sheet of collagen fibrils (2mm thickness). The coracohumeral ligament extends postero-laterally and envelops the tendon. It has been suggested that this sandwiching effect may help to prevent tendon delamination.

Nakajima further considered the differences between the joint and bursal sides of the supraspinatus tendon as an explanation for intratendinous partial thickness tears. The tendon bundles were found to differ on both the joint side and the bursal side depending on the distance from the insertion.

At the tendon–bone interface a stepwise transition is seen. The stages of tendon, fibrocartilage, calcified fibrocartilage, and bone are thought to optimize the distribution of forces over the attachment site, which minimizes stress concentrations, and facilitates angular change.

**Function of the rotator cuff**

The rotator cuff is of prime importance in glenohumeral motion, ensuring that the humeral head is kept in contact with the glenoid. Three groups of muscles act on the shoulder joint: scapulohumeral, axioscapular, and axiohumeral. The first group consists of the rotator cuff, the dynamic stabilizers of the shoulder, and the deltoid, a prime mover. The axioscapular (including rhomboids and serratus anterior) and the axiohumeral (latissimus dorsi and pectoralis major) are important in joint motion and force generation.

The supraspinatus is a humeral head compressor and arm abductor. The subscapularis is primarily an internal rotator, and infraspinatus an external rotator. Both these muscles compress the humeral head against the glenoid during abduction. Furthermore, the subscapularis acts as a restraint to anterior displacement of the humeral head. Teres minor is an external rotator working in conjunction with infraspinatus.

During abduction the rotator cuff muscles hold the humeral head against the glenoid, counteracting the vertical shearing action of the abducting deltoid. The compressive force increases up to 90 degrees of abduction, beyond this it gradually reduces. At 90 degrees the resultant force of abduction and compression in an unloaded limb approximates to body weight.

The direction of the resultant force is not constant as the arm is abducted. This leads to alteration in the position of the humeral head relative to the glenoid. In the case of abduction in the scapular plane with neutral rotation, the force is initially directed downward to the inferior border of the glenoid. At between 30–60 degrees of abduction the high shear forces cause movement of the vector to the superior edge of the glenoid, and with further abduction this moves back to the centre.

**Incidence**

It has been shown that there is an incidence of 9.5 per 1000 of patients with shoulder pain presenting to primary care. Of these patients it was found that 74% had signs of impingement and 85% had evidence of painful or torn rotator cuffs. A recent systematic review looking, more specifically, at rotator cuff tears has shown that in an unselected cadaveric population the incidence of both partial and full thickness tears is 30.24%. The incidence of tears increases with age and many now consider this to be part of the normal ageing process.

**Pathogenesis**

In 1934 Codman put forward the theory that the cause of rotator cuff disease (RCD) was actually an intrinsic degeneration of the tendon, but subsequent opinion moved towards external factors being the main component in the aetiology. It was thought that mechanical compression of the tendons of the cuff caused the tendon to tear. Changes in the morphology of the structures surrounding the supraspinatus outlet were thought to cause stenosis and compress the cuff underneath the acromion leading to attrition. Currently consensus has drifted back towards Codman's original theory supporting a combination of repetitive microtrauma and age-related degeneration.

**Intrinsic causes**

A degenerated tendon is more likely to rupture than a normal tendon during physiological loading. Riley and colleagues have histologically examined supraspinatus tendons looking at the organization of the tendon collagen fibres and the appearance of the tendon fibroblasts. They showed that degenerative changes within the tendon increase with age, and more severe degeneration is associated with tendon damage. They also showed that there were changes in collagen composition and cross-links associated with the physiological loading conditions; however, there is a higher rate of collagen turnover in degenerate (ruptured) tendons. Within these degenerate tendons the expression of matrix metalloproteinase (MMP) enzymes (produced by tenocytes to mediate the matrix turnover) is altered, suggesting that tendon degeneration is an active, cell-mediated process. It was hypothesized that tendinopathy may result from an imbalance between synthesis and degradation of the tendon, perhaps due to failure to regulate specific MMP activities in response to repeated injury or mechanical strain.
The evidence for tendon degeneration has been further supported by the detection of highly sulphated glycosaminoglycans (GAGs) in inflamed supraspinatus tendon. These GAGs are associated with amyloid deposition. Others have shown that patients with chronic tears showed deposition of amyloid in 70% of tendons, compared to only 25% of those with acute traumatic tears. Amyloid has a fibrillar ultrastructure forming extensive antiparallel pleated sheets making it resistant to proteolytic digestion. Therefore once deposited in tissue it tends to remain and accumulate, ultimately leading to irreversible changes in the structure of the affected tissue.

Sano and colleagues looked at tendon thinning, the presence of granulation tissue, and partial thickness tears. They found that the more degenerate tendons were weaker. Degeneration was significantly greater in tendons that failed at their insertion.

There is evidence that granulation tissue itself may weaken the tendon insertion by inducing osteochondral destruction. The chemical mediators, interleukin-1 beta, cathepsin D, and MMP-1 were present at the insertions of 16 torn supraspinatus tendons but not in controls. Macrophages and multinucleated giant cells were found at the tear site.

Blood supply

It is likely that rotator cuff tendon vascularity, particularly in relation to the supraspinatus, is one of a number of intrinsic factors contributing to RCD.

The vascularity of the supraspinatus tendon has been a focus of interest since the time of Codman. He described the critical zone of the supraspinatus tendon, half an inch proximal to the insertion, which appeared anaemic and hypothesized that perfusion had a crucial role in tendon pathology.

He stated ‘tears of the supraspinatus tendon had much to do with overuse of the arms in an abducted position without giving the tendons time to let their circulation do its duty’. Against this it has been suggested that the supraspinatus tendon blood supply is the same as the infraspinatus and consequently can not be responsible for the high rates of failure reported.

The majority of authors have concluded that the supraspinatus tendon blood supply differs from that of the other rotator cuff tendons. The critical zone of Codman probably represents a hypovascular area, caused by anastomosis of vessels originating from the greater tuberosity and the supraspinatus muscle belly. The tenuous vascularity of this area not only makes it more vulnerable to degeneration, but also modifies any attempts at repair.

Mechanical properties

Standard textbooks, books on surgical technique, and original research papers tend to promulgate an anatomically incorrect depiction of the torn supraspinatus. Illustrations in these texts portray supraspinatus as a homogeneous flat tendon, whereas in fact it is a distinctly heterogeneous tendon, a feature that has marked clinical relevance. Nakajima and Fukuda showed quite elegantly that the central tendon is markedly denser and stronger than the rest of the tendon on histological preparations of the supraspinatus tendon. They demonstrated how the central thick tendon migrates towards the anterior margin of the tendon as you move towards its insertion. Itoi confirmed this work and showed that the anterior third was by far the strongest with a strength to failure of 411N, the mid portion 152N, and the posterior third just 88N. Nakagaki et al. and Bigliani et al. supported this work and provided correct illustrations of the nature of the tendon. Others have shown how the superior (bursal side) of the tendon is twice as strong as the articular side. Gagey et al. introduced the concept of the fibrous frame of the rotator cuff. These workers performed three-dimensional reconstruction of magnetic resonance imaging scans and demonstrated the deep fibrous reinforcement of the supraspinatus that is the central oblique tendon. They showed how supraspinatus has one tendon, whereas subscapularis is multipennate and they show how the single tendon of supraspinatus inserts into the anterior extremity of the greater tuberosity. This pattern of migration of the central oblique tendon has been confirmed by Roh et al. This central oblique tendon (that we will term the anterior column), being the strongest part of supraspinatus, remains intact when all around it the tendon fails. In effect it acts as a firebreak and determines the pattern of posterosuperior rotator cuff tearing. From these observations a hypothesis was developed that there is a definite and progressive pattern of cuff tear extension that is determined by the special anatomy of this tendon. Understanding this pattern (Figure 4.2.2) allows the surgeon to predict which structures are contracted and need to be released, and to develop a plan to close the defect using fundamental surgical techniques such as rotationplasty, rather than treating each surgery as a lucky dip or magical mystery tour.
Subacromial impingement is compression of the subacromial bursa and the supraspinatus tendon between the anterior acromion and the coracoacromial ligament superiorly and the humerus inferiorly.

A recent study has suggested that the subacromial bursa is a proinflammatory membrane that may be responsible for shoulder pain. Blaine et al. demonstrated the presence of various inflammatory cytokines (TNF, IL-1, IL-6, COX-1, and COX-2) in bursal specimens from patients with subacromial bursitis and RCD. Some of these cytokines (IL-1, IL-6) have been reported to play an important role in mediating the catabolism of collagen. It has been suggested that removal of the subacromial bursa, which is rich in Substance P receptors, is the key to pain relief in acromioplasty.

The peritendinous changes in RCD may be a secondary phenomenon. Increased tension in the CAL, secondary to tendinopathy, may stimulate new bone growth leading to the spur seen on radiographs, and this spur may cause more damage. Structural features such as lateral sloping of the acromion and glenoid version may also have an extrinsic effect in cuff degeneration.

This does not exclude the role of acromial morphology in the impingement syndrome. Bigliani et al. described three distinct types of acromion (types I–III, see Box 4.2.1). The relationship with full thickness cuff tears was recorded: 3% in type I, 24% type II, and in type III 73%. They studied 420 cadaveric scapulas and concluded that acromial morphology was not age dependent, but that spur formation was.

Box 4.2.1 Bigliani grade of acromial morphology

- Type I: flat, found in 17% of specimens
- Type II: curved, 43%
- Type III: hooked, 40% of which 14.2% had associated spur formation.

Position of the scapula may have an influence on the supraspinatus as it passes under the arch formed by the acromion and CAL. A forward scapula posture, caused by a combination of forward head posture and increased kyphosis, may cause an outlet stenosis and effectively squeeze the tendon as it passes through.

Recently the idea of internal impingement has surfaced. Some surgeons noted arthroscopically that patients with attrition of the posterosuperior labrum also had attrition of the posterosuperior cuff insertion, and that as the shoulder was maximally abducted and externally rotated (the ABER position) these areas contacted. This was termed PSI or posterosuperior internal impingement and may be the cause of shoulder pain in throwing athletes. Similarly an anterosuperior labral lesion has been seen alongside attrition of the biceps pulley and this has been termed ASI, or anterosuperior internal impingement.

Relevance of impingement to rotator cuff tears

Neer estimated that 95% of lesions of the rotator cuff were the end result of impingement. This is often quoted but generally accepted as historical and excessive. Neer’s hypothesis was based on cadaveric and preoperative observations. It is not difficult to believe that direct attrition may occur on the bursal surface of the supraspinatus.

More recently support for impingement in the aetiology of cuff tears has come from two-dimensional finite element modelling of the supraspinatus tendon. Impingement simulated by a 1-mm indentation on the bursal side of the tendon was found to be a stress riser in the area of the critical zone. Effects were found throughout the tendon, not just on the bursal side, which was thought to suggest a role for impingement in the aetiology of joint side tears.

Whatever the role of impingement in the aetiology of rotator cuff tears, acromioplasty does not appear to prevent their occurrence. Hyvonen et al. followed-up 96 shoulders without rotator cuff tears for 9 years after open acromioplasty and found 12 full thickness and seven partial thickness tears.
The pattern of rotator cuff tears

This chapter has shown how repeated tensile or compressive overload can cause changes within the ageing rotator cuff. Macroscopically this leads to the initiating event, which is the rim-rent lesion. The rim-rent lesion can be demonstrated by ultrasound or by arthroscopy (Figure 4.2.3). This lesion is constantly situated 7mm behind the biceps pulley just posterior to the insertion of the anterior column. Gradually the rim-rent peels further back off its footprint of insertion into the superior facet of the greater tuberosity. As it does so secondary reactive changes occur on the bone, which becomes sclerotic and nodular. These nodules appear on radiographs as tiny sclerotic rings and are often misreported as cysts, although tiny true cysts can also occur. Eventually the deep surface rim-rent will peel so far back that it emerges on the bursal side as a pinhole full thickness tear. This gradual enlargement of the deep surface partial thickness tear may take years to evolve. During this time the supraspinatus is weakened and its normal centring effect is lost. The head subluxes upward and secondary impingement occurs between the bursal surface of the cuff and the acromion.

These secondary reactive changes can be seen by placing an arthroscope into the bursa. The bursa becomes fibrillated, and then wears through and the bursal surface of the cuff becomes damaged and fibrillates—this is the impingement lesion of Neer. Reactive changes will occur on the acromion and have been classified into four grades by Uhtoff (see Box 4.2.2).

Box 4.2.2 Uhtoff grade of acromial pathology

- Firstly there is a loss of areolar tissue under the acromion
- Then the coracoacromial ligament and the fibrous pad that represents its footprint of insertion into the acromion thicken
- Thirdly there is fibrillation of the insertion of the coracoacromial ligament
- Finally there is eburnation of the undersurface of the acromion and loss of the footprint of insertion of the coracoacromial ligament.

Meanwhile the cuff tear extends, either slowly, or it may suddenly give with even mild trauma. Knowledge of the normal morphology of the tendon explains the pattern of tear exposed at surgical repair. Knowledge of the morphology of the capsule explains the contractures which occur, and that will need to be released during surgical reconstruction. We must always remember that the tendon and capsule merge and blend towards their combined insertion, and that for a full thickness tear to occur, both capsule and tendon must have dis-inserted. The tendon retracts, but the capsule contracts.

As the small tear extends into a moderate tear the anterior column, being so strong, acts as a firebreak and resists extension, and so instead of becoming a larger crescentic tear, the tear becomes asymmetric or L-shaped. At the same time the superior capsule, having dis-inserted contracts back towards the glenoid, pulling the cuff, with which it is merged, along with it. The coracohumeral ligament reinforces the superior capsule and, as this powerful thickening of the capsule contracts, it pulls the anterior column with it, towards the coracoid. This determines the releases that will be necessary for a small to moderate tear.

Now a singular event happens; at 3–5cm the tear extends over the North Pole of the humeral head, causing a buttonhole (boutonniere) situation. Just as in the proximal interphalangeal joint of the finger when a boutonniere lesion occurs, the joint buttonholes up through the tear and the lateral slips get stretched out and sublux around the joint. In the case of the shoulder, the lateral slips are the anterior column to the front and infraspinatus to the rear. Because the infraspinatus has subluxed backwards and cannot be retrieved from under the acromion at surgery the surgeon may erroneously think that it too has torn, but this is hardly ever the case. The capsule at the junction of the supra- and infraspinatus contracts severely and it is the release of this junctional scar that allows advancement of supraspinatus in large cuff tears. This junctional scar is hidden under the acromion and the suprascapular nerve runs underneath the spinoglenoid ligament just medial to this contracture. Long head of biceps hypertrophies and may start to fray. The capsule continues to contract. The muscle bellies, being defunctioned, waste away.
Finally, the tear continues to extend and retracts right back to the edge of the glenoid rim. The anterior column may still be intact, although now very stretched. The anterior column uproots, uncovering long head of biceps, which now becomes painful, frays further, and can sublux or rupture. As the biceps pulley fails, the superior margin of subscapularis may tear and the humeral head now subluxes forward as well as upward. The capsule contracts further. Infraspinatus subluxes further back yet, contrary to popular opinion, rarely tears, although the tendon is stretched out and the muscle belly wasted, it has no function. The junctional scar becomes even thicker. This is the classic ‘bald head tear’.

Arthritic change may now occur between the North Pole of the humerus and the acromion, as well as the surfaces of the humerus and superior pole of the acromion, which are maintained in a subluxed position. This arthritic change is called ‘cuff tear arthropathy’ and is the end stage of the spectrum of cuff disease. Two per cent of the population over the age of 80 will have cuff tear arthropathy.

### Conclusions

The aetiology of supraspinatus tendon failure is multifactorial. Intrinsic and extrinsic factors combine, resulting in the high prevalence reported in cadaveric and radiological studies. These factors are intimately related to normal supraspinatus structure and function. There is now a good body of evidence that RCD is an intrinsically initiated phenomenon, with the changes in the surrounding structures being a secondary feature. It is, however, simplistic to seek a single cause of rotator cuff failure; rather it is appropriate to consider how the pieces of a complex puzzle fit together.

### Further reading

Summary points

- Arthroscopic techniques have revolutionized the surgical management of rotator cuff disease.
- Arthroscopic subacromial decompression (ASD) is accepted as a well-established method for the treatment of symptomatic impingement after conservative treatment has failed.
- Appropriate patient selection is paramount to a successful outcome.
- Attention to detail including patient set-up, maintaining optimum fluid pressure and portal placement are essential to achieve successful outcomes.
- Error diagnosis is the commonest cause of failure following ASD.
- Thorough debridement of the subacromial bursa forms a key element of ASD. Aggressive bony resection with violation of deltoid origin can cause undesirable outcome.
- Many large studies indicate good to excellent results for ASD in over 85% patients.

Rotator Cuff Repair:

- Surgery for rotator cuff repair has evolved from open to mini-open to all arthroscopic.
- Arthroscopic rotator cuff surgery can be challenging as cuff tears present in a variety of shapes and sizes with variable tendon quality.
- Number of classifications exist for rotator cuff tears but it is important to understand the tear geometry to enable good repair.
- Traumatic cuff tears in the active population causing functional loss, irrespective of the age of the patient, constitute an indication for rotator cuff repair.
- Key principles in arthroscopic cuff repair include assessment of the tear, release and tendon mobilisation, secure attachment of the tendon to the prepared footprint and regaining movement and its control.
- Number of portals are utilised for arthroscopic rotator cuff repair though most can be accomplished by the four portal technique.
- Direct tendon to bone repair, margin convergence, single row and double row repair are some of the commonly used repair techniques.
- Arthroscopic surgery has facilitated ‘Accelerated rehabilitation programmes’, which are gradually replacing the more traditional post-operative immobilisation protocols following rotator cuff repair.

Arthroscopic Subacromial Decompression

Arthroscopic resection and repair techniques have completely transformed our management of rotator cuff disease, and continue to evolve and improve. Arthroscopic subacromial decompression (ASD) is the operation of choice when dealing with primary subacromial impingement syndrome of the shoulder. A carefully taken history will reveal a patient aged between 40 and 50 years with pain on reach and exercise, difficulty getting to sleep but little awakening, a painful arc on elevation that interferes with recreation, yet the patient continues in their normal work routine. Clinical examination will show positive impingement signs. Investigations should include radiographs to look at the acromial shape and an ultrasound scan to exclude a rotator cuff tear. Local anaesthetic with or without steroid injections in the subacromial space (Neer’s test) will further confirm the diagnosis and is a good predictor of the outcome of ASD.

Conservative treatment involves turning the dysfunctional cuff into a functional cuff again. Two facets need to be addressed: pain and function. The pain can be eased by injection of cortisone (in any form) into the subacromial bursa, and refraining from those activities that aggravate the condition (reach, sport, and overhead work). Therapists can then supervise muscle retraining, starting with scapular control, and then working on to glenohumeral control.

Indications for Surgery

Indications for surgery are failure of proper conservative treatment, in the patient aged over 40 who has true impingement, which has been abolished temporarily by subacromial injection of local anaesthetic. While an impinging acromial spur is an indication for ASD, patients can present with impingement symptoms without bony spurs and require ASD (Figure 4.3.1). ASD is also indicated in secondary impingement after failed non-operative treatment including calcific tendinitis. It is important to ensure that the patient has full passive motion and no capsular stiffness when considering arthroscopic subacromial surgery. If they are stiff the diagnosis is wrong!
Contraindications

There are no absolute contraindications to ASD; however, the results of ASD in the following situations are usually poor and should be avoided:

- *Glenohumeral stiffness*: impingement should not be diagnosed in the presence of restricted motion
- *Secondary impingement as a result of instability*: subclinical instability is often seen in overhead athletes and can lead to subacromial impingement. The primary pathology must be dealt with before considering ASD
- *Hyperlaxity*: the results of ASD in patients with hyperlax joints are not as favourable and can be disappointing
- *Impingement secondary to a large os acromiale*: this type of impingement is a ‘dynamic impingement’ due to flexion of the os with deltoid contraction. Fusion of the os acromiale is unpredictable with failure of fusion in up to 50% of cases. Excision of the os, maintaining the deltoid insertion from the deltopectoral fascia, may be more appropriate but the evidence either way is poor.

History

Dr Harvard Ellman, who published his results in 1987, pioneered this technique and now this is the benchmark throughout the advanced world. In the properly selected patient, ASD should give excellent or good results in 88% of patients. These days there is no place for open decompression except as a method of exposure for open cuff repair. Open acromioplasty evolved from Neer’s first description where a wedge of anterior acromion was removed using an osteotome, and ended with the two-stage Rockwood acromioplasty. In this technique the first stage was to remove the full thickness of the acromion that extends anterior to the acromioclavicular joint (ACJ). The second stage is to remove a wedge of anterior acromion extending from the initial cut and exiting the inferior surface of the acromion 1.5cm (three burs’ breadths) posterior to the anterior cut. This technique is now copied arthroscopically.

Impingement classification: Copeland–Levy

The Copeland and Levy classification is a useful descriptive arthroscopic grading system for impingement lesions on both the acromial and bursal surfaces (‘kissing lesions’) (Figure 4.3.2 and Figure 4.3.3).
Complications

The complication rates for ASD are very low, with reports ranging from 0.7–3%.

Complications of interscalene regional blocks and general anaesthesia are rare, but with increasing use are sometimes encountered. Interscalene blocks can cause a Horner’s syndrome when the stellate ganglion is affected by the local anaesthetic, or a hemi-diaphragmatic palsy if the phrenic nerve is anaesthetized.

Rarely, nerve compression problems have been reported with the lateral decubitus position, including superficial radial nerve compression, contralateral lateral femoral cutaneous nerve neuralgia, and contralateral peroneal nerve palsy. This is easily avoided with due diligence in positioning. Erroneous portal placement may make surgery more difficult. This is especially so when swelling due to fluid extravasation distorts the anatomical landmarks. Bleeding in the subacromial space during surgery can be troublesome and is caused by lacerating the acromial branch of the thoracoacromial trunk with the shaver. This vessel runs around the circumference of the acromion between the deltoid and the coracoacromial ligament. This can be controlled with electrocautery at the anterior acromial edge. Bleeding can also occur from the bone itself and is controlled by increasing the pump pressure. An aggressive release of the anterior structures may release a portion of the deltoid as well, producing a deltoid sag anteriorly. ASD should not be performed in cuff-deficient shoulders as it can result in proximal migration of the humeral head and predispose to anterosuperior escape of the humeral head. If subacromial debridement is indicated, humeral escape can be minimized by leaving a portion of the coracoacromial ligament intact and performing a reverse acromioplasty or tuberoplasty. Wound infection is low in shoulder arthroscopy and reported to be less than 1%. Capsulitis with resultant stiffness in the shoulder is well documented post ASD.

Failure of treatment

Erroneous diagnosis leading to the failure of ASD is the most common complication of arthroscopic acromioplasty. Up to 50% of acromioplasty failures can be attributed to incorrect diagnosis. Other causes of failure after ASD are inadequate or excessive bone removal from the anterior acromion, scarring between the cuff and the acromion and the failure of rehabilitation.

Technique

Setup

Regional interscalene block with or without a general anaesthetic is commonly used in the beach chair or lateral decubitus position. It is essential to ensure the following:

- All pressure points are well protected
- Prolonged strong traction should be avoided (lateral decubitus)
- Patient should be adequately warmed, usually with a warm air blanket
- Large saline usage can be reduced with good anaesthesia and control of bleeding with thermal radiofrequency.

Portals

It is useful to palpate and mark the outline of the lateral clavicle, acromion, scapular spine, the ACJ, and the coracoid with a marking pen. This helps in accurate portal placement.

Three portals are commonly used (Figure 4.3.4), in the following order:

1) **Posterior portal** is the common starting portal and is in the ‘soft spot’ of the shoulder—2cm below the posterolateral corner of the acromion and 2cm medial to this line. This gives the ability for a initial glenohumeral arthroscopy for the diagnosis of possible associated glenohumeral articular cartilage damage, labral tears, and the opportunity to assess the rotator cuff tear from its undersurface, along with the intra-articular long head of biceps tendon and subscapularis

2) **Anterior portal** is lateral to the coracoid process and below the coracoacromial (CA) ligament, at the level of the ACJ
externally and within the rotator interval internally. This portal is used for instrumentation from anteriorly and can also be used for ACJ excision.

3) Lateral portal is approximately 2cm posterior to the anterior lateral corner of the acromion and 4–6cm inferior to the lateral border of the acromion. It is best to create the portal using an outside-in technique with a spinal needle. This portal is used for instrumentation.

![Image](https://example.com/image.png)

**Fig. 4.3.4**

Portals for arthroscopic subacromial decompression.

Glenohumeral arthroscopy

A systematic arthroscopy of the glenohumeral joint is performed, with palpation of structures via the anterior portal.

Bursoscopy

The subacromial space is entered via the posterior portal. To adequately classify the impingement the scope must be within the subacromial bursa. To ensure this, it is essential to withdraw the arthroscopic sheath completely out of the shoulder and whilst palpating the posterior edge of the acromion, direct the sheath and introducer upwards into the subacromial space. The undersurface of the acromion can be felt against the introducer tip and directing the tip towards the anterior and lateral aspect of the acromion will ensure correct placement of the scope, as this is the most capacious part of the bursa. We introduce the scope with the camera looking down onto the cuff and visualization of the white dome of the cuff confirms correct placement.

Occasionally, inflamed and thick bursal tissue will obscure the view of the rotator cuff. In this situation, sweeping the introducer sheath in the bursa might help to break adhesions. The structures to be identified in the subacromial space are the CA ligament, the rotator cuff, and the anterior edge and the lateral edge of the acromion, as these will help orientation within the small space (Figure 4.3.5). The camera is then turned 180 degrees to look at the undersurface of the acromion. Before using the resector examine the opposing surfaces of the rotator cuff and the acromion for impingement lesions that are classified according to the Copeland–Levy classification system. The bursal surface of the cuff is examined for any tears.

Acromial resection

The lateral portal is created and used for soft tissue and bone resectors. ASD consists of subacromial bursectomy, CA ligament recession or resection, and anterior acromioplasty. Having assessed the impingement lesion, the subacromial bursa is debrided from the acromial undersurface and the surface of the rotator cuff. It is particularly essential to debride the posterior curtain of bursal tissue that can obstruct the view while working in the subacromial space. There is no need for a cannula in the lateral portal as it can sometimes restrict the movement of the shaver within the bursa. A soft tissue shaver or a radiofrequency wand can be used for soft tissue debridement. The wand provides the facility of coagulating any bleeders that might disrupt visualization. The CA ligament is peeled off from the acromial undersurface. Care is taken to preserve the deltoid muscle fibres. Using sweeping movements, the acromion is cleared to define the anterior spur. It is also important to carry this process laterally to clearly define the lateral bony edge of the acromion. Medially, the debridement is limited to the ACJ.

The CA ligament is released, rather than excised, as patients have complained of postoperative ‘clicking’ with excision of the ligament. It has been shown that the ligament regenerates and reattaches to the acromion over time. Bleeding from the acromial branch of the thoracoacromial artery may disrupt visualization and this can be controlled with fluid pressure management or electrocautery.

The amount of acromion resection can be determined by the amount of anterior acromion 'hanging' below the anterior deltoid origin. This is assessed by placing the shaver tip between the anterior acromion and the deltoid (Figure 4.3.6).
Acromioplasty is performed by beginning laterally at the anterolateral corner of the acromion and progressing medially to the ACJ capsule. To achieve a flat acromion, more bone must be resected anteriorly than posteriorly. The anterior resection is progressively tapered posteriorly. The resection is carried out so as to have a smooth transition zone without bony ridges. The arthroscope is now switched to the lateral portal. The resector is introduced via the posterior portal and the sheath of the resector is laid flush against the posterior acromial undersurface. If an adequate decompression has been achieved the posterior undersurface can be used as a ‘cutting block’ to continue resection until satisfactory clearance is achieved (Figure 4.3.7).

**Results**

The results of ASD are good to excellent in over 85% of patients in many large studies. The better results are in studies where strict inclusion and exclusion criteria are used, excluding secondary impingements, stiff shoulders, rotator cuff tears, and workers’ compensation cases.

ASD is accepted as a well-established method for the treatment of primary impingement syndrome. It allows the surgeon to evaluate the glenohumeral joint and address any intra-articular pathology at the same time. Patient selection on the basis of correct diagnosis of primary impingement syndrome is the key to a successful result. While the advantages of ASD are well documented, issues of a learning curve and adequacy of bone resection are pertinent.
In Chapter 4.2 we covered the pathomechanics of rotator cuff tears. In order to manage cuff tears we need to understand the pathology, nature of the tear, and the type of tear.

The operative approach for rotator cuff repairs has evolved from the classic open approach to a minimally invasive, or deltoid-sparing, approach, then finally to an ‘all-arthroscopic’ repair. This evolution has resulted from an improved understanding of rotator cuff tear patterns and advancements in arthroscopic instrumentation and techniques. The ability to repair the rotator cuff without detachment of the deltoid is a tremendous benefit to the patient, offering decreased pain associated with the cuff repair, avoidance of complications related to deltoid reattachment, and optimization of the rehabilitation process.

Classifications

The key to understanding the pattern of rotator cuff tearing is the central oblique tendon (Figure 4.3.8), which runs from the middle of the muscle to the anterior leading edge of the tendon at its insertion. The most common cuff tears involve the supraspinatus and infraspinatus tendons. Such tear patterns are known as posterosuperior rotator cuff tears. Posterosuperior cuff tears originate behind the thickened anterior oblique cord of supraspinatus and extend posteriorly. The term anterosuperior rotator cuff tear is defined as a lesion of the cuff that includes full thickness tears of the supraspinatus, extending anteriorly to involve the rotator interval structures and potentially the subscapularis tendon.

In order to optimally manage rotator cuff tears it is essential to understand the tear pattern and be able to document this. Many classifications exist for various aspects of cuff pathology. The following classifications are some that have relevance in our clinical practice.

**Tear size: Cofield classification of tear size**

- Small: <1cm
- Medium: 1–3cm
- Large: 3–5cm
- Massive: >5cm.

**Tear propagation pattern: Ellman and Gartsman classification (Figure 4.3.9)**

- Crescent
- Reverse L
- L-shaped
- Trapezoidal
- Massive tear full thickness rotator cuff tears.

---

**Fig. 4.3.8**

Central oblique cord of supraspinatus (macroscopic, ultrasound, and arthroscopic views).
Cuff tear retraction in the frontal plane: Patte classification (Figure 4.3.10)

- Stage 1: proximal stump close to bony insertion
- Stage 2: proximal stump at level of humeral head
- Stage 3: proximal stump at glenoid level.

Topographic classification of rotator cuff tears in the sagittal plane: Habermeyer classification (Figure 4.3.11)

- Sector A: anterior lesions—subscapularis tendon, rotator interval and long head of the biceps tendon
- Sector B: central superior lesions—supraspinatus tendon
- Sector C: posterior lesions—infraspinatus and teres minor lesions.

Fatty muscle atrophy: Goutallier classification

- Stage 0: normal muscle
Indications

The presence of chronic degenerative cuff tears is well accepted and over 24% of patients over the age of 60 years will have an asymptomatic, full thickness, degenerative cuff tear. These people generally do not require a rotator cuff repair and have compensated for the functional loss of cuff muscles adequately. However, a traumatic episode with extension of the chronic tear may tip the balance and lead to weakness and pain. This group often do benefit from functional restitution.

Within the active population, no matter the patient’s age, an active sporting individual with a traumatic rotator cuff tear is an indication for rotator cuff repair. A fully functional cuff is necessary to return to demanding functional activities. Rotator cuff tears also increase in size over time. Partial thickness tears have been shown to progress to full thickness tears, and small full thickness tears progress to large to massive full thickness tears.

Even prior to the imaging available now, Codman stated that in a traumatic cuff tear in an active patient:

> If such a syndrome is present I do feel that not only is exploration indicated but that it should be strongly urged, for immediate suture should be a simple and successful operation. Delay means retraction of the tendon and a much more serious problem.

The advent of advanced imaging in the form of magnetic resonance imaging (MRI) and ultrasound scans has made the diagnosis of the presence of a cuff tear easier, but not the ability to easily differentiate between a chronic degenerative tear and an acute traumatic tear. This still relies on good, sound clinical judgement.

The decision to proceed to a rotator cuff repair should be made prior to confirmatory imaging. Ultrasound can confirm the presence and size of the tear, along with associated pathology such as biceps involvement. MRI is useful to assess the quality of the rotator cuff muscles for muscle atrophy and fatty infiltration.

Muscle atrophy and fatty infiltration of the torn rotator cuff muscles has been shown to be associated with higher rates of failure of repair and poorer functional outcomes. There is also a correlation between muscle atrophy, fatty infiltration, and age; cuff tear size; and length of symptoms. However, rotator cuff muscle atrophy has also been shown to be a product of increasing age even in the absence of a tear. This should all factor into the decision-making process and prognostication, but one should not make a decision for surgery based on the muscle atrophy and fatty infiltration alone.

The indications for surgery are:

1) Active person (usually between the ages of 40–70 years)
2) Usually an episode of injury
3) Rotator cuff weakness and pain, which interfere with daily life
4) A proven rotator cuff tear on MRI or ultrasound.

Requirements for surgery:

1) Full passive range of glenohumeral motion
2) Surgeon with adequate skills, experience, and facilities
3) Postoperative rehabilitation
4) Compliant patient.

Contraindications

Absolute contraindications for arthroscopic rotator cuff repair include ongoing active infection and medical contraindications to appropriate anaesthesia. It should not be undertaken unless adequate facilities, equipment, and instruments are available and the surgeon appropriately skilled and experienced in undertaking arthroscopic reconstructive shoulder procedures.

Relative contraindications include: significant glenohumeral arthrosis, joint stiffness, massive tears with significant retraction, muscle atrophy, and fixed humeral head elevation.

Results

The results of arthroscopic rotator cuff repair are equivalent to, and possibly better than, traditional open repairs. Most studies show good to excellent results in over 90% of cases. Cuff integrity has been reported to range from 71–94%, as assessed by ultrasound, MRI, computed tomography arthrogram or magnetic resonance arthrogram. The variation in the literature is due to differences in patient selection, techniques, follow-up, and imaging methods. However, it is clear that the failure of repair integrity is associated with the following factors: tear size and retraction, advancing age, muscle atrophy, and fatty infiltration and quality of the tendon tissue.

Table 4.3.1 summarizes some recent large studies with results of arthroscopic cuff repair surgery of full thickness tears.

* Indicates studies with double-row rotator cuff repair technique only. CTA, computed tomography arthrogram.

Most of the more recent studies appear to show that improved results can be obtained with double-row repairs, stronger anchors and sutures, and improved techniques. Advancements in our understanding of the cuff tear biology and developments in the field of orthobiologics may show further improvements in these results over the forthcoming years.

Principles

Bigliani described five factors that facilitate favourable results in rotator cuff repair surgery. These are:

1) Perform an adequate subacromial decompression
2) Maintain the integrity of the deltoid origin
3) Mobilize the torn tendons
4) Repair the tendons to bone
5) Carefully stage and supervise the rehabilitation programme.

Bunker described six principles:

1) Assess the cuff tear
2) Release the capsular contractures
3) Reintroduce healing biology
4) Reattach the tendon to its anatomical footprint
5) Protect the repair
6) Regain movement and its control.

These were described for open cuff surgery, but the principles are identical for arthroscopic repair. The only difference is the surgical approach.

Repair of the tendon only comprises one component of the factors listed. This highlights the importance of assessment of the tear retraction, pattern, and mobility; performing adequate releases to allow a repair without tension; and the biological preparation of the tendon and the bone for healing. "Prior proper preparation prevents poor performance!"

Technique

Portals (Figure 4.3.12)

Portals are created in the following order, depending on their requirement:

1) Posterior portal for initial glenohumeral arthroscopy and later posterior instrumentation
2) Lateral portal is utilized for initial traction and debridement of the rotator cuff tendon edges. It is then used for preparation of the footprint area, the release of adhesions, and bursectomy. And viewing for a lateral "50-yard" view of the rotator cuff
3) Superior lateral portal is made outside-in, about 1cm lateral to the lateral border of the acromion. It is used for footprint preparation, tendon edge debridement and anchor insertion, and knot tying, obtaining a good 45-degree dead-man’s angle for anchor insertion.
mobilization and preparation is the key to a good tension-free repair. Small tears (discussed earlier). Mobilization of the cuff may be required underneath the cuff, as well as above. Adequate cuff mobilization is the most effective strategy for repair (Table 4.3.2). Bridge techniques with a medial and lateral anchor have simplified this. We prefer the technique described by Boileau

Large tears

The technique for repairing large cuff tears depends on the tear pattern. Recognition of the correct tear pattern will help determine the most effective strategy for repair (Table 4.3.2). The principles and techniques apply equally for large and massive tears as for small tears (discussed earlier). Mobilization of the cuff may be required underneath the cuff, as well as above. Adequate cuff mobilization and preparation is the key to a good tension-free repair.
Fig. 4.3.13
Simple and double row techniques for small tears.

Suture passing can be accomplished with numerous devices. Generally, there are three main categories:

1) **Cuff penetration and suture retrieval**: these instruments penetrate the cuff and retrieve the suture from the anchor. They should be passed through a portal remote and perpendicular to the viewing portal—generally the anterior, posterior, or Neulase portal (e.g. CleverHook®, Mitek; PathSeeker®, Mitek; Arthro-Pierce®, Smith & Nephew)

2) **Suture shuttle relays**: a shuttle relay or suture is loaded through the instrument and passed through the cuff. The suture from the anchor is passed through the shuttle relay and passed back through the cuff (e.g. Spectrum system®, Conmed; Accu-Pass®, Smith & Nephew)

3) **Suture punches**: the original Caspari suture punch has evolved to many new forms. The anchor suture is loaded into the jaws of the punch. The tissue is grasped by the jaws and a modified needle pushes the suture through the cuff. This is done perpendicular to the cuff edges, usually via the lateral portals.

The majority of large tears can be repaired by margin convergence techniques or a double-row repair. We prefer a double-row repair wherever possible. Margin convergence cannot be performed if there is no adequate anterior cuff for side-to-side sutures. This is only present if the central oblique tendon of supraspinatus is not involved, i.e. anterosuperior tears. In these situations a double-row repair is preferred.

The long head of biceps is often involved in anterosuperior cuff tears and can be incorporated into the repair, as with open surgery. This is a ‘dynamic’ tenodesis.

**Margin convergence (Figure 4.3.14)**

The preparatory steps are the same as for a small tear, as listed earlier, but more extensive releases may be required. This can be achieved viewing from the lateral portal and mobilizing from the anterior, posterior, and superolateral portals.

Side-to-side (margin convergence) sutures are passed from the posterior to anterior portal, using a penetrating grasper or shuttle relay system. These are tied through the anterior portal, working from medial to lateral.

The tear is then converted to a small tear and this can then be repaired as a small tear with a suture anchor repair.

**Double-row repair (Figure 4.3.15)**

We prefer to use a simplified technique, which does not involve intra-articular knot tying. This is a modification of Boileau’s two-anchor technique, using four anchors. This technique is suited to large C-shaped tears and some L tears.
Subscapularis

Arthroscopic repair of subscapularis (Figure 4.3.16) is technically feasible and results are as good as open repairs in the hands of suitably skilled and experienced surgeons. Subscapularis tears, similar to supraspinatus tears, originate on the articular side of the tendon and progress in a similar manner to other cuff tears. LaFosse has classified these on the basis of intraoperative evaluation and preoperative computed tomography scans (Table 4.3.3).

<table>
<thead>

</tr>
<tr>
<td>V</td>
<td>Complete lesion of tendon but eccentric head with coracoid impingement and fatty degeneration classified as more than or equal to stage III</td>
</tr>
</tbody>
</table>

Type I–III lesions can be repaired from inside the glenohumeral joint, viewing from posteriorly and working from anteriorly. It is often useful to flex the shoulder to 90 degrees to improve visualization, and also externally rotate to improve access to the lesser tuberosity.

Fig. 4.3.14
Margin convergence techniques.

Fig. 4.3.15
Double-row technique for large tears.
In chronic tears, it might be difficult to easily identify the tendon edges. Using a radiofrequency probe the scarred tissue in the rotator interval can be debrided from lateral to medial, releasing the superior glenohumeral and coracohumeral ligaments from their humeral attachments, thus exposing and mobilizing the tendon. The scope can be moved to an anterolateral portal for an improved medial view and preparation continued. Often a second, more medial portal is required for anchor placement and suture passing. The coracoid and conjoined tendon should be identified before creating this portal and a spinal needle used to locate the safe placement lateral to the coracoid.

Repair of the tendon is performed from inferior to superior, with cuff suture-anchors in the lesser tuberosity. A footprint reconstruction can be achieved by using mattress sutures inferiorly and medially, followed by simple sutures laterally and superiorly.

The long head of biceps is often affected and is best managed with a tenodesis. This can be incorporated in the most superior suture anchor fixation. The suture-loop technique, popularized by LaFosse, ensures a strong fixation of the tendon.

Postoperative rehabilitation

Advances in our understanding of tendon healing and tendon responses to immobilization, along with developments in the field of shoulder rehabilitation, has allowed us to progress from the traditional enforced and prolonged periods of immobilization. Rehabilitation goals following surgery are to implement a continuum of exercises that restores optimal function while protecting the anatomic integrity of the injured or repaired tissues.

Rotator cuff repairs should not be performed under any tension and the tear should be assessed on-table through a range of motion (passive motion) confirming the security of the repair. The fixation should be rigid enough to allow this also (similar to fracture fixation surgery). There is evidence that moderate stresses can be placed on the suture line before the end of 3 weeks to improve collagen tissue healing and increased stresses within certain limits enhances healing and improves joint function.

New ‘accelerated’ rehabilitation programmes provide very low loads through the cuff as measured by electromyography. Each exercise combines passive motion, scapula control, core stability, and proprioception early postoperatively, thus establishing a better basis for strengthening later. The exercises allow a progression of intensity and load that is within the healing tissue’s capabilities. Closed-chain exercises are an integral part of accelerated rehabilitation programmes. They can be started early and used throughout the rehabilitation process.

A key element in rehabilitation is the successful transition in the flow of exercises from the protected exercises of the acute phase to the functional phase. This can be achieved without complete immobilization. Accelerated rehabilitation promotes functional recovery and reduces postoperative pain, which allows patients an early return to desired activities. These exercises and protocols are available on the website http://www.shoulderdoc.co.uk. The protocol we use is shown in Box 4.3.1.

**Box 4.3.1 Accelerated Rehabilitation Protocol following rotator cuff repair**

**Pre-op (Prehabilitation)**

- Range of motion Exercises
- Maximise shoulder strength of deltoid, intact cuff muscles and scapula stabilisers.

**Day 1 – 3 weeks**

- Shoulder immobiliser abduction pillow (night use) – wean off as tolerated.
Passive / Active Assisted ROM in all directions as tolerated
- Level 1 Exercises (<20% EMG), which combine and concentrate on proprioception, scapula setting and core stability. Closed chain exercises are incorporated.
- Wean off sling over 1-3 weeks, as tolerated.

3-6 weeks:
- Do not force or stretch
- Isometric exercises in neutral as pain allows – up to 50% maximum voluntary contraction
- Open Chain Exercises as tolerated
- (Level 2-3 Exercises)

6 weeks +:
- Progress to full active and resistance exercises in all ranges
- (Level 3 Exercises)

Summary points

- LHB pathology is a common cause of anterior shoulder pain
- Clinical evaluation and diagnostic imaging are both imprecise
- Isolated biceps pathology may be present in the younger athlete
- Degenerative biceps pathology is often associated with rotator cuff pathology
- Failure to treat concomitant LHB pathology is a cause for surgical failures in many other shoulder conditions

Introduction

The long head of the biceps tendon (LHB) is an enigmatic structure but is also an important cause of shoulder symptoms. Though its anatomy is well described, understanding of its surrounding restraints and structures such as the rotator interval are still being evaluated. More problematically for surgeons its function is still hotly debated, and poorly defined, leading to contention regarding potential surgical treatment.

This chapter will attempt to clarify the current understanding of the role and pathology of the LHB at the shoulder, and propose treatment strategies that are appropriate for the available evidence, and attainable for modern arthroscopic treatment modalities.

Anatomy

The LHB arises from the supraglenoid tubercle and the superior glenoid labrum. Its origin is, however, variable, and most anatomical studies have shown the labral origin to be more common. The intra-articular course is extrasynovial, and it exits the glenohumeral joint via the intertubercular (bicipital) groove, between the lesser and greater tuberosities, and carries a synovial reflection down within this groove.

At the point of exit from the joint a complex set of restraints exist. The ‘biceps sling’ comprising the superior glenohumeral ligament (SGHL), anterior band of the coracohumeral ligament, and capsule of the rotator interval, forms the anterior (or medial) restraint. The leading edge of the supraspinatus (anterior column) forms the posterior restraint. Failure of any of these structures may lead to instability. The course of the tendon within the bicipital groove is constrained, and vulnerable to many pathological abnormalities. At the inferior limit of the groove it passes beneath the tendon of the pectoralis major, before merging into the lateral muscle belly.

The intra-articular course of the tendon is oblique, variable depending on shoulder rotation and elevation, and is subject to significant shearing forces, which predispose the tendon to pathological changes.

The primary function of the biceps is at the elbow as a flexor and forearm supinator. The function of the long head at the shoulder is still unclear. Evolutionary change has rendered the LHB less functional at the shoulder in humans, and anatomical, biomechanical, neurophysiological, and radiological studies have produced conflicting results. The LHB contributes to 7–10% of abduction strength, but only with the humerus in external rotation. The head depressor effect of the LHB is also minimal, though more interest has recently been focused on its role as a secondary anterior stabilizer in the unstable shoulder.

Diagnosis

The clinical evaluation of LHB pathology is notoriously imprecise. Unfortunately current imaging investigations are only moderately more accurate, truly leaving dynamic arthroscopic diagnosis the gold standard investigation.

Clinical evaluation of the shoulder has been dealt with in Chapter 4.1, but there are certain specific points regarding diagnosis of LHB pathology that warrant further attention.

The history, typically, is of well-located, anterior shoulder pain that the patient can point to at the bicipital groove. This pain may radiate down the arm, along the biceps muscle belly, but can extend as far as the hand, usually along the radial border of the forearm towards the thumb. This referred pain needs to be distinguished from radicular pain of cervical origin. The painful clunk of a subluxing tendon is quite specific, but is an infrequent symptom. SLAP (superior labral tear from anterior to posterior) lesions may present with deep-seated pain on certain activities, or with pain associated with instability, or shoulder pain in a young patient with negative clinical signs of rotator cuff pathology.

Palpation of the tendon in the bicipital groove, classically described with the arm in 10 degrees of internal rotation, is a useful sign, but correlation with the contralateral shoulder is important. Clinical tests such as Speed’s test, Yergason’s test, and biceps instability test, are poorly validated, and a recent paper has reported sensitivity and specificity of 50–67% for palpation and Speed’s tests in the diagnosis of partial thickness tears.
The clinical diagnosis of SLAP lesions is no easier. Many tests have been proposed, and many variations exist, the most widely defined being the O’Brien active compression test and the Biceps Load II. The AERS (abduction external rotation supination), Mayo shear, anterior superior SLAP test, and biceps tension tests are also commonly used.

Imaging

Plain radiography has a limited role in the diagnosis of LHB pathology. The two views that may show bony changes associated with arthritis, malunion of fractures, and loose bodies are the anteroposterior in external rotation and the Fisk view, an axial view centred on the bicipital groove.

Arthrography and computed tomography arthrography were the first imaging techniques to visualize the intra-articular tendon, but these have been largely superseded by ultrasound (US) and magnetic resonance imaging (MRI).

Both MRI and US can demonstrate the entire LHB tendon from origin to the musculotendinous junction, and gross pathology such as dislocation and rupture are well shown by both modalities. The spatial resolution, and dynamic capability of modern US now provides advantages in diagnosing partial tears, subtle dynamic instability, and the hourglass lesion. Unfortunately, studies have still only reported moderate accuracy of MRI (37% concordance with arthroscopic findings) and US (49% sensitivity). These findings are largely due to both techniques being poor at demonstrating partial thickness tears, which usually occur on the deep surface of the tendon.

Inflammation and intrinsic degeneration

As an intra-articular, but extrasynovial structure, the LHB is prone to tenosynovitis. The tendon is also subject to significant shearing forces in its oblique course though the glenohumeral joint. The forces acting on the tendon vary with arm position, notably rotation and elevation, though in the majority of functional positions the tendon bears upon the medial wall of the groove, that is, the lesser tuberosity and the biceps sling. Tenosynovitis is, by definition, an inflammatory condition and is reversible in the majority with conservative measures.

Box 4.4.1 Pathology affecting the LHB

- Tenosynovitis (impingment)
- Tendinosis
- Partial tears/rupture
- Hypertrophy (hourglass)
- Instability
- Biceps anchor lesions (SLAP).

Tendinosis represents irreversible degenerate change within the tendon. This is commonly seen in association with subacromial impingement and degenerate rotator cuff disease. Progressive degenerate change may lead to ‘hypertrophy’, ‘atrophy’, and partial tendon tears and eventually rupture. Though the link between tendinosis and pain is less clear, partial thickness tears are often symptomatic and cause mechanical symptoms in the shoulder. These tears are usually on the deep surface of the tendon, often at the entry to the bicipital groove or within the groove itself, and therefore interfere with the smooth gliding of the tendon over the biceps pulley and within the groove.

Rupture

Rupture of the LHB, often termed ‘spontaneous’, is a well-recognized clinical entity, producing the characteristic ‘Popeyes’ sign of the descended lateral muscle belly. Males in their fifties and sixties, often with manual occupations, are most frequently affected, and often have no or only a short history of preceding symptoms. The rupture itself often heralds the resolution of symptoms, and many ruptures therefore never present to orthopaedic surgeons. The cosmetic deformity is also usually well tolerated in this patient population.

The functional deficit produced by rupture (and also by surgical tenotomy) is again only demonstrable at the elbow, with a loss of 20% of forearm supination strength and 8–20% of elbow flexion strength. This deficit is generally well tolerated in the elderly, but in the sporting population and manual workers may be more significant.

Hourglass biceps

The ‘hourglass biceps’ is a term describing mechanical entrapment of an enlarged or hypertrophic tendon within the glenohumeral joint on elevation. It is analogous to the bucket-handle meniscal tear or the triggering of a flexor tendon in the hand, leading to a loss of active and passive movement. The LHB glides passively into the bicipital groove on elevation of the arm, but enlargement of the tendon can block this excursion, and the tendon buckles and impinges between the humeral head and the superior glenoid. This leads to a loss of the terminal 10–20 degrees of elevation, often with associated discomfort. With time, tendon delamination and tears occur, though this phenomenon may also cause progressive damage to the tendon restraints, and tendon instability.
Instability of biceps

Dislocation of the LHB was the first recognized pathology of the LHB described in the first part of the nineteenth century. It remains one of the most common indications for surgical treatment of the LHB. Instability may be dynamic, defined as subluxation, or static, as in a fixed dislocation. The majority of instability is medial (anterior), though posterior (lateral) instability may occur with dislocations and supraspinatus tears. The failure of the biceps sling allows medial displacement of the tendon, which in turn causes abrasion of the LHB on the subscapularis tendon, first recognized by Walch as the ‘hidden lesion’, of a LHB dislocation and partial thickness, deep surface subscapularis tear.

Medial biceps instability has been classified by Walch (Figure 4.4.1) and may occur anterior to the subscapularis (the least common), into the substance of the tendon (partial subscapularis tear), or beneath the tendon a condition that has to be associated with a full thickness subscapularis tear.

The importance of lesser grades of instability is also now appreciated, especially in sporting injuries, and has been described to be present in up to 45% of arthroscopies for rotator cuff tears.

Sports injury

Anterosuperior internal impingement

Isolated LHB pathology is particularly important in the athlete. The overhead and throwing athlete are particularly vulnerable and instability, partial tears, and SLAP lesions are all common.

Anterosuperior internal impingement (ASI) is a novel diagnosis that has been brought to light by dynamic arthroscopic studies. At arthroscopy, abrasion is seen on the anterosuperior labrum, just in front of the biceps origin with a corresponding ‘kissing’ lesion at the LHB pulley. It is thought that these two structures shear against each other in the follow through phase of throwing when the arm is in adduction and internal rotation and rapidly decelerating. It is commonly seen in sports injuries but how to manage it remains contentious. At the present state of knowledge, the use of a sports physiotherapist to change the pattern of follow through may be the best management, but it is unpredictable.

Posterosuperior impingement

Another common condition in the athlete is posterosuperior impingement (PSI). This is a complex syndrome involving repetitive forced contact between the deep surface of the supraspinatus and posterior labrum and may lead to posterosuperior labral fraying, tears, and deep surface cuff pathology. A tight posterior capsule, anterior capsular laxity, and instability have all been implicated in its pathogenesis.
Superior labral anterior posterior lesions

It was only following the advent of shoulder arthroscopy that lesions of the superior labrum and biceps anchor were recognized. Snyder first described the ‘SLAP’ lesion in 1990, in relation to the throwing athlete, and it is now recognized as an important cause of shoulder dysfunction, and a common indication for surgery.

Snyder described four types of lesion, and although these have been expanded to include many subtypes and associated instability lesions, the original classification still describes the four major types of lesion well (Figure 4.4.2).

Fig. 4.4.2
Snyder classification of SLAP tears. Type I is fibrillation; type II is avulsion of the origin of biceps; type III is a bucket-handle tear; type IV is a complex bucket handle tear extending into the tendon. Reproduced from Snyder, S.J., Karzel, R.P., and Del Pizzo, W. (1990). SLAP lesions of the shoulder. Arthroscopy, 6, 274–9, with permission from Elsevier.

SLAP lesions may be produced either by the acceleration or deceleration phases of the throwing movement, as well as compression injuries with proximal displacement of the humeral head. There is also an overlap with anterior instability and superior extension of the classical Bankart lesion as well as posterosuperior impingement, which may lead to posterior SLAP lesions.

Type I SLAP lesions describe degenerative fraying of the superior labrum. They may be found prematurely in athletes, or in association with the normal ageing process. Anterosuperior fraying is most common in ageing, while posterosuperior fraying raises the possibility of PSI. Type II lesions are the most common lesions requiring surgical intervention. True bicipital/labral avulsions must be carefully distinguished from a mobile meniscoid labrum, which is a normal variant. Type III lesions are less common and the type IV lesion poses particular decision-making difficulties with respect to repair of the entire complex or labral repair and LHB tenodesis.

Surgery

Indications

The primary indications for surgical intervention in biceps pathology are mechanical lesion such as instability, entrapment, and partial tendon tears. Secondary indications are refractory pain due to tendosynovitis and early tendinopathy, and treatment of concurrent rotator cuff disease, instability, and arthritis. Determining the relative contribution of the LHB to shoulder pain is difficult, but careful arthroscopic evaluation can prevent surgical failures due to missed LHB pathology.

A LHB rupture in a young patient or manual worker may also be an indication for early surgery, which should be performed within 6 weeks of rupture to be successful and restore strength.

Contraindications

As loss of the LHB from the shoulder has little, or no, consequences on shoulder function there are few contraindications for surgical intervention. Unnecessary intervention obviously subjects patients to the risk of the surgical procedure, but the possibility of neglecting bicipital pain must always be considered.

One contraindication to tenotomy is in the pseudoparalytic arm with anterosuperior escape due to a large rotator cuff tear. In this situation, active elevation will not be restored with a simple tenotomy. Tenotomy is also contraindicated in young active patients where a tenodesis should always be performed.

Tenotomy

Arthroscopic biceps tenotomy is the simplest, most reliable, and probably most common surgical intervention to the LHB. Releasing the tendon close to its origin allows the tendon to retract outside the glenohumeral joint, and will relieve bicipital symptoms at the shoulder effectively. This technique was popularized in the 1990s in Europe, and many studies have confirmed its
The limitations of this procedure are the cosmetic deformity often produced, a small incidence of persistent muscle belly cramping on activity, and the loss of elbow flexion and supination strength. It is of interest that not everyone who undergoes surgical tenotomy shows the cosmetic ‘Popeye’ sign after surgery. This is either due to the tendon still being held by vinculae, or, more commonly, a hypertrophied tendon retracts into the sulcus but then gets trapped there like a cork in a bottle.

Box 4.4.2 Treatment options

- Physiotherapy
- Injection (US guided)
- Debridement ± subacromial decompression
- Tenotomy
- Tenodesis
- SLAP repair.

Tenodesis

Open tenodesis was historically the treatment of choice for bicipital pathology. Many techniques were described, and many more have recently been described as arthroscopic techniques. There are broadly three groups of techniques: soft tissue techniques using suture fixation of the tendon to other tendons or the transverse humeral ligament; fixation of the tendon to bone using sutures and anchors; and fixation of the tendon within the bone of the proximal humerus (Figure 4.4.3). The first technique is evidently the simplest, and the last the most mechanically secure.

SLAP repair

The different classes of SLAP lesion require different surgical approaches. Type I lesions do not require intervention, or merely debridement if found in association with other pathology. Type II lesions require repair of both the superior labrum and biceps anchor. This is usually achieved with suture anchors placed anterior and posterior to the LHB origin. Type III lesions can usually be excised, though an attempt to repair very peripheral tears may be indicated. Finally the treatment of type IV tears will depend on the extent of damage to the biceps tendon itself. A combination of excision and repair may be used for the labral portion of the tear, and the decision between LHB tendon repair or tenodesis will depend on the extent of bicipital involvement both in terms of percentage cross-sectional tearing and extent of tear propagation along the length of the LHB.

Results of surgery

The results of surgery to the biceps tendon are difficult to assess due to the majority of series including associated rotator cuff repair, subacromial decompression, debridement, and stabilization procedures. There are a few papers, however, where isolated tenotomy, tenodesis, and SLAP repairs have been reported.

Isolated arthroscopic tenotomy in patients with irreparable rotator cuff tears has been reported, with good results. Poor function of the teres minor is, however, associated with poorer results. Manou and colleagues in a small series showed that complementary acromioplasty did not confer additional benefit and Walch confirmed this finding if the preoperative acromiohumeral distance is less than 7mm. Indeed, a large cuff tear is a contraindication to releasing the conacocromial ligament with anterior acromioplasty as this may lead to anterosuperior escape.

The results of isolated tenodesis have been reported both in the presence of advanced rotator cuff disease and for isolated LHB pathology. For the former group the results of tenodesis appear equivalent to tenotomy, and for the latter group 77% of patients
could return to their sporting activities.

The published results of SLAP repair have been favourable but more variable. The heterogeneity of lesions, associated pathology, and different surgical approaches makes interpretation of the literature difficult.

### Special circumstances

There are certain conditions, or procedures, apart from rotator cuff disease that warrants attention to the LHB.

#### Osteoarthritis and shoulder arthroplasty

Primary glenohumeral osteoarthritis commonly produces LHB symptoms. Osteophytes in the groove, loose bodies, and joint effusions may all cause symptoms. Intra-articular injections may be partially effective by addressing symptoms generated by the LHB. Both in arthroscopic treatment of early osteoarthritis and during joint replacement addressing the LHB by tenotomy or tenodesis is recommended.

#### Proximal humeral fractures and their fixation

The rational for treatment of the LHB in fractures and their fixation is similar to that of osteoarthritis. The LHB is frequently damaged at the level of the fracture and any degree of malunion affecting the bicipital groove, usually at its superior or inferior boundaries, will lead to poor gliding properties of the tendon. Persistent anterior shoulder pain following malunion should alert the surgeon to possible LHB pathology, and LHB tenodesis at the time of fracture surgery should always be considered.

### Conclusion

The LHB is a fascinating structure. Recognition of its importance in generating shoulder symptoms is currently high, and much new research is emerging.

Further understanding of its role at the shoulder and clarification of the basic science of its pathology is needed before consensus on its treatment will be reached. Future advances will include further development of imaging techniques, particularly US, and scientific clinical results will guide treatment options, in particular in terms of surgical technique. Reconstructive procedures to stabilize the unstable tendon, and potentially repair tendon tears, which have to date proved unsuccessful, would be a great advance, and with the advance of arthroscopic techniques will hopefully be realistic goals in the near future.

Frozen shoulder

DOI: 10.1093/med/9780199550647.003.004005

Summary points

- Frozen shoulder is caused by a contracture of the capsule
- Counterintuitively not all patients recover completely
- At arthroscopy spectacular angiogenesis is seen
- Pathology shows bands and nodules of type III collagen populated by fibroblasts and myofibroblasts
- Arthroscopic capsular release has improved the management of this condition.

Introduction

Codman coined the term frozen shoulder in 1934. He said it was difficult to define, but then went on to propose a definition which has not been bettered in 70 years. He stated ‘this is a condition which comes on slowly with pain over the deltoid insertion, inability to sleep, painful incomplete elevation and external rotation, the restriction of movement being both active and passive, with a normal radiograph, the pain being very trying and yet all patients are able to continue their daily habits and routines’ (Box 4.5.1).

The problem is that many of these features are shared by other common shoulder conditions such as rotator cuff disease. However, there is one clinical feature that distinguishes capsular contracture from all other conditions, restriction of passive external rotation in the face of a normal radiograph. There are only two pathologies that cause limited passive external rotation: firstly damage to the joint surface such as occurs in arthritis, head splitting fractures, and locked dislocation (all of which have an abnormal radiograph); and secondly contracture of the ligaments. Since the radiograph is normal this condition can only be due to contracture of the ligaments.

Box 4.5.1 Codman’s criteria for contracted (frozen) shoulder

- Condition comes on slowly
- Pain at deltoid insertion
- Inability to sleep
- Painful incomplete elevation and external rotation
- Restriction of movement being both active and passive
- The pain being very trying
- Yet patients continue in their daily habits
- Radiographs are normal.

Codman stated, ‘Even the most protracted cases recover with or without treatment in about two years’. This statement has been repeated from text to text without any questioning of the evidence. It has led to the commonly held view that this is a benign condition that resolves completely. However, Simmonds stated ‘complete recovery is not my experience’ and DePalma stated ‘it is erroneous to believe that in all instances restoration of function is attained’. Shaffer et al. (1992) in a very detailed follow-up study found that at 7 years, 50% had mild pain, stiffness, or both. They found that 60% had measurable restriction of passive mobility and they concluded ‘this made us question whether this is a benign self-resolving condition’. Griggs et al. who stated that ‘even amongst the patients who were satisfied, a substantial number were not pain free’ confirmed these findings. Ten per cent had mild pain at rest, and 27% had mild or moderate pain with activity. Forty per cent of the satisfied patients had abnormal shoulder function. Our own studies at 2–5 years showed that although 86% had an improvement in their level of pain, this did not mean that they had no pain. Only 53% had no pain, 33% had an occasional pain, and 14% had marked residual pain. These findings have been confirmed by the largest ever study from Oxford (Hand and Carr) on 273 patients followed for up to 20 years. Using a functional score they demonstrated that 40% of their patients had mild to moderate persistent symptoms at 7 years.

The arthroscopic appearance is spectacular. Firstly there is evidence of capsular contracture with a reduced joint volume. The capsule is thickened and difficult to penetrate with the arthroscope and the joint difficult to navigate due to capsular contracture. The spectacular feature is angiogenesis (Figure 4.5.1). This is most marked in the rotator interval area. As the disease progresses into the stiff and contracted phase, the angiogenesis declines and thick white scar can be seen and palpated within the capsule. The early studies of the pathology in capsular contracture of the shoulder showed dense collagen causing fibrosis and marked vascularity in the capsule. Lundberg made the first link between this condition and the other contractile diseases such as Dupuytren’s disease, when his histopathologist, Dr Norden, noted that the histology of the shoulder capsule showed compact or dense collagen with many cells that were fibroblasts. Hannafin et al. took biopsies at arthroscopy and showed that in the first phase of this disease there was a hypervascular appearance of the synovium with underlying normal capsular architecture; in stage two there was pervascular scar formation and extensive scar formation in the underlying capsule; and in the final phase extensive capsular fibroplasias. This was confirmed by Bunker and Anthony in 1995 where, using immunocytochemistry, the cells were...
shown to be mainly fibroblasts. These authors showed for the first time contractile myofibroblasts, the pathognomonic cell of contracture seen in such diseases as Dupuytren’s contracture. These authors demonstrated a mass of type III collagen laid down in bands and nodules looking very similar to the histology of Dupuytren’s disease (Figure 4.5.2). Further confirmation has come from Killian et al. (2001) who showed a significant increase in fibroblasts, and under electron microscopy a loss of collagen fibril order and fourfold increase in fibre diameter. In summary, all the histological evidence to date shows that this is a capsular contracture of the shoulder (Box 4.5.2). Edwards and Carr have recently examined the inflammatory cells that are to be found near the synovium and around the vessels and have shown the presence of T cells, B cells, and mast cells.

The question then arises as to why this should happen? What precipitates the angiogenesis, and what orders the fibroblasts to accumulate and lay down collagen? Cell messengers (cytokines and growth factors) control these cellular responses and several groups have looked at cell messengers in capsular contracture. Hamada, in Japan, has found increased levels of vascular endothelial growth factor (VEGF) in stiff shoulders that may account for the angiogenesis that is seen at arthroscopy. Rodeo et al. found raised levels of transforming growth factor (TGF) beta and platelet-derived growth factor (PDGF) and suggested that these may act as a perpetual stimulus to fibrosis. Bunker et al. found elevated levels of fibrogenic growth factors (FGF) and this work has been elegantly confirmed by Colville’s group who took joint fluid from patients with capsular contracture and found that this tissue caused a 5000% increase in in vitro fibroblast proliferation compared with control groups.
On the cellular level, one may question why the scar that is laid down is not quickly remodelled as in normal healing? Bunker et al. looked at the question of remodelling that is mediated by MMPs (matrix metalloproteinases). They found an absence of MMP 14 and an elevation of the MMP inhibitor TIMP (tissue inhibitor of metalloproteinases). Hutchinson et al. actually treated patients with end-stage gastric cancer with marimastat, a synthetic TIMP, and found that within 4 months half their patients developed stiff shoulders and a quarter developed Dupuytren’s disease. When the marimastat was stopped the disease regressed. These studies show a tantalizing future where this disease could be treated medically if the molecular basis is better understood.

There has been very little work done on the genetics of capsular contracture. Family studies are difficult to do on conditions where two-thirds of those affected outwardly appear to return to normal. Bunker et al. found that patients with capsular contracture had a normal karyotype, that is they were 46XY if male and 46XX if female, but the cells from the shoulder capsule showed some clonal chromosomal changes. These changes were numerical trisomy of chromosomes 7 and 8, a similar finding to that in other studies of Dupuytren’s disease.

### Treatment of contracted (frozen) shoulder

The search engine Google will give you 33 60 000 websites that promise a surgery-free instant cure for frozen shoulder. These treatments range from herbal pastes applied to the feet to 12 weeks of osteopathic stretching, many with celebrity affidavits and newspaper cuttings attached!

Comparison of treatments is confounded by inadequate diagnosis, lack of controls, underpowered studies, and a failure to look at immediate results of intervention. These confounding factors apply equally to surgical as well as non-surgical studies.

Steroids have been shown in many randomized prospective controlled studies to have no benefit over home exercises. However, many papers can be criticized as they studied painful stiff shoulders, in other words primary and secondary frozen shoulder, so many of the patients would have had other shoulder disease. One paper performed arthograms of the study group and 11 of 36 had cuff tears, yet were kept in the study! In one recent randomized controlled study (Ryans 2005) patients receiving steroid has less pain than the placebo group at 6 weeks, without any improvement in movement, but by 16 weeks both steroid and placebo showed no difference in any outcome measure. In another randomized placebo-controlled study (Carette et al. 2003), the groups receiving steroid had significantly better SPADI scores than placebo at 6 weeks, without any measurable improvement in movement, but by 12 months steroid and placebo were improved to a similar degree with respect to all measurable outcome measures.

Diercks and colleagues showed that intensive physiotherapy prolonged the natural history of the disease from 15 months to 24 months and achieved a lower Constant Score of 76 compared to 87 in the control group who did home exercises. Once again we must stress that what the patients want is not for their disease to be prolonged from 15 to 24 months, but for it to end today. The Ryans (2005) study showed that the physiotherapy groups had improved movement at 6 weeks over steroid or placebo, but more pain, and no measurable difference at 16 weeks. Similarly the Carette (2003) study showed no difference between physiotherapy and placebo at any stage of follow-up.

Joint distension with or without steroids has been examined in a number of studies. Most of these studies are flawed by small numbers (just eight patients in one group), confounded by giving distension, steroid, and physiotherapy at the same time, by repetitive treatments (weekly distensions for 6 weeks in one study), by a lack of control groups (no peer-reviewed study with controls), and outcomes being examined at up to 2 years when 90% of untreated patients should have an improvement in outcome at that stage.

Manipulation under anaesthetic has been the mainstay of surgical treatment for decades. There are many studies showing good and relatively rapid improvement. Sneppen et al. showed that 75% of their patients attained a near normal range of movement, 79% were relieved of pain, and 75% returned to work within 9 weeks. However, manipulation is not without risk. Loew and colleagues examined the collateral damage caused by manipulation. They found that four patients out of 30 had an iatrogenic SLAP tear following manipulation, three had a partial tear of subscapularis, and four had a detachment of the anterior labrum. No patient had a fracture, dislocation, or cuff rupture. They examined the pattern of tearing of the capsule, the expected and desired effect of manipulation, by dividing the glenoid rim into thirds. Twenty-four of the 30 had a tear of the anteroinferior third of the capsule, 11 of the superior third, and 16 of the posteroinferior capsule. All patients had a significant improvement in movement, flexion improving by 70 degrees and external rotation by 50 degrees.

### Box 4.5.3 Treatment of contracted (frozen) shoulder

- Supervised neglect
- Physiotherapy
- Steroid injection
- Hydrolatation
- Manipulation under anaesthetic
- Arthroscopic release.

### Surgery for contracted (frozen) shoulder

Arthroscopic capsular release (ACR), in the hands of the expert shoulder surgeon, has transformed the management of capsular...
contracted, manoeuvrability is tricky, and the joint surfaces may be inadvertently damaged. It is the more radical the release the less need there is for any element of manipulation. The release is the most important element as the results are so much better than those of manipulation. There is also no doubt that prospective studies that can prove which of the four elements of the procedure are the most important. Intuitively it would seem that capsule, some surgeons inject cortisone, and most gently manipulate the joint. As yet there are no randomized controlled acting therapy, and the evidence is that no harm is done by intervening early.

Surgical lore dictates that it is an error to interfere during the early painful phase of the contracted shoulder, but is this true? Colville found that the converse was true and that patients did better the earlier that they were treated. Klinger et al. demonstrated effective treatment with ACR performed early in the disease process. In reality most patients are optimistic that the condition will resolve for the first 3 months, then go to their primary care physician who institutes conservative treatment for 3 months, and the patient only presents to the surgeon at around 6 months’ duration when conservative treatment has failed. The author’s preference is to operate on the severely symptomatic patient as soon as a definitive diagnosis is established, for ACR is the most effective and rapidly acting therapy, and the evidence is that no harm is done by intervening early.

Surgical lore also dictates that it is an error to intervene in diabetics, but is this true? Ogilvie-Harris (1997) showed that ACR was an effective treatment for the resistant diabetic frozen shoulder and this was confirmed by Massoud et al. (2002). Harryman and Matsen (1997) found no difference between the results of ACR in diabetics and non-diabetics. The evidence is that ACR is effective in diabetics.

**Indications**

In the past surgeons treated the contracted shoulder with neglect and reassured patients that it would get better in 18 months, or 2 years. Is that what the patient wants? Well I would suggest you ask the patient. Patients would like to be free of their pain, able to sleep at night, and able to move their arm. And they would like it today, or tomorrow at the latest, but they do not want to suffer for a further 2 years. ACR gives them the opportunity of rapid relief (30% better on day 1 and 80% better by day 5).

The indication for ACR starts with a proven diagnosis of contracture (all other causes of stiffness excluded, radiographs normal), intrusive pain, and jerk pain by day, awakening by night, and stiffness leading to a significant loss of function, all of which is getting worse and not better.

As with any musculoskeletal disorder there is a spectrum of disease. Some patients have a very mild form of contracture that resolves rapidly, and some have a very severe contracture. The latter can be detected easily. Men, with insulin-dependent diabetes, severe Dupuytren’s contractures, bilateral disease, external rotation tethered at minus 10 degrees, and failed previous manipulations, populate the severe end of the spectrum. The mild form is far more difficult to detect for with little stiffness it can be, and often is, confused with the impingement stage of rotator cuff disease. This confusion with impingement in the early stages of mild disease may be responsible for the good results obtained by fringe practitioners who amuse the patient whilst nature affects a cure. These people with mild disease will get better anyway, they probably will never be seen in a surgeon’s clinic, and they need no interference. The majority of patients lie somewhere in between these extremes. For them the key indication for surgery is night awakening. ACR should be considered if the pain is severe enough to awaken the patient from sleep every night, or many times a night. When this is accompanied by intrusive stiffness and jerk pain the case for ACR is strong. At this stage the risks and benefits of surgery should be explained to the patient. The risks are those of general anaesthesia, failure to improve in 10%, and an infection risk of about one in 3000. The patient then makes their decision, but thanks to arthroscopy the days of nihilistic neglect for the contracted shoulder are over.

**Contraindications to surgery**

The contraindications to ACR are mild disease with no awakening, resolving disease, and the patient who is unfit for surgery. The surgeon must always bear in mind that in 90% of patients the pain eventually abates and the patient must never be placed in harm’s way by the administration of anaesthesia, or by surgery.

**Procedure**

Arthroscopic release is, in reality, a combination therapy that consists of four elements: a washout, a variable release of the capsule, some surgeons inject cortisone, and most gently manipulate the joint. As yet there are no randomized controlled prospective studies that can prove which of the four elements of the procedure are the most important. Intuitively it would seem that the release is the most important element as the results are so much better than those of manipulation. There is also no doubt that the more radical the release the less need there is for any element of manipulation.

Whilst arthroscopic release is far easier than reconstructive surgery, such as arthroscopic cuff repair, it is not for the inexperienced. The capsule is very thickened and the joint space has a small volume. Entry into the joint can thus be difficult. The joint space is contracted, manoeuvrability is tricky, and the joint surfaces may be inadvertently damaged.
The patient must be told that they bear responsibility for the outcome of their surgery. All the surgeon is doing is releasing a joint that wants to stiffen and it is up to the patient to maintain the movement achieved at surgery. To this end they are shown Codman’s stooping exercises and instructed that these should be big and slow, tai chi rather than karate! This can be supplemented by range of motion exercises as demonstrated by Rockwood using a stick, pulley, and TheraBand.

Calcifying tendinitis

Summary points

- Calcifying tendinitis remains an enigmatic condition
- The pathology shows hydroxyapatite crystals lying in extra-cellular matrix vesicles
- There are two presentations, acute and chronic
- Acute episodes can be treated by analgesia and barbotage
- Chronic lesions can be treated conservatively, or by excision of the calcific deposit, arthroscopically or by barbotage.

Introduction

Periarticular calcification of the shoulder is frequently an incidental radiographic finding in asymptomatic patients. Some patients may have mild symptoms and a few will present with severe pain when these calcifications are undergoing resorption. The condition of formation and subsequent resorption of rotator cuff calcification is usually referred to as calcific or calcifying tendinitis. Although calcification may occur in the degenerate torn rotator cuff as a secondary process, the calcium deposition associated with calcifying tendinitis is transitory and does not lead to permanent damage of the involved shoulder.

Incidence

Estimates as to the incidence of rotator cuff calcification in the general population vary considerably with age and type of sample. Estimates vary between 2.7–8% of the population, but many of these are asymptomatic.

The distribution of calcific deposits within the rotator cuff has been well documented by several authors. Calcification within the supraspinatus is more likely to become symptomatic, probably because of subacromial impingement of the swollen area of tendon. Calcification is found in supraspinatus in 74–82% of symptomatic cases.

Calcifying tendinitis seems to be a disease of middle age with a peak incidence in the fifth decade, but rarely presents in the elderly. Therefore calcification must be self-limiting. In Bosworth’s series almost 10% of deposits vanished in 3 years of follow-up.

Most authors found a higher incidence of calcification in females with an incidence range of 57–77%. The right shoulder is involved slightly more frequently and 13–24% of cases are bilateral. Although there have been reports of an association between periarticular shoulder calcification and calcification around the hip there is no evidence of any association of calcifying tendinitis with any systemic disorder of calcium metabolism or medical conditions such as diabetes or gout. With regard to the rotator cuff itself, there is no correlation between significant rotator cuff disease and calcifying tendinitis although partial cuff tears occasionally occur when a calcific deposit bursts into the subacromial bursa.

Although cuff tears are not associated with calcifying tendinitis, the edges of a torn degenerate cuff may show some calcification radiographically. This has a characteristic stippled appearance and should be considered a separate condition with a clinical course which reflects that of the underlying cuff disease.

Classification

Various classification systems for calcifying tendinitis have been proposed. In general, anatomical and radiological classifications have not been very helpful in directing management. Bosworth classified the deposits according to their size and thought that large deposits were more likely to become symptomatic. Deposits have also been classified by the quality of their radiographic appearance. DePalma classified the condition by the duration of symptoms at presentation into acute, subacute, and chronic forms. These probably represent different stages in the evolution of the disease process and the distinction between acute and chronic presentations does help plan initial management.

Pathology

Macroscopically the calcium deposits seen in calcifying tendinitis are usually encapsulated in the substance of the tendon and have a chalky white appearance (Figure 4.6.1) or sometimes a more liquid consistency like toothpaste when incised. Histologically, the deposits are multifocal and are separated by areas of fibrocartilage that are usually avascular. The tendon surrounding the deposits is frequently abnormal, showing evidence of fibrillation and thinning. Under the electron microscope the calcium deposits appear as vesicle-like structures containing crystalline material. Chemical analysis has shown the crystals to consist of hydroxyapatite. Frequently there is a cellular reaction around the calcium deposits that may have a granulomatous appearance due to the presence of multinucleated giant cells. The deposits are often infiltrated by macrophages, polymorphs, and fibroblasts. Crystalline particles are often seen in the cytoplasmic vacuoles of the macrophages and giant cells indicating active phagocytosis of the calcified deposits. There is also frequently evidence of repair with fibroblasts and new capillary formation in the
adjacent tendon.

Fig. 4.6.1
Appearance of calcific deposit at surgery. The deltoid has been split and the subacromial bursa incised to reveal the chalky white deposit encapsulated in the supraspinatus tendon.

The pathogenesis of these findings is unclear. Codman originally proposed that calcification occurred within a degenerate cuff, and there is experimental evidence to support a link between degeneration, mechanical disruption, and subsequent calcification of the tendon in rabbits. The self-resolving nature of the disease and the epidemiology observed in humans is, however, against a mechanical cause. An attractive theory of cyclical changes within an initially macroscopically normal tendon has been advanced by Uhthoff and Sarkar. They have suggested that the site of calcification initially undergoes transformation into fibrocartilage. Calcium crystals are then deposited in matrix vesicles that eventually coalesce to form deposits that gradually replace the fibrocartilage. After a variable resting period, spontaneous resorption of calcium occurs as vascular channels grow into the deposit and macrophages start to phagocytose the material. Phagocytosis is accompanied by the laying down of granulation tissue that is eventually remodelled to form normal tendon, thereby completing the cycle. The aetiology of the initiating fibrocartilagenous transformation in this cycle remains unexplained but tissue hypoxia might provide the initiating stimulus.

Clinical presentation

The initial formation of calcium deposits rarely causes significant symptoms. However, patients may be aware of vague discomfort in the shoulder for many months before an acute attack. This mild clinical presentation is referred to as chronic calcifying tendinitis. The pain is frequently referred over the outer aspect of the upper arm, particularly over the deltoid insertion. Patients frequently exhibit tenderness over the cuff insertion at the site of the deposit and may have a decreased range of elevation due to pain. A large deposit in the supraspinatus tendon can cause symptoms of subacromial impingement and patients may exhibit a painful arc and have a positive impingement signs.

The acute phase of calcifying tendinitis is usually very painful and associated with the resorption of the deposits. The clinical picture in many ways resembles that of a septic arthritis or acute gout. Patients complain of severe night pain and rest pain, and hold the affected shoulder in adduction and internal rotation. The patient resists any attempt at moving the shoulder and any movement elicited is likely to be scapulothoracic in origin. The shoulder is generally tender and warm to touch. The source of the severe pain in this acute condition is probably from within the tendon itself since there is little evidence of acute bursal inflammation either macroscopically or histologically. At surgery the calcified material often squirts out when incised and has a more liquid consistency than in the chronic situation. The probable mechanism of acute pain is therefore increased intratendinous pressure resulting from inflammation around the resorbing deposit. A more ill-defined fluffy appearance on radiograph, indicative of resorption, has been described in the acute situation.

Investigations

Deposits are usually easily seen on radiographs in the subacute or chronic phase (Figure 4.6.2). In the acute phase the calcification may be very difficult to visualize radiographically because of its diffuse nature. Acute calcifying tendinitis can, however, usually be distinguished clinically from other causes of severe shoulder pain. Magnetic resonance imaging is unhelpful as the calcified deposit and the tendon give the same dark signal. The white cell count and sedimentation rate are normal in calcifying tendinitis and frequently elevated in infection. Serum urate may be elevated in acute gout. In cases of doubt the glenohumeral joint should be aspirated to exclude an effusion.
Plain anteroposterior radiograph of the shoulder of a 53-year-old female with symptoms of subacromial impingement showing a large calcific deposit in the supraspinatus tendon.

Management

Acute calcifying tendinitis

The main priority in acute cases is pain relief. Opiate analgesia as well as anti-inflammatory medication is usually required. A subacromial injection of long-acting local anaesthetic (e.g. bupivicaine) is usually of benefit and some authors have advocated needling or barbottage of the deposit under ultrasound control following local anaesthetic infiltration to relieve pressure within the painful tendon, accompanied by lavage of the subacromial space.

Corticosteroids have an effect on reducing vascular proliferation and macrophage activity, so they may contribute to a prolongation of the resorption process despite providing transient symptomatic relief. In a comparison between steroid injection and local anaesthetic injection alone no significant difference in outcome was observed in one study. Therefore the use of corticosteroid is not recommended.

Chronic calcifying tendinitis

Cases of chronic or subacute disease usually respond to conservative measures consisting of local therapy including heat, ultrasound, and local anaesthetic injections into the subacromial bursa. Physiotherapy is useful in maintaining the range of motion of the glenohumeral joint. In resistant cases surgery is probably the most dependable way of dealing with large symptomatic deposits. The most commonly accepted indications for surgery are constant pain that interferes with the activities of daily living, and a failure to improve after 3 months of conservative treatment.

Surgical removal of calcium deposits gives good results in most series. Gschwend reported good or excellent results in 25 of 28 cases and DePalma reported 96% good results but the time taken to recover from surgery was quite long. Only 53% had recovered by 6 weeks and a further 30% took 10 weeks. At operation the question arises whether to perform an acromioplasty. Vebostad reported on 43 cases in which one of three procedures had been carried out: arthroscopic excision of the deposit, excision of the deposit, and acromioplasty alone. There was no difference in the results between the three groups with 80% having good or excellent results.

Arthroscopy

Arthroscopic techniques are now the gold standard for excision of calcific deposits with 90% success rates in many studies. However, arthroscopic excision of the deposit is technically demanding. Visualization of the deposit may be difficult and good preoperative localization is helpful with plain films or ultrasound either preoperatively or intraoperatively. Probing the tendon with a needle at the site of the radiographic deposits may produce an exudate that can aid operative localization. The deposit is debrided with a synovial resector and debris removed with suction.

Barbottage

The needling and subsequent irrigation and aspiration of chronic and subacute calcific deposits under radiographic control has been described. This technique is most useful when there is radiographic evidence of resorption of calcium (diffuse calcification) and is less effective at breaking up the hard chalky substance of a large well-defined lesion. Overall 75% of patients treated with this method were improved at a minimum of 1-year follow-up. This technique has also been reported under ultrasonic guidance, thereby avoiding the use of radiographic screening.

Another minimally invasive approach that has recently been reported is the use of a lithotripter to provide high-energy extracorporeal shock waves to calcifications within the rotator cuff. However, the technique appears to be less effective than barbottage or arthroscopic excision; often requires multiple treatments, and patients don't like it. Time will tell whether it may provide a useful alternative to surgery in the future for patients with well-localized deposits.
Summary

Most patients with calcifying tendinitis will have minimal symptoms and can be treated conservatively. The spontaneous resolution of the condition makes the evaluation of the various popular operative and non-operative treatments difficult. Patients who present with acute symptoms in the resorbing phase of the condition will have a good result if treated symptomatically but the treatment of subacute and chronic cases is less clear. There are no prospective randomized studies comparing different treatments, and these should be a priority of future clinical research. The pathological processes involved in the evolution of calcifying tendinitis continue to be unravelled but the initiating stimulus for the fibrocartilaginous metaplasia and the stimulus for calcium resorption remain elusive.

**Summary points**

- The fundamental principle or essence of the shoulder is concavity compression. Stability of the shoulder is the condition in which a balanced centralizing joint reaction force (CJRF) exists to maintain concavity compression of the glenohumeral joint whatever the position of the limb and hand.
- Instability is a symptom. It can be defined as the condition of symptomatic abnormal motion of the joint. It refers to a perturbation of concavity compression. It is not a diagnosis.
- Instability is the result of perturbations of structural factors and non-structural factors.
- The clinical syndrome of instability is a disturbance of one or more of these factors in isolation or together. The relative importance of each factor to the syndrome can change over time. The relationship between these factors is described by the Stanmore triangle.
- Both structural and non-structural factors can be perturbed by arrested or incomplete development (dysplasia) or by injury (disruption).
- The aim of treatment is the restoration of (asymptomatic) stable motion by restoration of the CJRF and so restoration of the condition of concavity compression.
- Management follows simple principles: surgery should be undertaken within the context of a well-considered rehabilitation program largely centred around optimizing rotator cuff function.
- Failures of management are often due to failure of or incomplete diagnosis, failure of healing, inadequate attention to patient- and pathology-specific rehabilitation programs, or insufficient attention to lifestyle considerations.
- Disrupted anatomy is restored, preferably by anatomic operations with predictably good outcomes. Dysplastic anatomy is augmented, often by non-anatomic operations with less predictable outcomes. Revision stabilizations are generally nonanatomic, and have higher failure rates.

**Stability: definition**

Stability of any articulation can be defined as *asymptomatic normal mechanical behaviour at rest and in motion*. It depends on structural integrity and intact neural control systems (afferent, efferent, and neuromuscular connections). For the glenohumeral joint (GHJ) stability is therefore the product of a functionally (not necessarily anatomically) intact rotator cuff, competent capsular and labral structures, a sufficient surface arc (or surface area) of contact between humeral head and glenoid, and an intact neuromuscular system comprising central and peripheral connections. Motion about the centroid of rotation and ‘containment’ of the humeral head on the size-mismatched glenoid is the result of concavity compression. This is generated by the centralizing joint reaction force (CJRF) of the rotator cuff (including the tendon of the long head of biceps, LHB), and is facilitated by the conformity of the glenoid/labral surface. Rotator cuff competence is a function of centrally-driven activation, and the strength and inertia of the cuff muscles. Shoulder joint position sense and motion are the product of right parietal cortical programming (the parietal ‘reach region’), and visual, vestibular, and cervical afferent inputs. Mechanoreceptors in the capsulolabral structures, tendon, and muscle, and the gliding planes (acromio–coraco–deltoid, and scapulothoracic) maintain this activity.

**Instability: definition**

Instability is usefully defined as the condition of *symptomatic abnormal motion of the joint*. This universal definition combines the mechanistic view and the clinical perspective, and distinguishes the pathological state from the constitutional state of laxity, in which anatomical anomalies may exist, but which does not necessarily cause impairment of function. Since it is a symptom, the term implies recognition (a cerebral cortical event) of the abnormal motion (a difference in position, motion direction, or motion velocity has been identified). Thus ‘instability’ cannot be determined by examining the shoulder under anaesthetic (EUA). Laxity (looseness) of the GHJ can be determined by EUA either by comparison of the perceived abnormal with the perceived normal side or by reference to what is considered a normal range of laxity for the population.

**Instability: aetiology**

The relationship between the dominant factors in creating stability in the GHJ can be described by an equation (see Box 4.7.1).

**Box 4.7.1 The stability equation**

\[
\text{Stability (CJRF)} = \text{RO}^0 + \text{SAC}^0 + \text{CLPM} + \text{NS}^0
\]

where: a–d = proportional values of the factors; these vary from case to case; CJRF = centralizing joint reaction force; CLPM = capsulolabral proprioceptive mechanism; NS = neurological control mechanisms; RO = rotator cuff anatomy and function; SAC
Each factor varies in relevance to the individual patient, but several points are applicable:

- Everyone starts life with a rotator cuff, the anatomy of which varies very little (although subscapularis can vary in the 'height' of its attachment to the lesser tuberosity). The GHJ will remain stable in the partial absence of medial capsulolabral structures (for instance, after surgical release for frozen shoulder syndrome) providing the rotator cuff function is normal. The tendon of the LHB has a special role in linking rotator cuff activity, humeral head position, and overall upper limb position, particularly in activities requiring optimal close-packing of the shoulder and elbow. Many anomalies of the intra-articular tendon are described, and isolated rupture of the tendon does not lead to humeral head instability, provided the closely associated components of the rotator cuff remain intact. In contrast, senile rotator cuff rupture presents as superior GHJ instability.

- The surface arc of contact or surface area of contact (SAC) can vary. The commonest reason for this is a bony Bankart lesion. Rarer causes are segmental dysplasia of the glenoid, congenital glenoid version anomalies, and humeral head defects (Broca or Hill–Sachs, and McLaughlin lesions).

- The capsulo-labral proprioceptive mechanism (CLPM) can vary considerably. The labrum can be absent, hypoplastic, or dysplastic, and ligament anomalies are well recognized in subjects with no instability. The incidence of ligamentous anomalies in patients with atraumatic structural instability is the same as the general population. Lax individuals do not appear to have a greater prevalence of anomalies of ligament morphology. However, they may have a greater joint volume, a more capacious joint, and more elastic ligaments than normal.

- Neural control systems are readily deranged by central or peripheral neurological conditions. It is recognized that aberrant muscle activation or suppression contributes to GHJ instability, and diseases of the cerebellum and basal ganglia may present with shoulder instability, particularly of the scapulothoracic joint. It is not known if there are variations in the densities or function of mechanoreceptors in the capsule and labrum in patients with atraumatic structural and muscle-patterning instability (see later in this chapter).

The clinical syndrome of instability is a disturbance of one or more of these factors in isolation or together, and the relative importance of each factor to the syndrome can change over time. The pathologies causing instability comprise structural (RC, SAC, CLPM) and non-structural (NS) elements (Box 4.7.2 and Figure 4.7.1). The structural elements may be damaged by extrinsic force (traumatic structural); acquire microtraumatic lesions over time (atraumatic structural); or be congenitally abnormal, or comprised of abnormal collagen. The non-structural elements can be congenitally abnormal or can be acquired over time as perturbations of neuromuscular control, particularly at periods of skeletal growth.

Box 4.7.2 Structural and non-structural causes of GHJ instability are based on perturbation of the elements of the stability equation

Stability (CJR) = RC + SAC + CLPM + NS
structuralnon-structural

Note that the CLPM can be disturbed structurally (discontinuity or dysplasia), and non-structurally (deafferentation).

Fig. 4.7.1
The aetiology of GHJ instability. ATS, atraumatic structural factor(s); CNS, central nervous system; MP, muscle patterning (neuromuscular; PNS, peripheral nervous system; TS, traumatic structural factor(s)). Notes: 1) For any individual the diagnosis of GHJ instability may include one or more cause(s). For instance a hyperlax (dysplastic) individual who has had recurrent painful non-traumatic GHJ dislocations and who sustains a dislocation of the GHJ by the acute application of extrinsic force leading to disruption of the CLPM will have acquired a traumatic structural instability on a background of atraumatic instability; two pathologies are present in the one shoulder. 2) The eventual ‘equation’ of the diagnosis of instability for an individual can be defined as:

Instability = (TS) + (ATS) + (MP)

where a, b, c are proportionality factors: not all individuals will have all elements present at presentation. However, pathology can change over time, and the importance of each factor in the instability diagnosis may change (see Figure 4.7.2). Thus treatment...
strategies may need to change.

### Classification: the Stanmore (instability) triangle

The combined concepts that structural (traumatic and atraumatic) and neurological system disturbances can cause instability, the observation that more than one pathology can be present in the shoulder at the time of diagnosis, and that pathology can change over time led Bayley to the classification of instability as a continuum of pathologies, which can be graphically displayed as a triangle (Figure 4.7.2). The polar pathologies are labelled types I (traumatic instability), type II (atraumatic instability), and type III (neurological dysfunctional or muscle patterning). Polar groups I and II and the axis I–II representing the spectrum between the two poles correspond to the TUBS-AMBRI classification which also allows for a spectrum of structural shoulder pathology but which does not admit those shoulders in which there is no structural (traumatic or atraumatic) cause for the instability. The characteristics for each polar group are given in Box 4.7.3. Jaggi has further subdivided polar group III into peripheral, central, positional, protective, and combination subtypes (personal communication). The interpolar spectrum describes dual pathologies in which traumatic, atraumatic and muscle-patterning factors play a variable role in the emergence of instability.

---

**Box 4.7.3 Characteristics of the polar groups of the Stanmore classification**

- **Group I—Traumatic structural:**
  - Significant injury
  - Often a Bankart lesion
  - Usually unilateral
  - No abnormal muscle patterning
The clinical syndromes of glenohumeral joint instability

Group I (traumatic structural instability)

The traumatic structural group includes the TUBS (Traumatic, Unilateral, Bankart lesion present [in the anterior instability type], Surgery usually indicated) group but also includes the posterior traumatic instability characterized by the McLaughlin or Reversed Hill–Sachs lesion and posterior labral damage or locked posterior dislocation. Instability can thus be recurrent (acute or chronic) or persistent (acute or chronic). Luxatio erecta is a version of anterior instability, usually of the more elderly, and may be associated with infracavicularplexopathy, and extensive bruising indicative of rupture of the circumflex vessels. In general shoulder clinics, acute recurrent anterior GHJ instability is the commonest form of instability. Assessment is based on the history of the initiating event, the examination is discussed in Chapter 4.1 and investigation is best undertaken by magnetic resonance arthrography (MRA) or EUA and arthroscopy.

Treatment comprises, in principle, surgical intervention for most cases in which capsulolabral or rotator cuff disruption is evident. There remains controversy regarding the choice of open versus arthroscopic surgical techniques.

Group II (atraumatic structural instability)

In this group the incidence of ligamentous anomalies is the same as the population of traumatic instabilities. Within this group is the population defined as AMBRI (Atraumatic, often Multidirectional, often Bilateral, treated by Rehabilitation/physiotherapy)—in the original definition of AMBRI, surgical treatment by Inferior capsular shift is indicated if rehabilitation fails. This concept may be flawed: some patients will fall into the category of subgroup II/III and so will possess some neuromuscular control aberration. These patients may fail surgery because of the muscle-patterning behaviour, and may have a substantially greater probability of developing instability or postcapsulorrhaphy arthropathy if surgery is undertaken. The decision to operate should not be made on the basis of failed physiotherapy.

This group also contains a subgroup of individuals with benign hypermobility syndrome (of which Ehlers–Danlos syndrome is a variant), characterized by a Beighton score of greater than five out of a total possible nine points. Hypermobility may be limited to the upper limbs. These patients may present with pain rather than overtly abnormal displacements.

Anterior atraumatic instability is less common than posterior types. Posterior structural anomalies (including posterior glenoid dysplasia, excessive glenoid retroversion, glenoid hypoplasia, and medialized posterior capsular attachment) create the environment in which obligatory positional posterior displacement may occur during elevation of the arm in the sagittal plane. If abnormal clinically obvious muscle activation appears at the onset of this motion, then the diagnosis is modified to acknowledge the muscle patterning: the case is group II/III (peripheral subtype). If the muscular activation occurs during the motion, and appears to be provoked by the position of the arm at the shoulder, then the diagnosis is still II/III but with the suffix (protective subtype). If there is no clinically or electrophysiologically-proven aberrant muscle activation then the condition is labelled II (positional subtype).

Scapular dyskinesis is common, and reflects the attempt by the scapular postural muscles to maintain scapulohumeral homeostasis. Serratus anterior can be suppressed in some cases: the aberrant muscle activity now affects the scapular primarily. This represents a scapulothoracic (STh) type III condition. The total diagnosis is therefore STh(III)/GHJ(II).

Assessment of the structural diagnosis is by MRA and/or diagnostic arthroscopy. These are complementary, not alternatives; MRA is useful to look for capsular detachments, bony defects, and the bulk and quality of rotator cuff muscles (particularly subscapularis, for the anterior, and infraspinatus, for the posterior types), while arthroscopy is useful to look for the subtleties of internal lesions of occult instability: bicipital and deep surface cuff lesions, soft tissue Broca defects, internal impingement lesions, and external impingement lesions.

Treatment comprises rehabilitation, avoidance of activities promoting the instability, pain management, and surgical intervention in selected cases. The variants of mediolateral or laterally-based inferior capsular shift with augmentation of dysplastic labral tissue are complemented in some cases of glenoid insufficiency by glenoid augmentation using autologous bone blocks (anteriorly and/or posteriorly), or glenoplasty (the Scott posterior glenoplasty).
Muscle-patterning instability (MPI) comprises aberrant activation of large muscles identified by dynamic electromyography (latissimus dorsi, pectoralis major, and anterior deltoid have been characterized thus far) and simultaneous suppression of the rotator cuff (infraspinatus has been characterized thus far: whether suppression of infraspinatus reflects whole rotator cuff suppression or specific suppression of the infraspinatus is not yet clear). MPI can be clinically obvious, in polar group III, but may be occult, requiring dynamic electromyography (DEMG) for confirmation of the suspicion of the existence of MPI in the presentation (as in types II/III and III/II instabilities).

Demographic characteristics

Patients with abnormal muscular activation leading to ‘pure’ MPI appear to present in a trimodal distribution with peaks at 6, 14, and 20 years. The mean age at onset of symptoms was 14 years and the mean duration of symptoms before presentation was 8 years. In the under 10 years age group there were more females (71% vs 47%), greater laxity (estimated with the Beighton score, 63% vs 29%), and bilaterality (54% vs 42%), with fewer presenting with pain (17% vs 50%). As age increased laxity decreased and pain increased. Bilaterality did not appear to be associated with gender, laxity, or pain. Laxity was associated with gender but not pain or bilaterality. These observations suggest different aetiologies for the MPI in the three cohorts.

Bayley (2005) used DEMG in latissimus dorsi (LD), pectoralis major (PM), anterior deltoid (AD), and infraspinatus (IS) to evaluate the patterns of muscular activation in patients who clearly demonstrated, visibly or by palpation, apparently abnormal muscular activation immediately before and during dislocation of the GHJ in the outpatient clinic. These muscles were chosen because they were reliably accessible. Early pilot studies were expanded into a cohort study of over 1000 cases of glenohumeral instability (GHI) seen at the Royal National Orthopaedic Hospital, a tertiary referral centre, over a 22-year period (1981–2003), from which DEMG data were extracted. The results are summarized in Box 4.7.4.

Box 4.7.4 Characteristics of patients displaying aberrant muscle-patterning GHJ instability (MPI)

1) 52% of the entire cohort of patients with GHI had abnormal muscle activation (muscle-patterning, MP) during a standard set of movements
2) 47% of unidirectional GHI had MPI
3) 27.6% of anterior GHI had MPI, involving PM, or PM + LD coupled
4) 84.8% of posterior GHI had MPI, involving LD, or AD + suppressed IS coupled
5) 83.8% of multidirectional GHI had MPI, involving LD > PM > AD
6) 100% of inferior GHI had MPI, involving PM + LD coupled
7) One or two muscles were implicated in 88% of unidirectional and 92% of multidirectional MPI
8) Clinical impression of MPI instability was incorrect in 12% of cases
9) Clinical impression was correct but the wrong muscles were identified in 33%
10) Further abnormal muscles were identified by DEMG in 32.9% of cases.

MPI was diagnosed, clinically and/or electrophysiologically, in 494 shoulders (45% of the entire cohort of 1097 shoulders) of 386 patients. In 44% the MPI affected both shoulders. The dominant arm was affected more often in right-handed patients, the non-dominant more often in left-handed patients. The central neurological basis for these differences remains obscure. There were 323 shoulders with ‘pure’ MPI; 161 shoulders presented a mixed picture of MPI in addition to either traumatic or atraumatic structural causes for the instability.

The value of recognizing this form of instability is given by the success of specialist physiotherapy using biofeedback techniques versus conventional therapy for retraining abnormal muscle activity: 76% of patients had either no change or a deterioration of their condition with conventional therapy (including conventional strengthening exercises) compared with 61% of patients overall achieving improvement in their condition with specialist therapy. The incidence of iatropathic arthropathy increases with inappropriate surgery in those with type III instability while no type III in which surgery was not performed developed arthritis.

Dynamic electromyography

Given the limitation that only four muscles have been studied in depth, the evidence strongly suggests that these, and perhaps other muscles, are implicated in many cases of instability. Inappropriate activity in PM, LD, and AD, with suppression of IS appear either singly or as couples in the generation of instability in shoulder with and without capsular collagen insufficiency. Whether suppression of IS reflects specific inappropriate inactivity in IS alone or reflects abnormal activation of the rotator cuff as a whole remains unknown.

DEMG provides additional information about abnormal muscle activation or suppression in subtle MPI in which clinical examination has a low specificity and sensitivity. DEMG was found to be most useful in patients presenting with pain, glenohumeral capsular insufficiency, and occult muscle patterning, categorized as the interpolar group II/III. Given that a chance of a successful outcome for rehabilitation of patients with MPI (symptoms abolished or controlled) was diminished fivefold for anterior and tenfold for posterior instability after inappropriate surgery in patients with MPI, it is clear that the identification of this specific cohort is important. These patients contribute to the failures of the AMBRI group after rehabilitation (if MPI has not been recognized). It is noteworthy that the pathology is not defined by direction but rather that the direction of instability is determined by the pathology.

In MPI rehabilitation is used as the first mode of treatment: there is usually a change in aberrant muscle activity within 6 months. Therapy has to go on for at least 2 years, possibly for cortical re-imprinting to be re-established. There is a 25% recurrence rate
within 2 years, needing 'top-up' therapy, including inpatient treatment in which a multidisciplinary approach is favoured. The value of specific suppression of specific muscles by injection of botulinum toxin is unclear in MPI.

Multidirectional instability

Multidirectional instability (MDI) is not a diagnosis but a symptom. Multidirectional laxity is assessed by EUA. It may be difficult to determine when a lax shoulder is centralized during EUA. Fluoroscopy is invaluable in such cases. An individual shoulder may have the same pathology (i.e. group I, II, or III pathology) causing instability in each of more than one direction, or more than one pathology (e.g. group I in one direction, and group II/III in the other direction), thus distinguishing 'simple' MDI from 'complex' MDI. The underlying diagnoses of the different directions of instability are distinguishable by the history, clinical observations, arthroscopy, and/or MRA (Figure 4.7.3) supplemented by DEMG where necessary. Each pathology is treated separately, with rehabilitation of MPI elements taking priority.

![Diagram of Multidirectional Instability](Click to view larger)

Fig. 4.7.3
Characteristics of multidirectional instability for a simple diagnosis (one type of pathology accounts for all directions of instability) or complex diagnoses (more than one type of instability pathology account for the several directions of instability). ‘Single diagnosis’ means that the pathology creating the instability in both or all directions is the same. ‘Multiple diagnosis’ means that the pathology of each direction of instability is different. It follows that the treatment of a case in the multiple-diagnosis MDI set is different for each direction: an inferior capsular shift might be the appropriate intervention for the II component, but the III (muscle-patterning) component should also be considered, and almost universally should be treated first. Many patients experience satisfactory return of sufficient stability with successful treatment of the III component (which is easier in the un-operated shoulder) and choose not to proceed to capsular surgery. The numbers refer to numbers of shoulders studied.

Management of glenohumeral instability

Having diagnosed the specific pathology (-ies), treatment is directed at each element in the instability syndrome. The pathology of instability can be expressed as a useful equation acting as a checklist to define the management strategy (Box 4.7.5). The aim of treatment is the restoration of (asymptomatic) stable motion by restoration of the CUTF, optimization of the angular range of stability, and so restoration of concavity compression. Management follows simple principles (Figure 4.7.4): surgery should be undertaken within the context of a well-considered rehabilitation programme largely centred around optimizing rotator cuff function. In general, disrupted anatomy is restored, preferably by anatomic operations with predictably good outcomes. Dysplastic anatomy is augmented, often by non-anatomic operations with less predictable outcomes. Revision stabilizations are generally non-anatomic, and have higher failure rates.

Box 4.7.5 The instability pathology equation

\[
\text{Instability} = (\text{traumatic structural})^n + (\text{atraumatic structural})^n + (\text{neurological})^n \times P \times t
\]

or

\[
\text{Instability} = (I)^n + (II)^n + (III)^n \times P \times t
\]

where: \(n = \) proportionality coefficient (different for each patient); \(P = \) ‘patient factors’, e.g. epilepsy, athetosis, other dystonias; \(t = \) time.
Fig. 4.7.4

Management strategies.

Notes:
1) Treatment includes interventions to restore anatomy to the near-normal state ('anatomical') and those which enlarge or augment surface area of contact, or reduce joint capacity ('non-anatomical').
2) The rationale for the restoration (of humeral head surface contour) or augmentation (of glenoid surface area) of the angular range of stability is described by the following equation:

\[
\text{Angular range of stability} = \frac{\text{glenoid arc length}}{\text{radius of humeral head}} \times \frac{360}{2\pi}
\]

3) The risk of complications including failure to achieve stability increases for non-anatomical interventions. 4) Revision of non-anatomical operations for failure has a high rate of complications. 5) Rehabilitation takes priority: optimization of rotator cuff function frequently restores sufficient stability even in an anatomically-deranged joint.

The surgical treatment of structural dislocation depends upon the pathology detected on plain radiographs, MRA, and arthroscopy. Of the structural elements the capsulolabral pathology (CLPM) is the most common. Structural SAC lesions are becoming more frequent due to the increasing professionalism of contact sports leading to bone damage to the glenoid. Finally rotator cuff (RC) structural damage is common in dislocation in middle and old age, and is more commonly recognized these days.

The labrum is often torn during traumatic dislocation. This can be the classic Bankart lesion, where the labrum tears from the bone along the anteroinferior quarter of the glenoid. A variety of Bankart variants have been described such as the ALPSA (anterior labrum periosteal sleeve avulsion) lesion and the Perthes lesion. The Bankart tear may extend into a SLAP lesion, or extend around the inferior glenoid, or even involve the entire circumference of the socket. These lesions will need to be released (as they often heal in an abnormal position), reduced to their proper position on the glenoid rim and re-attached using suture anchors to a freshened bed so that they can heal strongly in an effective position. Labral repairs for patients at the Polar I position can be done either arthroscopically or by classic open surgery through a deltopectoral approach.

The glenohumeral ligaments may stretch or tear, or avulse from the humeral surface as a HAGL (humeral avulsion of the glenohumeral ligaments) lesion. The ligaments may be thin, stretched, or elastic if the patient lies on the I/II line, as the majority do. If the ligaments are loose and baggy then they will need to be repaired at the time of surgery. The capsule is often globally loose and may need to be tightened South to North and often East to West as well. At open surgery this is easy to do. The capsule is opened using a vertical capsulotomy and three sutures are placed to close the rotator interval. This will usually effect the necessary inferior capsular shift. As the capsulotomy is closed it can be overlapped East to West making sure that it is not overtightened. If more of a shift is required then a Neer T-shaped capsulotomy is performed. The rotator interval is closed and then a South to North double-breasting is performed to create a full and proper Neer inferior capsular shift. The vertical capsulotomy is then closed with as much double breasting East to West as required.

This is where things get difficult at arthroscopic surgery. All capsular shifts depend upon closing the rotator interval. If the interval is not securely closed then any South to North plication will merely open the rotator interval more, negating the effect of the capsular shift. Arthroscopic rotator interval closure can be performed, but is not easy, because the anterior working cannulae themselves take up most of the interval. To place more than one suture in the interval is more difficult still. To place three sutures in the interval arthroscopically is just showing off, very few surgeons have the requisite skill to do this. Double breasting is just not possible arthroscopically. This means that the further down the Polar I/II line towards the Polar II end becomes more and more difficult to perform arthroscopically.

If there is bone loss to the anteroinferior glenoid then this bone loss will need to be made good. This can not be done using a ligamentous repair and will need bone to be transferred to make up the SAC loss. The normal way to do this is a Bristow-Latarjet transfer of the coracid process. This operation is performed using a deltopectoral approach. The musculocutaneous nerve must be exposed and protected throughout the procedure. The bone surfaces of the coracid and the glenoid neck must be decorticated so that the coracid will unite to the scapula. The coracid is attached with one or two AO lag screws.

If the defect is larger than usual, too large for a coracid transfer, then a tri-cortical bone block may be needed from the pelvic rim to make up the SAC defect.

In the middle aged to elderly patient the dislocation may be complicated by tearing of the rotator cuff itself. In these patients recurrent dislocation is not the long-term problem, it is the cuff tear itself, and this will need to be repaired.

Summary points

- The design of the surface replacement arthroplasty has evolved over the past 20 years. From cemented prostheses such as the SCAN, to cementless prostheses such as the Copeland, the basic concept and design of the surface replacement favouring maximal bone preservation has remained constant.
- Indications and surgical technique have been refined over this period, the latest modification being the use of computer-assisted navigation to optimise the size and position the implant in situ.
- Surface replacement prosthesis has demonstrated clinical results at least equal to those of conventional stemmed prostheses.

Introduction

The only part of any prosthesis that is of use to the patient is the new, shiny joint surface. The patient is unaware of whether this surface is fixed by a stem or cement or whether it is a pure surface replacement.

Development of the Copeland surface replacement arthroplasty (CSRA) for arthritis began in 1979, with the first clinical use of the prosthesis occurring 7 years later, in 1986. In 1993, hydroxyapatite coating was introduced to allow biologic fixation with bony ingrowth. Simple instruments were designed to allow anatomic placement of the humeral head based on identifying the centre of the sphere. Once this point has been identified, the prosthesis can be positioned to replicate the original anatomic bearing surface, including version, offset, and angulation.

The basic concept and design of surface replacement was to remove as little of the bone stock as possible and not to breach the humeral shaft. Initial fixation was by a cementless press fit single peg of taper fluted design using a hydroxyapatite coating for osseointegration (Figure 4.8.1). The head was made of cobalt-chrome, and the glenoid component of ultra-high-molecular-weight polyethylene (UHMWP). The radius of curvature of the head and glenoid were designed to conform with each other. Eight head sizes replicate the original anatomic bearing surface, including version, offset, and angulation. The surface replacement prosthesis has demonstrated clinical results at least equal to those of conventional stemmed prostheses.

History

Zippel in Germany implanted two surface replacements that were fixed by a transosseous screw but no follow-up is recorded for these cases. Steffee and Moore in the United States were implanting a small hip-resurfacing prosthesis into the shoulder and, in Sweden, in greater numbers, a surface replacement SCAN (Scandinavian) cup was being used as a cemented surface replacement. It was based on the same surface replacement philosophy that the CRSA was designed on.

Potential disadvantages of the glenoid and stemmed prosthesis
The most frequent shoulder arthroplasty performed is a stemmed cemented total shoulder replacement. However, there are certain disadvantages to this type of design. The most common component to fail is the glenoid component with a reported incidence of radiolucent lines on radiographs as high as 30% and a significant rate of late loosening of the glenoid component over time. Glenoid failure may be associated with significant bone loss and cause major problems when revision surgery is undertaken, sometimes making the revision ‘impossible’.

Similar problems can occur with stemmed humeral components, albeit less frequently. The bone loss, however, can be very marked, and revision from a stemmed humeral implant can be extremely difficult, often requiring splitting the humerus to remove the stem and cement. This may result in perforation of the shaft and fractures. Fractures may also occur at the stem tip due to stress risers in the area (Figure 4.8.2), and are difficult to treat, especially in this elderly and infirm group of patients. In cementless stems, reaming of the bone can result in a fracture.

Deformities in the humeral shaft can occur with previous fractures and may pose a challenge getting a stemmed prosthesis past the deformed area. Similarly, it is not possible to use a stemmed implant in the presence of other metalware such as a nail or screw in the medullary cavity of the humerus. Although screws and nails can be removed, the stem of an elbow replacement coming up the shaft may preclude a stemmed shoulder replacement altogether.

An additional problem with stemmed fixation is that of ‘pilot error’. It has been shown that approximately 30% of the unsatisfactory results after shoulder replacements are due to component malposition and that, if version is incorrect by more than 15 degrees, this can lead to a painful shoulder. Incorrect placement can and does occur, and removal and repositioning of a stem is a major reconstruction problem. One always has to bear in mind what would happen if the joint should fail and thus plan a backup or revision procedure.

There is no evidence to indicate why the humeral stem should extend half the length of the humerus, sometimes with the cement tracking down to the elbow. On the other hand, one needs only to resurface the damaged surface of the humeral head to achieve comparable results and function to the stemmed prosthesis.

Potential advantages of the surface replacement (Box 4.8.1)

- The head is anatomically seated, restoring anatomical variations of version, offset, and angulation in each individual patient
- There is no requirement for intramedullary canal reaming or cementation, making it a less traumatic and safer procedure in an elderly patient given the lowered risk of fat embolus or hypotension
- There are no complications associated with an intramedullary canal previously filled with cement, fracture fixation devices, or a stem from elbow arthroplasty. If there is a malunion at the proximal end of the humerus with secondary osteoarthritis, the malunion can be left undisturbed, the tuberosities intact, and just the humeral articulation resurfaced
- Unlike stemmed prostheses, there is no stress riser effect that could result in a shaft fracture at the tip of the prosthesis
- Resurfacing can be used in congenital abnormalities of the humerus that do not permit the passage of standard intramedullary stemmed prostheses
- Revision surgery to a stemmed prosthesis or arthrodesis can be performed easily as there is no loss of bone stock and no cement to retrieve from within the humeral shaft.

Indications and contraindications

The commonest indication for surface replacement is arthritis, either degenerative or inflammatory. Other indications are mild avascular necrosis, instability arthropathy, post-trauma arthritis, post-infective arthritis, and arthritis secondary to glenoid dysplasia.
or epiphysis dysplasia. This prosthesis could be considered for Seebauer type I cuff tear arthropathy.

### Box 4.8.1 Advantages of surface replacement

- No stem constraints
- Allows simple accurate anatomical resurfacing
- Offset is correct
- Less invasive surgery
- No canal reaming
- No stress riser at end of stem
- Easier revision
- Bone stock conserving.

The best results are achieved in cases of osteoarthritis where the rotator cuff is intact. Conversely, suboptimal results are seen in individuals with cuff tear arthropathy and also in instances of post-traumatic arthritis. The surface replacement arthroplasty can be used in circumstances of moderate erosion of the humeral head, by bone grafting the defect. If there is more than 60% contact between the undersurface of the trial prosthesis and humeral head, after it has been milled, then it would be suitable for surface replacement. In other words, up to 40% of the humeral head surface area may be replaced by bone graft.

The contraindications for surface replacement arthroplasty include active infection, bone loss of the humeral head exceeding 40% of the surface, and acute fractures. Cases with an irreparable cuff tear would be suitable for the extended articular surface (EAS) replacement or a reverse shoulder arthroplasty.

Approximately 92% of our cases requiring shoulder arthroplasty receive a surface replacement. It is our opinion that surface replacement should be the standard prosthesis of choice for all cases, unless specifically contraindicated. The question now is not when to use a surface replacement, but what are the limited residual indications for a stemmed implant?

### Hemiarthroplasty versus total shoulder arthroplasty using the surface replacement prosthesis

When deciding to do a hemiarthroplasty or a total arthroplasty, one must balance the possibility of longer-term glenoid wear and loosening in a total replacement with the possibility of late glenoid erosion in a hemiarthroplasty, necessitating conversion to a total replacement.

Our surface replacements had a 1% revision rate over 4 years. A survivorship analysis of the two groups in our series showed 97.1% survival of the hemireplacements and 81.7% survival of the total replacements. (Log rank test \( p = 0.0028 \)). The total shoulders functioned slightly better, but revision rates were higher in the total shoulder group (18.3%) as compared to the hemiarthroplasty group (2.1%) (\( p < 0.0001 \)) (Figure 4.8.3).

We perform and recommend hemiarthroplasty now as a general rule, with the glenoid being replaced only infrequently, in view of the long-term results in our series.

### Surgical pearls (Box 4.8.2)

The detailed surgical technique is outside the scope of this chapter, but the reader is referred to its detailed description in the article by Copeland and colleagues for further information.

### Results of surface replacement from other groups
Good clinical early results have been obtained with cups developed by Steffee and Moore (1984), and by Jönsson et al. (1986). Zippel in Germany implanted two surface replacements that were fixed by a transosseous screw but no follow-up is recorded for these cases. Rydholm and Sjögen from Sweden reported the results of the “SCAN cup” in 1993 and 2003. Rydholm performed 84 SCAN cups, a hemispherical cemented cup, in 70 patients, and 72 cups in 59 patients were followed for 4.2 years (range, 1.5–9.9 years). The clinical results obtained showed 94% of the patients being pleased regarding pain relief and 82% reporting improved shoulder mobility. Shoulder function was significantly improved. Radiographs were analysed regarding the position of the cup, proximal migration of the humerus, and glenoid attrition during the follow-up period. Any change of the distance between the superior margin of the cup and the greater tuberosity and/or change of inclination of the prosthesis were regarded as signs of prosthetic loosening. With that definition, 25% of the cups were found to be loose at follow-up. Prosthetic loosening, however, had no bearing on the clinical result. Progressive proximal migration of the humerus in 38% of the shoulders and central attrition of the glenoid in 22% of the shoulders did not show any relationship to gain of mobility, pain relief, or functional ability. Of note, no central fixation peg was used for this cup. Long-term follow-up at 13 years included 54 cups in 46 patients (13 patients deceased, no revisions). Six cups had been revised 10 years (range, 5–16 years) after the index operation (four for persistent pain, one for stiffness, and one for prosthetic loosening). Pain at rest on a 100-mm visual analogue scale was 15mm (range, 0–62mm) and pain on motion was 32mm (range, 0–88mm). Twenty-six (50%) could comb their hair (compared with 56% at first follow-up), 32 (62%) could wash their opposite axilla (90% at first follow-up), and 31 (60%) could reach behind (77% at first follow-up).

Fink prospectively evaluated 45 Durom cups in 39 patients (30 women, 9 men) with rheumatoid disease. The average follow-up was 45.1 ± 11.6 months with a minimum of 36 months. Fifteen shoulders had an intact cuff (group A), 18 had a partial tearing or a repaired rotator cuff (group B), and 12 shoulders a massive cuff tear (group C). In group A rheumatic shoulders, the Constant score increased from 21.5 ± 9.6 points preoperatively to 66.1 ± 9.8 points at 36 months postoperatively; in shoulders of group B, from 19.6 ± 9.7 points preoperatively to 64.9 ± 9.6 points at 36 months postoperatively; and in shoulders of group C, from 17.5 ± 8.7 points to 56.9 ± 9.8 points at the latest follow-up examination. All shoulders were pain-free at the latest examination. No complications, component loosening or changes of cup position were observed.

Alund et al. reported on 40 shoulder surface replacements for rheumatoid disease using the SCAN prosthesis. They reported one revision to total shoulder replacement, and 39 shoulders were followed up for a mean of 4.4 years (0.9–6.5 years). The median Constant score was 30 (15–79), mean proximal migration of the humerus 5.5mm (standard deviation [SD] 5.2mm) and mean glenoid erosion 2.6mm (SD 1.7mm). Proximal migration and glenoid erosion did not correlate with shoulder function or pain. Radiographic signs of loosening (changes in cup inclination combined with changes in cup distance above the greater tuberosity) occurred in one-quarter of the shoulders. At follow-up, 26 patients were satisfied with the procedure, despite poor shoulder function and radiographic deterioration.

The Copeland Mark III prosthesis results

From 1993, the entire non-articular surface (implant–bone interface) of the glenoid and humeral components has been hydroxyapatite coated. The initial mechanical press-fit is thus followed later by a biological fix with bony ingrowth due to the hydroxyapatite coating. This is the current Mark III design. Between September 1993 and August 2002, 209 shoulders underwent surface replacement arthroplasty at our unit using the Mark III prosthesis with hydroxyapatite coating. Clinical and radiological outcome was assessed at an average duration of follow-up of 4.4 years. No evidence of radiolucrency was seen in any humeral implant. Thomas et al. reported a 6.3% incidence of lucencies in their series using the Mark III implant. Asymptomatic non-progressive lucency of less than 2mm was seen in seven of the 29 glenoid components inserted, which did not require further treatment.

Six shoulders (2.8%) required revision surgery (one malposition of glenoid, two instability, and three painful arthroplasties). Using the Kaplan–Meier analysis, the probability that the implant would survive to the start of the tenth year after surgery was estimated to be 96.4%. The results of Mark III CSRA are comparable to conventional stemmed prostheses. There was no difference between hemiarthroplasty and total shoulder arthroplasty in terms of functional outcome. No hemiarthroplasty has been revised for

Box 4.8.2 Surgical pearls

- Confirm that patient position allows arm to extend and adduct adequately on table
- Have a low threshold for an acromioplasty and acromioclavicular joint excision
- Expose the junction of the head and anatomic neck adequately, a crucial step requiring removal of all osteophytes on the humerus
- Accurately identify the centre of the humeral head before proceeding
- If in doubt about the size, downsize
- Preserve as much of the bone reamings in the patient’s blood as possible to augment any bone loss in the humeral head; up to 40% bone loss can be reconstituted during a surface replacement
- Remember to perform soft tissue release/balancing as necessary
- Drill the glenoid surface to stimulate bleeding and fibrocartilage regeneration
- Reconstruct soft tissues carefully, including repair of the deltoïd during closure
- Do not be too aggressive with the acromioplasty and acromioclavicular joint excision in cases with poor or irreparable rotator cuff; consider using the deltopectoral approach in these cases
- Do not use the prosthesis in cases of fracture or if bone loss from the head is greater than 40%
component loosening.

Table 4.8.1 summarizes the results of surface replacement prostheses published thus far.

HA, hydroxyapatite; VAS, visual analogue score.

Revision surgery is greatly simplified having originally implanted a cementless surface replacement. At the time of revision of a surface replacement arthroplasty, the only bone lost is the bone that would have been removed had a stemmed prosthesis been used at the first operation. There is no need to remove a cemented stemmed prosthesis, which can be associated with loss of bone stock, perforation, and fracture of the humeral shaft. The preservation of bone facilitates revision to a stemmed prosthesis or to glenohumeral arthrodesis.

**Conclusions**

Surface replacement of the shoulder has been proven to be at least as successful as stemmed implants in the treatment of shoulder arthritis. The hydroxyapatite coating has been a major advance in reducing lucent lines and loosening. The bone-preserving nature of the implant allows it to be used in most situations, including cases of deformity. If complications do occur, then they can be more easily treated, and the results of surface hemiarthroplasty appear to be comparable with stemmed hemiarthroplasty. The geometry and mechanics of the shoulder joint are now much better understood. It is no longer justifiable to continue with intramedullary (either cementless or cemented) fixation in a straightforward arthritic problem.

**Future considerations**

Future prostheses for the shoulder are likely to be of the bone-preserving nature. As materials improve, prosthesis wear will hopefully become less of a problem. Modern technology allows for more accurate preoperative planning. Computer assistance during surgery could translate this planning to a practical solution to optimize implant position and soft tissue balancing, which ultimately with improved materials should increase longevity of the prosthesis and improve function after shoulder arthroplasty. The next challenge facing us will probably be that of regenerating the surface.
**Further reading**

Summary points

- Stemmed shoulder replacement remains the gold standard for shoulder with an intact rotator cuff.
- The scarred capsule must be released before the implant is introduced.
- This chapter discusses the merits of total shoulder replacement versus hemiarthroplasty and the management of complications.

History

Gluck of Berlin was probably the first surgeon to implant a humeral head made from ivory. However, most people recount the story of Emile Pean and how he replaced the destroyed shoulder of a young Parisian in 1893. The implant was made of platinum and vulcanized rubber. The implant had no hope of survival in the face of active tuberculosis and was removed 2 years later, the patient surviving both operations.

Credit must be given to Charles Neer for giving us the first successful shoulder replacement. The Neer prosthesis was designed for the management of complex fractures and first used in 1955. Later Neer extended its use to rheumatoid and osteoarthritis of the shoulder. A high-density polyethylene glenoid component was soon added to the metal humeral implant. The original Neer prosthesis was so well designed that for three decades it remained the gold standard.

During the 1980s surgeons were realising that a greater range of implants was needed to replicate the patient’s own anatomy. In particular, the diameter of the humeral head (at 48mm or 50mm according to manufacturer) was noted to overstuff the shoulder of small women whose native head size was 38–43mm. Thus the mono-block Neer implant was replaced by a number of modular implants. Specifically the stem and head of the humeral components were interchangeable, allowing a better fit to the patient’s normal anatomy. However, the large head diameter was kept, the neck length being reduced, and this failed to solve the problem.

A decade later careful anatomical studies by Iannotti and co-workers in the United States, Roberts and Wallace in the United Kingdom, and Boileau and Walch in France led to the understanding of variable anatomy. In particular it was noted that the head diameter varied from 38–50mm, that the version of the shoulder was peculiar to the individual (and not a constant 30 degrees), but most importantly that the centre of the humeral head was not directly in line with the centre of the humeral shaft, giving us the concept of posterior and medial offset (Figure 4.9.1). A third generation of prostheses now came on the market with variable head diameters and the ability to offset the head on the prosthetic shaft, thereby replicating the patient’s own anatomy more accurately. The price paid for this accuracy was increased complexity of the prosthesis (Figure 4.9.2).
There is no doubt that the philosophy of surgeons undertaking total shoulder replacement has changed over the years. Surgeons now understand that shoulder replacement is a soft tissue procedure as much as a bony one. A 'soft tissue procedure' means optimizing rotator cuff function, releasing the contracted capsule, and repairing the subscapularis strongly enough to allow early movement with no risk of retear.

The aim of shoulder replacement has always been to alleviate pain, improve movement, increase function, and allow the patient to maintain their own independence. These benefits should be expected to last for a minimum of 10–15 years.

The implants used currently have a number of similarities and none can claim that their clinical outcome is any better than another. With regard to implant design there is now a move towards perfect anatomical replacement of the humeral head. This is possible with a surface replacement and increasingly it is so with stemmed implants. Whilst to date there is no evidence that this drive towards anatomical replacement has had any effect on clinical outcome, it has a beneficial effect on any glenoid component in so much that it seems to reduce migration and loosening and, as a consequence, improve longevity.

Whether a glenoid component should be inserted or not remains contentious. What can be said from a review of the literature is that any series comparing hemiarthroplasty (HA) to total shoulder replacement (TSR) does seem to indicate that total shoulders do better, at least in the short to medium term. With regard to whether a surface replacement or a stemmed humeral component should be used, there is no comparative data. It does not appear that humeral loosening of either a stemmed or a surface implant is significant. The only potential problem is the difficulty of access to insert a glenoid component with the head still in place if resurfacing is used (Figure 4.9.3).

Finally, the role of postoperative mobilization and therapy cannot be understated. It is crucial for any surgeon undertaking this type of surgery that they have access to an experienced network of therapists such that early and appropriate mobilization can start immediately after surgery.

The deltopectoral approach is standard for stemmed shoulder replacements. A skin incision is made over the deltopectoral groove along the line connecting the coracoid to the midpoint of the lateral aspect of the humerus (Figure 4.9.4). Three structures cross the deltopectoral interval: two arteries and one vein. The arteries are branches of the thoracoacromial trunk: the deltoid artery and the acromial artery. The acromial artery can be preserved, but the deltoid artery must be ligated and divided. The deltoid artery has two patterns. The commonest pattern gives off a large pectoral branch as it emerges from the thoracoacromial trunk, and then passes directly into the bulk of the deltoid muscle. The less common variant runs alongside the cephalic vein giving off a series of much smaller pectoral branches. This second pattern confuses the novice shoulder surgeon who incorrectly thinks that these are tributaries of the cephalic vein when actually they are branches of the variant deltoid artery. The deltopectoral interval is always developed medial to the cephalic vein, with preservation of its major tributaries leaving it on the deltoid muscle. The cephalic vein must never be taken off the deltoid. The cephalic vein should be preserved if possible. There is usually no need to release the deltoid muscle either proximally or distally although it is useful to free the undersurface of the muscles from the humerus and rotator cuff so that the head can be pushed back freely when it comes to exposing the glenoid. Be careful for the axillary nerve runs on the deep surface of the deltoid and can be entrapped in scar, particularly following fractures of the humeral neck. The terminal branch of the posterior circumflex artery sends a small anastomosing branch that enters the bone lateral to the insertion of pectoralis major, a vessel that can easily be torn whilst mobilizing deltoid.
Incising the clavipectoral fascia at the lateral edge of the conjoined tendon up to, or through, the coracoacromial ligament exposes subscapularis and the anterior capsule. It is often helpful to release the top half of the insertion of pectoralis major in order to gain a better exposure of the inferior capsule.

The subscapularis is incised at its insertion on the lesser tuberosity along with the subjacent capsule. The junction of the middle and lower third of the subscapularis is demarcated by the anterior circumflex vessels. These should be ligated or coagulated and divided. It is also important to leave a 1-cm stump of subscapularis/capsule for reattachment of the muscle to the humerus. Alternatively, the lesser tuberosity can be osteotomized from the humerus, being reattached at the end by sutures or anchors (Figure 4.9.5).

Finally, as with all joint replacements, it is important to release contractures, particularly of the anterior and inferior capsule. Patients suffering with arthritis often suffer with significant stiffness resulting in marked contracture. It is only if these contractures are released that a significant improvement in range of motion be obtained. Plainly care must be taken when releasing the inferior capsule as this could result in damage to the axillary nerve. The latter will result in a deltoid paralysis, which is a catastrophe. Some surgeons actually dissect the quadrilateral space and place a silastic sling around the axillary nerve and its accompanying posterior circumflex artery and vein, whereas other surgeons make a point of seeing the neurovascular bundle so that it can be protected throughout the procedure. With the axillary nerve seen or placed in a protective sling the inferior capsule can be released, and this is the key to glenoid exposure and regaining a good range of movement postoperatively.

The superior capsule must now be released, including the coracohumeral ligament, and if necessary the long head of biceps (Figure 4.9.6).
Pathology

The principal indications for joint replacement in the shoulder are inflammatory/rheumatoid arthritis, degenerative joint disease, secondary osteoarthritis, avascular necrosis, and trauma. Added to this in a special category is cuff tear arthropathy and this is discussed in Chapter 4.2.

In rheumatoid or inflammatory arthritis the disease process is typically erosive with loss of bone and cyst formation. In this condition the glenoid can be markedly eroded anteriorly and superiorly. In addition there is often thinning of the rotator cuff with superior subluxation of the humeral head. Erosion of the glenoid may be of such severity that it is insufficient to support a glenoid component. Any bone cysts should be curetted and filled with either bone graft or cement. Again any soft tissue contracture should be released. Repair of the rotator cuff may not be feasible because the tendon tissue is so poor.

Degenerative joint disease can present with significant deformity of both the humeral head and glenoid. The glenoid is eroded posteriorly with posterior subluxation of the humeral head. The latter is often flattened anteriorly. Added to this there can be a number of large osteophytes surrounding the whole of the humeral head with loose bodies either inferiorly or posteriorly. Capsular contractures are common and will need to be released at surgery.

The treatment of patients with avascular necrosis of the humeral head can be rewarding at least in the short term. In most cases a HA is all that is required and good results can be expected. Patients are often relatively young and the soft tissues around the shoulder are well maintained. Because of their young age these patients may need regular and long-term follow-up as at some stage revision is likely.

Joint replacement in post-traumatic arthritis is probably the most difficult and is often unrewarding. The normal anatomy can be so distorted that the surgeon can experience significant difficulties navigating the joint. In these cases the glenoid may not be damaged and may not require replacement. Paramount to the success of the operation is reconstruction of the fractured tuberosities. These must be re-attached strongly to the humeral shaft in the correct anatomical location allowing movement to resume as soon as possible after surgery. If the tuberosity has to be osteotomized and reattached this can be both difficult and lead to diminished function.

The role of shoulder arthroplasty in acute trauma falls outside the remit of this chapter. Plainly an implant should only be used in cases that cannot be treated by open reduction and internal fixation or where there is a significant risk of avascular necrosis. Surgical techniques used are significantly different from those used in arthritis. Obtaining correct humeral length, alignment, and version are critical to success. Further difficulties arise from the fixation of the greater and lesser tuberosities to the prosthesis and humeral shaft. Bony union can also be unpredictable. Implant manufacturers have responded to these difficulties and their implants have been modified for use in the trauma scenario.

Indications and contraindications (Box 4.9.1)

Shoulder arthroplasty is indicated in all the earlier discussed clinical situations, in patients who are suffering sufficient pain, loss of movement, weakness, and reduced function. Pain remains the principal indication particularly if the patient is having difficulty sleeping and requires strong analgesia on a regular basis. Patients who undergo total shoulder arthroplasty do improve the range of motion of their shoulder, but surgeons should beware operating for this symptom in isolation. A patient with a stiff yet pain-free shoulder will not do as well as one with a painful yet mobile joint.

Before embarking on shoulder arthroplasty it is important to assess the status of the bone stock, not only of the humerus but especially the glenoid. Is there sufficient bone stock to support a glenoid component? This can be assessed by radiographs, particularly an axillary view, or by computed tomography scan. It is important to allow for any correction of deformity. Any deficit in the rotator cuff should also be assessed as this may affect outcome.
Patient motivation is an important factor in the success of the operation. The patient has to be committed to a surgical procedure and the lengthy postoperative rehabilitation programme. The patient must have a realistic expectation and an ability to follow advice as appropriate. The experience of the surgeon and supporting team, particularly physiotherapists, are vital factors. Finally, the least significant factor is the prosthesis itself.

The principal contraindication to surgery is lack of bone stock to support the prosthesis. This usually affects the glenoid side. If the deltoid muscle is not functioning then any arthroplasty will be unsuccessful. The better option here would be an arthrodesis.

Rotator cuff deficiency may cause difficulties. If the shoulder is concentric on the glenoid (Seebauer I) with a small tear (less than 2cm) a standard shoulder replacement is effective, but if the tear is large then a CTA head or a reverse shoulder can be used. If, however, the shoulder is subluxed upwards (Seebauer II) then a reverse implant should be used (Figure 4.9.7).

Infection is a definite contraindication. Infection will usually be encountered in the revision situation. Again this contraindication is not absolute in so much that two-stage surgery can often be successful. The first stage involves the removal of any metalwork or prosthesis and the debridement of soft tissues and bone. The second stage involves insertion of the prosthesis covered by appropriate antibiotics.

Finally, a neuromuscular disorder can make the outcome of TSR unpredictable. With good medical management in conditions such as epilepsy and Parkinson’s disease the results of surgery can often be quite gratifying.

**Box 4.9.1 Indications and contraindications for shoulder replacement**

**Indications**

- Primary osteoarthritis
- Rheumatoid arthritis
- Avascular necrosis
- Post-traumatic arthritis
- Other inflammatory arthritides:
  - Psoriatic
  - Pigmented villonodular synovitis (PVNS)
  - Ankylosing joint disease
  - Synovial chondromatosis
- Secondary osteoarthritis:
  - Post-dislocation or dislocation surgery
  - Acromegalic arthropathy
  - Primary glenoid dysplasia
- Cuff tear arthropathy (CTA):
  - Seebauer type I selective hemiarthroplasty
  - Seebauer type II reverse polarity replacement.
♦ Active infection
♦ Paralytic dislocation
♦ Lack of bone stock.

Relative contraindications
♦ Previous infection
♦ Syringomyelia.

**Total shoulder replacement or hemiarthroplasty?**

The insertion of a glenoid component is still controversial (Figure 4.9.8). Long term, the problems are that HA may lead to glenoid erosion and TSR may lead to wear or loosening of the glenoid component.

In the interim the patient wants to have the best result in terms of pain, movement and function. There is no doubt that TSR wins out over HA in the short to medium term. There are four level-one evidence studies (prospective randomized controlled studies) that show this. Gartsman’s study (2000) on 51 randomized patients, operated on by the same surgeon, using the same prosthesis and followed for 3 years with UCLA (University of California–Los Angeles) and ASES (American Shoulder and Elbow Surgeons) scores showed that the TSR had better pain relief, better patient satisfaction, better function, and better strength. Three of the HAs came to revision for painful glenoid erosion during the study, but none of the TSRs came to revision. Kirkley’s study (2005) on 41 randomized patients also had three HAs come to revision for painful glenoid erosion during the study, but none of the TSRs were revised. The study by Sandow et al. (1998) on 32 randomized patients showed that the TSR group had significantly less pain, and the study by Jónsson (1998) on 49 randomized patients showed significantly better Constant scores for the TSR group. Of course all these studies suffered from low numbers so Kirkley did a meta-analysis (2005) combining these randomized studies and showed that the TSR group had significantly better pain relief, significantly better function, and better movement than the HA group (Figure 4.9.9).

There is also a lot of level 2 and 3 evidence (not randomized) that TSR fares better than HA. In our study (Haines and Trail 2006) on 124 patients, both groups improved significantly and equally, with a small trend towards better results for pain and movement in the TSR group but the major cause for revision was glenoid pain due to erosion in 12% of the HA group. The Tornier group (2003), in a study of 601 TSR compared to 89 HA, showed good to excellent results in 94% of the TSR group compared to 86% of the HA group, with the TSR group having better scores for pain, mobility, and activity, and their conclusion was that TSR was better than
HA. Finally Bigliani and co-workers (2007) did a meta-analysis that included 23 non-randomized studies with 1952 patients and showed that the TSR group had significantly better pain relief, significantly better elevation, significantly better gain in elevation, significantly greater gain in external rotation, and significantly better patient satisfaction. There is no more to be said.

So what about the late results? Well there is no doubt about painful glenoid erosion following HA. It was bad enough for revision surgery in 12% of our study, 12% of Gartsman’s study, and 12% of Kirkley’s study. In Sperling and Cofield’s long-term study 72% of the HA group had glenoid erosion on radiographs at 10 years.

And what of glenoid revision following TSR? Sperling and Cofield had a 97% survival of their glenoids at 10 years. In the Radnay and Bigliani meta-analysis of 1952 patients only 1.7% of sockets needed revision. In Bunker’s study with a minimum 10-year follow-up there was a 94% survival for the glenoid. The TSR versus HA debate will continue to rumble on but evidence is now stacking up for the superiority of TSR in the short to medium term, and greater survival of TSR in the long term.

What is also of note is that improvements in glenoid component design, preparation of the glenoid, fixation including cementing techniques, and, interestingly enough, an anatomical humeral head replacement have resulted in a lower incidence of migration and loosening and potentially better long-term survival.

### Results

Whilst it is difficult to prove, I have no doubt that the results of shoulder replacement continue to improve and certainly have become more reproducible. This is a testament to all of the surgeons who have helped develop prostheses as well as the techniques of surgery. With regards to the results themselves, these are now being reported from all corners of the globe. Generally these are extremely favourable, although interpretation can be difficult given the lack of standardization of outcome evaluation. In Europe the Constant score, and more recently the Oxford score, and in the United States the ASES score have been used. Unfortunately these are not interchangeable. As such it is probably more sensible to break the scores down into their various components, particularly pain relief, range of motion, strength, and finally function.

It is not possible to report on every single article that has been written on shoulder arthroplasty. As such I have chosen six with the largest numbers and the longest follow-up. These have been summarized in Table 4.9.1. As can be seen in most series the authors report extremely good pain relief and an average range of motion of between 100–110 degrees of abduction and 110–120 degrees of forward flexion; internal rotation to the buttock or lower lumber spine and an external rotation of 40–50 degrees. As a result of this there is a significant improvement in function. Perhaps more importantly authors are now reporting that these improvements continue for 10 or 15 years.

### Complications

As with all joint replacements, whilst most patients can expect a good to excellent result some will get a complication. These can arise during the procedure, immediately afterwards and in the long term (Box 4.9.2).

#### Box 4.9.2 Complications of shoulder replacement

- **Intraoperative:**
  - ER 17–43°
  - 2 infections
  - 2 humeral loosening
  - 1 infection
  - 2 glenoid wear

- **Trail and Nuttall (2001):**
  - 105 RA 8.8 years
  - Flexion 61–78°
  - 4 HHR TSR
  - Abduction 47–67°
  - ER 16–36°
  - Kaplan–Meier at 8 years 92%

- **Deshmukh et al. (2005):**
  - 320 mixed 14.0 years (subset)
  - Kaplan–Meier at 20 years 85%
  - 3 cases of dislocation
  - Revision as end point
  - 2 infection
  - 4 perioperative fractures

- **Haines et al. (2005):**
  - 124 OA Up to 11.6 years
  - Flexion 64–103°
  - 2 cases of fractures at the shaft of the humerus
  - Abduction 53–92°
  - 1 case of instability
  - ER 11–39°
  - 5 HHR TSR
  - Kaplan–Meier at 12 years 90%
  - 4 glenoids revised

ER, external rotation; HHR, humeral head replacement; OA, osteoarthritis; RA, rheumatoid arthritis; TSR, total shoulder replacement
Peri-operative complications include nerve or blood vessel injury, peri-prosthetic fractures, and, on occasion, implant-related problems.

The axillary and musculocutaneous nerves are always at risk during shoulder replacement. At a recent audit at Wrightington Hospital (Wigan, United Kingdom) we were able to identify 17 instances of neuropraxia of various nerves after shoulder arthroplasty. As all these patients had concomitant supraclavicular nerve blocks it was not possible to know clearly whether these injuries had occurred as a direct result of surgery or the block itself. Fortunately all these recovered although one took 12 months. More significant and permanent injuries, however, can occur, particularly to the axillary and musculocutaneous nerves. The axillary nerve can be damaged during an inferior capsular release. The musculocutaneous nerve lies on the undersurface of the short head of biceps and can be damaged when this muscle is retracted. Damage to either nerve can leave the patient with a significant functional deficit. It is therefore important that any damage should be identified at the time of surgery and rectified. Postoperative neuropraxia should be monitored, and if at 6 weeks there has been no improvement then electromyographs obtained. The latter will often distinguish between neuropraxia and definitive nerve damage. For the latter it is important that further exploration and nerve repair is undertaken as appropriate. Finally, later management might involve some form of tendon transfer.

Fortunately vascular injuries following TSR are rare. The author has seen two in over 17 years of consultant practice. As would be expected, diagnosis is relatively straightforward. Indeed if prompt help is summoned by way of vascular expertise including an arteriogram and bypass grafting, then a good outcome can be expected. It should also not be assumed that this compromise has occurred as a direct result of surgical trauma. In one case in the author’s practice intraluminal occlusion was found quite distal to the surgical site. It was assumed that this was ‘an accident waiting to happen’ perhaps precipitated by external rotation of the arm. Whatever the circumstances the surgeon should not hesitate to seek urgent advice and must not prevaricate in the vain hope that things will improve spontaneously.

Periprosthetic fractures can include fractures of the glenoid but more commonly the humerus, the latter as a result of overzealous manipulation of the upper extremity during exposure, particularly external rotation, but also inadvertent reaming and finally impaction of the prosthesis. The commonest follows external rotation and takes the form of a spiral fracture. Plainly great care should be taken when the humeral head is exposed, particularly in patients with fragile bone. Management of this problem is fortunately relatively straightforward and involves the insertion of a longer-stemmed humeral component and the application of cerclage wires (Figure 4.9.11). It is, however, important that the stem of the humeral component extends beyond the end of the fracture by at least two diameters of the radius of the humerus. Interoperative fracture of the glenoid, however, would probably preclude the insertion of a glenoid component. Fixation should be attempted. In most circumstances this can be undertaken by the use of a lag screw.
Postoperatively there are two major complications: infection and instability. Infection after TSR is relatively uncommon with most published series reporting an incidence of between 1–2%. As with all arthroplasty, one must assume that the implant was contaminated at the time of surgery. Infection can present immediately after surgery or somewhat later (12 months after surgery). A number of factors increase the likelihood of infection, particularly previous surgery, diabetes mellitus, and systemic corticosteroids. Multiple organisms have been described, particularly *Propionibacterium acnes*, *Staphylococcus aureus*, and *Staphylococcus epidermidis* and even *Candida*. *P. acnes* is an aerotolerant anaerobic Gram-positive rod that is sensitive to clindamycin, erythromycin, tetracyclines, piperacillin, and penicillin G. It is sensitive to ultraviolet light. It is a commensal in the skin of the face and shoulder girdle, accounting for the incidence of acne in these sites. It is therefore a specific risk to shoulders and not to the hip and knee and is difficult to grow in the laboratory. In a significant number of cases no organism can be identified. Continuing antibiotic use or poor bacteriological techniques may account for this. The C-reactive protein (CRP) and white cell count (WCC) can be normal in 40% of revision cases where infection is later confirmed by biopsy. When infection has been confirmed either by clinical means, cultures, or blood tests, then two-stage revision surgery is the only remedial treatment. The first stage involves removal of the implant and the insertion of an antibiotic-loaded cement ball and stem which fits down the humerus like a HA or packing the space with gentamicin beads. The second stage is removal of the antibiotic-impregnated cement spacer and the reinsertion of a new prosthesis. In the author’s experience this type of surgery is relatively successful. It seems to result in a resolution of the infection leaving the patient with a relatively pain-free and mobile shoulder joint.

The time interval between the two stages of surgery depends on the clinical situation but should be a minimum of 3 months. Prior to the second stage it is crucial that the patient’s wounds have healed and that there has been no recurrence of infection. Added to this, blood parameters including erythrocyte sedimentation rate, CRP, and WCC should all be normal. If there is any uncertainty then an open biopsy of soft tissues and bones should be undertaken to exclude infection prior to the second stage.

The incidence of dislocation varies widely (Figure 4.9.10). In most cases it arises as a result of poor surgical technique, that is, malalignment of the components, particularly excessive humeral retroversion, excessive soft tissue release, or poor reconstruction. Version is variable but the average humeral retroversion is 21 degrees. Glenoid version has to be performed by naked eye, for it is difficult to measure even radiographically.
With regard to the soft tissues, release of contractures is key to the procedure but must not lead to damage of the rotator cuff or subscapularis. At the end of the procedure the subscapularis muscle should be firmly attached to the lesser tuberosity. Thereafter, therapy whilst allowing movement should protect this repair, at least in the early 4–6-week period after surgery.

In the author’s opinion instability can be extremely difficult to treat. If revision surgery is contemplated this should involve an assessment of the alignment of the prosthesis and muscles around the shoulder. Whilst realignment of the humeral component is relatively straightforward, that of the glenoid can be more difficult. The removal of a cemented glenoid component can result with insufficient bone being left for the insertion of a second. Treatment is very difficult; the alternatives include insertion of a corticocancellous bone graft or impaction grafting technique where appropriate. The results of these are unpredictable and leaving the patient with a HA will not correct instability.

Instability can occur after failure of the subscapularis repair. Mobilization and reinsertion of the subscapularis can be successful. This can be reinforced by a pectoralis major transfer. Of all revision surgeries for instability however, in the author’s experience, the most successful has been the revision of an anatomical shoulder replacement to a reverse implant. This can stabilize the shoulder but it relies on the presence of good glenoid bone stock to support the glenosphere.

Failure of the rotator cuff is common in the elderly patient a decade or more from surgery. This can occur after minor trauma and result in the patient presenting with a sudden loss of movement, particularly abduction and external rotation. In the author’s experience the clinical picture is usually typical. In the first instance treatment is often a course of physiotherapy. Cuff repair in the degenerate cuff of the 80-year-old following shoulder replacement is doomed to failure, and one way out may be revision to a reverse polarity replacement.

Loosening of the glenoid component, may be the current rate-limiting step in TSR (Figure 4.9.11). Glenoid lucent lines remain a concern. Historical papers report a high incidence of lucent lines, but these could be detected in the recovery room and were thus a sign of poor surgical technique. However, studies using modern cement techniques are also of concern. Mansat had lucent lines in 67%, but complete lucent lines in only 35%, yet had no case of glenoid loosening and no revision for loosening. The Torrent multicentre group study had lucent lines detectable on day 1 in 60% of cases (a sign of poor technique) and 25% were progressive. The good news is that despite these high figures for lucent lines, glenoid revision rates are low with a figure of 1.7% in the meta-analysis of 1952 cases undertaken by Bigliani and co-workers.

When the glenoid loosens, management means revision surgery; the principal indication being pain. With the newer modular implant the ease of surgery has increased because the head can be separated from the stem of the humerus; this makes any approach to the glenoid easier to undertake. The removal of cemented mono-blocks from the humerus, however, is notoriously difficult. Reconstruction of a glenoid relies on either the insertion of a corticocancellous graft or impaction grafting techniques. These are highly specialized and should only be undertaken in units familiar with these techniques. This type of surgery involves a significant amount of time, resource, and equipment. If reconstruction of the glenoid is not possible then the patient will have to be left with a HA.

Acromioclavicular joint

Introduction

The acromioclavicular joint (ACJ) is the sole skeletal connection between the upper limb and the axial skeleton and provides both strength and stability to the shoulder. The three-dimensional alignment of the joint, particularly in the sagittal plane, is very variable which should be borne in mind, especially when trying to inject the joint. It is rare to find anyone older than 35–40 years of age without some evidence of degenerative change. The ACJ is also one of the most commonly injured joints of the body, accounting for 12% of all dislocations. Controversies regarding indications for surgical treatment of the joint, and the bewildering choice of procedures described, makes this small joint the subject of a disproportionate amount of debate and discussion amongst shoulder specialists.

Acromioclavicular joint arthropathy

Clinical presentation

There are two different groups of patients who present with arthropathy of the ACJ. The first patient is relatively young, in their twenties or thirties, usually male with a background of sporting injury or heavy manual work. Arthropathy in these patients can develop subsequent to a discrete, single episode of trauma to the shoulder or a history of taking part in a contact sport. Heavy manual work with a large amount of overhead lifting may contribute to the development of ACJ arthropathy. The early onset of arthropathy in this group may be related to premature damage to the intra-articular fibrocartilage disc in a similar model to that seen in the knee following meniscal injury.

The second group of patients suffering from the symptoms of ACJ arthropathy are middle-aged and may give a history of manual work or sport. However this is not consistent and presumably there is a constitutional element as with most other joints. The onset of symptoms can often be slow with long periods of minimal discomfort.

The clinical symptoms, signs, and investigations for ACJ pathology are dealt with in Chapter 4.1.

Initial treatment

The treatment of patients with mild to moderate arthropathy of the ACJ is non-surgical in the first instance. Advice can be given regarding activity modification, both at work by avoiding overhead tasks and in recreation. For instance, it is not uncommon for patients with a painful ACJ to fail to realise that swimming a mile three times weekly to keep fit is aggravating their arthritic ACJ. Regular analgesia and anti-inflammatory medication can also be discussed, although its effectiveness in the longer term is often not sustained.

Intra-articular injections of steroid are often advocated as an effective treatment of ACJ arthropathy. Whilst this is certainly worth trying in the patient without advanced arthropathy, it is the author’s view that the beneficial effects are often not sustained. Placing the injection accurately can also be difficult and may be improved by the use of ultrasonography or fluoroscopy.

Surgical treatment

Surgery provides a safe and effective option if conservative treatment has failed, and in patients with severe arthropathy. The principle of surgery involves excising the distal end of the clavicle. Debate regarding whether the procedure is best done open or arthroscopically remains and also the optimal length of clavicle to excise.

Excision of the distal clavicle is usually attributed to Mumford whose name is attached to procedures such as the ‘mini-Mumford’ or ‘arthroscopic Mumford’. According to the literature it is unclear whether Mumford or Gurd performed the first clavicle excision as
Surgical anatomy

The ACJ is planar and has no inherent bony stability. Stability of the joint is therefore provided by the coracoclavicular ligaments and the ACJ ligaments with the joint capsule itself playing a minor role.

The conoid ligament inserts more medially on the conoid tubercle of the clavicle than the trapezoid ligament. Selective ligament sectioning work by Fukuda, has demonstrated that the conoid is responsible for constraining anterior and superior displacement of the clavicle, particularly under high load. The trapezoid ligament contributes less to vertical stability of the clavicle but help to stabilize the ACJ under axial compressive load.

The capsule of the ACJ is thickened superiorly and inferiorly to form discrete acromioclavicular (AC) ligaments. The superior AC ligament is more substantial and thicker (2–5mm) than the inferior ligament and provides rotational stability of the joint.

The lateral edge of the trapezoid ligament is 16.7mm ± 2.4mm from the articular surface of the clavicle. The medial edge of the trapezoid ligament is 28.2 ± 5.7mm from the end of the clavicle. Looking at the conoid ligament, this inserts on the clavicle between 33.5–49.7mm from the articular surface. There were no significant differences between men and women for the trapezoid ligament insertion although there was for the conoid insertion which was closer to the articular surface in women. The superior AC ligament inserts on the clavicle medially for 5.5mm ± 1.7mm in men and only 3.6mm ± 0.78mm in women. The acromial attachment of this ligament extended for 8.1mm in men and 4.7mm for women.

If we first consider open surgery, it is clear that in order to expose the distal clavicle, the superior AC ligament has to be incised and a limited amount of the deltoid-trapezial fascia has to be reflected. The minimum amount of bone that should be resected in order to abolish bone contact postoperatively has been shown by Branch to be 5mm. However, this will inevitably lead to loss of stability as the superior AC ligament is also lost and most surgeons recommend an excision of at least 10mm to avoid postoperative pain due to persistent posterior impingement of the clavicle on the acromion. As long as the excised segment is no more than 15mm, the trapezoid ligament should not be damaged.

Arthroscopic excision of the distal clavicle has the perceived advantages of avoiding the pain and potential morbidity of an open surgical exposure and allows resection of the clavicle without disrupting the deltoid-trapezial fascia. It is also said that arthroscopic excision preserves the superior AC ligament, leading to better preservation of rotational and horizontal stability, although this may not be the case given the evidence presented earlier. If the standard excision of 5mm of clavicle is carried out, this will almost certainly lead to complete detachment of the superior AC ligament in most patients, particularly females. If one wishes to preserve the clavicular attachment of the superior AC ligament it would seem more logical to excise no more than 3–4mm of bone from the clavicle and perhaps a similar amount from the acromion. A secondary advantage of an arthroscopic resection is the ability to perform glenohumeral inspection and treatment of occult pathology.

There are two approaches for arthroscopic ACJ resection: the direct and indirect methods. The common indirect approach involves exposing the ACJ through the subacromial bursa. The advantages of this technique are that the approach is familiar to the surgeon and that secondary impingement can be treated as appropriate. The direct approach involves establishing a viewing portal directly posterior to the ACJ with an anterior working portal; however, establishing a good view initially can be difficult.

Results of surgery

Surgical treatment of ACJ arthropathy is both effective and safe. There have been numerous series published giving results in patients having either open resection or arthroscopic resection.

Two studies have attempted to compare open with arthroscopic resection. Freedman et al. randomized 17 military recruits with ACJ pain into two groups; the first group underwent open ACJ resection whereas the second group underwent indirect arthroscopic resection. The only significant finding was that patients in the arthroscopy group had a better improvement in their pain score from baseline to 1 year postoperatively. They highlighted trends suggesting that the arthroscopy group had better results in all the parameters measured, including return to sports, subjective results, and objective shoulder assessment. However, the study groups were small and the authors acknowledge that their results should be interpreted with caution.

Flatow et al. also compared the results of open versus arthroscopic ACJ resection. Their study, however, was retrospective and looked at pain relief only and they did not make any objective assessment. The arthroscopic approach used in this study was the direct technique. They reported good pain relief in both groups, although pain relief occurred much sooner in the arthroscopy group, in fact 3.4 months earlier.

Complications of surgery and their treatment

Patients who have an unsatisfactory result following ACJ excision can be split into three groups: those who have persistent pain in the shoulder following good surgery; those patients with pain and/or instability as a result of excessive bone resection; and finally those patients who have pain due to inadequate resection. Clearly in the first group, the failure is with the initial diagnosis rather than a fault of the surgery and the patient must be reassessed and the correct cause of the symptoms established. This is unfortunately rather more difficult after surgery than before. Inadequate bone resection is an uncommon cause of failure of arthroscopic resection. The solution is revision surgery, although the surgeon must be cautious to avoid going too far the other way and resecting too much bone.

The second most common complication after an incorrect diagnosis is the patient with pain due to having had an excessive amount of bone resected from the distal clavicle. This problem is usually seen in patients who have had open surgery. Open
surgery will defunction the stabilizing constraints of the AC ligaments. If the resection compromises the coracoclavicular ligaments as well then the patient may develop painful instability of the clavicle, which is quite miserable and difficult to treat. The patient may have the worst of all worlds, with impingement of the acromion against the resected clavicle in elevation, local soft tissue irritation caused by instability of the distal clavicle, and scapular fatigue caused by failure of the link between the clavicle and acromion or scapula—what could be called clavicoloscapular dissociation. Stress views of the ACJ will show an increased width in the resection gap with load bearing, which can sometimes be quite dramatic. An x-ray or fluoroscopy of the ACJ with the upper limb fully elevated will sometimes demonstrate acromioclavicular impingement even if the joint space with the arm at rest is 1–2cm. Occasionally some of this group of patients will require revision reconstructive surgery. The author currently uses a semitendinosus free tendon graft that is used to restore stability to the ACJ through a figure-of-eight loop between tunnels in the acromion and distal clavicle. If the clavicle is also vertically unstable, a second loop is passed between the coracoid process and clavicle. Initial stability can be improved between the coracoid and clavicle by using a suture anchor, sling, or TightRope® (Arthrex) suture.

**Acromioclavicular dislocations**

**Aetiology**

Dislocations of the ACJ are common injuries, representing around 12% of all dislocations around the shoulder and 8% of all dislocation injuries of the body. By far the commonest mechanism of injury is a fall, landing directly on the tip of the shoulder. The joint can be dislocated as a result of a direct blow to the clavicle, this mode of injury producing some of the more unusual dislocation types as described subsequently.

**Classification**

ACJ dislocations are universally classified according to the system proposed by Tossy in 1963 and Allman in 1967. These initial classifications were amalgamated to describe the three most common types of dislocation. Three further dislocation patterns (IV, V, and VI) were added by Rockwood in 1984.

A grade I injury involves a partial disruption of the ACJ capsule and ligaments with no deformity or instability. A grade II injury involves complete disruption of the ACJ ligaments although the coracoclavicular ligaments are broadly intact and may be partially damaged. There may be some minor causal displacement of the acromion although this is often not seen, particularly initially, as the intact coracoclavicular ligaments continue to provide vertical stability. On examination of the ACJ, there is usually some anteroposterior laxity of the joint due to the disruption of the ACJ ligaments. A grade III separation describes an injury in which there is complete disruption of both the ACJ ligaments and coracoclavicular ligaments. This is responsible for the typical ACJ dislocation as seen on radiographs and apparent on clinical examination. However, there is no appreciable posterior displacement of the clavicle and due to the contribution of the intact deltotrapezial fascia, the clavicle is not grossly unstable and there is usually not more than 100% displacement of the acromion relative to the clavicle. Grade IV and V injuries are relatively uncommon but occur in roughly equal proportions and it is important to differentiate them from the more common injuries as results with conservative treatment are often disappointing. A grade IV injury is similar to a grade III with complete tears of the AC and coracoclavicular ligaments, except that there is significant posterior displacement to the extent that the distal clavicle pierces the deltotrapezial fascia and becomes button-holed in an irreducible manner. A grade V dislocation involves extensive separation of the deltotrapezial fascia normally attached to the distal clavicle. This allows significant displacement of the acromion on the clavicle and certainly more than 100% of the thickness of the distal clavicle. A grade VI injury is extremely rare and will never be seen by most shoulder specialists in their lifetime.

**Examination and diagnosis**

The diagnosis of an acute ACJ injury is not particularly difficult. The patient gives a history of acute pain in the shoulder following a fall or direct blow to the shoulder. The pain is sharp and localized to the tip of the shoulder. Examination of the patient reveals tenderness over the injured joint with or without the deformity associated with a dislocation. The distal clavicle should be located by direct palpation and an assessment made of vertical and AP stability. Alignment of the distal clavicle with the acromion should be ensured to avoid missing a grade IV injury. Plain radiographs are usually sufficient to confirm the diagnosis. A standard AP of the shoulder will be taken as part of a trauma series along with an AP view of the ACJ. These views will allow distinction to be made between grade II, III and grade V injuries. It should be borne in mind that due to pain, the patient with a grade V injury may be reluctant to allow the injured arm to hang and in supporting it, may reduce the separation seen on the AP view to resemble a grade III injury. In this situation, clinical examination will allow the correct grade to be diagnosed as these patients have significant vertical instability of the clavicle with no firm end-point. An axillary view is essential to allow diagnosis of a grade IV injury in which the distal clavicle will be seen to lie posterior to the acromion. In more subtle injuries a magnetic resonance imaging (MRI) scan will show ACJ capsule disruption, surrounding oedema and possibly signal change in the region of the CC ligaments.

**Treatment options**

The treatment of grade I and II injuries is non-surgical and consists of symptom relief with analgesia and anti-inflammatory medication. The arm should be supported with an immobilizer and ice packs can be applied to the injured area. Generally speaking, for grade I injuries the symptoms will resolve in a couple of weeks and the patient can return to normal daily and sporting activities relatively quickly. Patients with grade II injuries often experience discomfort for longer, perhaps 4–8 weeks, although treatment is similar. There is no evidence to suggest that prolonged immobilization of grade II injuries facilitates a more prompt recovery or reduces the incidence of later onset pain and arthropathy. Patients should be warned that chronic discomfort is not unusual following a previous grade II injury and may require subsequent surgery.

At the opposite end of the spectrum, most doctors would recommend surgical treatment of grade IV, V, and VI injuries. As their classification suggests, these types of dislocation involve significant displacement with associated soft tissue disruption. Grade IV
injuries if neglected or more commonly missed, are very painful, presumably due to the irritation of the trapezius by the distal end of the clavicle and can cause considerable late disability. Grade V injuries, whilst often not as painful initially, are associated with marked deformity due to the prominence of the distal clavicle under the skin. Contrary to popular belief, this deformity is largely caused by the weight of the upper limb pulling the shoulder downwards, with the clavicle remaining relatively undisplaced. Due to this loss or incompetence in the superior suspensory complex of the shoulder, the deltoid and pectoral muscles are required to work much harder than normal to support the upper limb, particularly when the patient is performing repetitive overhead activities. This often results in the patient experiencing fatigue pain located to the scapular region and chronic disability. The patient will complain of an inability to perform overhead activities, describing an aching or dragging sensation in the scapular region.

Whether to treat grade III injuries with surgery or not has been the subject of debate, discussion, and uncertainty for decades and it seems that a clear answer to this dilemma is no nearer than it was 20 years ago. Whilst it is true that most patients with a grade III injury cope perfectly well, both with the deformity and any minor discomfort, there are a minority who continue to be symptomatic and seek further treatment. This is apparent when reviewing the surgical treatment options available for reconstruction of the dislocated ACJ. Of course, if patients with grade III injuries never required surgery, it is unlikely that there would be so many different operations available for reconstruction described in surgical textbooks.

Results of conservative and surgical treatment of acromioclavicular joint dislocations

It is generally believed that grade I and II injuries to the ACJ are benign and patients do well once the initial pain of the injury has resolved. However, according to a review published by Shaw, post-traumatic arthritis is relatively common with 40% of patients reporting significant pain at 6 months post-injury and 14% reporting a high level of pain at a minimum of 1 year. Many of these patients ultimately required surgical treatment. Moushine et al. studied a group of 33 patients with grade I and II injuries managed conservatively. From this group nine patients required surgery for late ACJ symptoms (chronic pain).

The treatment of grade III injuries provides the most controversy of all ACJ separations and there have been hundreds of articles published on the subject. Dias and other authors have reported up to 50% of patients treated non-operatively will have residual symptoms of pain and weakness. Spencer has reviewed the literature on this subject and points out that there are in fact only nine papers that directly compare conservative treatment with some form of surgical management. Of course, the findings of some of these papers will be heavily influenced by the type of surgical procedure used during the study. Only three of these studies were performed prospectively. Perhaps the best known of all these studies is the work published by Bannister et al. in 1989. In this study 60 patients with grade III injuries were randomized to either standard conservative treatment or surgery with a Bosworth screw that was removed at 6 weeks. Forty-four patients were evaluated at 4 years post-injury. The results in the non-operative group showed 100% patients had good or excellent results; 84% of patients in the operative group had similar results with the remaining 16% fair. Five patients in the operative group had complications of their treatment including loss of reduction and metalwork problems. Despite reporting uniformly good results in the non-operative group, in fact four patients failed treatment and underwent surgery. Operated patients also took longer to return to work and sport. Despite stating that all patients in this study had grade III injuries, in fact 12 had displacement of more than 2cm which is much more likely to represent a grade V injury; these patients in Bannister’s study did better with surgical treatment. Of course it may be argued that there may be potentially better surgical treatments available today than in the 1980s and more objective methods of assessing shoulder function may alter the results seen.

Surgical treatment of acute acromioclavicular joint dislocation

Over the years, there have been numerous different surgical techniques described for the treatment of acute grade III–VI ACJ dislocations. These include direct repair of the coracoclavicular ligaments, usually with some method of temporary stabilization of the joint, using sutures, tape, screws, or plates. Stabilization of the distal clavicle has also been advocated by transfer of the coracoclavicular ligament, with or without excision of the distal clavicle, but this technique is more commonly used in the chronic situation. Currently, the preference seems to be towards reduction of the dislocation without formally repairing the disrupted coracoclavicular ligament, with indirect stabilization either with a hook plate, coracoclavicular screw, or using an arthroscopic technique to place sutures between the clavicle and coracoid process. The choice of technique depends on published results, the resources available to the surgeon and their expertise in open or arthroscopic surgery.

Applying a hook-plate to maintain reduction of the reduced ACJ is a relatively simple surgical procedure that has its advocates. The disrupted joint capsule can be repaired simultaneously with or without excision of the intra-articular disc. The plate will require removal at or around 3 months or earlier if there is evidence of osteolysis under the acromion. The hook is designed to be placed posterior to the ACJ and should therefore not interfere with healing or movement in the recovery phase. In a study from Salzburg the results in terms of shoulder function were significantly better in the surgical group, particularly when comparing pain and power.

Surgical complications were seen in four of 28 patients with one haematoma, two superficial infections, and one plate eroding the acromion. Surgical complications were seen in four of 28 patients with one haematoma, two superficial infections, and one plate eroding the acromion.

The use of a coracoclavicular screw for the treatment of an acute ACJ dislocation is widely attributed to Bosworth. Most surgeons would now use a partially threaded (10mm) 6.5-mm cancellous screw. It is imperative that the screw is placed centrally in the base of the coracoid process to minimize the possibility of pull-out and this can either be done with a conventional open approach or a percutaneous technique using a cannulated system and fluoroscopy. The thread of the screw should cross both cortices of the coracoid and the screw should not be tightened excessively as this will over-reduce the dislocation and lead to ACJ dysfunction. A disadvantage of this type of rigid fixation is that it must be removed before overhead movement of the upper limb can be allowed. Most surgeons would therefore plan to remove the Bosworth screw around 8 weeks after fixation, but there is a possibility of late displacement if the injured coracoclavicular ligaments have not fully healed by this stage.

Coracoclavicular sutures or slings are popular techniques largely because there is no requirement for hardware removal. Perhaps the simplest method within this type is to knot a Dacron® or PDS 5-mm tape over the clavicle after first passing it around the base of the coracoid. However, this does little to address anteroposterior instability of the clavicle and there is often subsequent loss in...
A novel technique using a TightRope® (Arthrex) suture (originally described by Wolf for the reconstruction of chronic acromioclavicular dislocations and subsequently adapted for use in the acute situation and described by Qureshi and Potter) has become popular over the last 3 years. It has all the advantages of the rigid coracoclavicular fixation of a Bosworth screw, with the benefit of flexibility as seen with the suture techniques. One major attraction is that the suture is placed using an arthroscopic technique, both ensuring accurate placement through the coracoid and minimizing disruption to the torn coracoclavicular ligament complex. Finally, as no rigid fixation is employed there is no need for hardware removal prior to a return to normal activities. To insert the TightRope® suture the base of the coracoid process is identified and debrided arthroscopically. A jig is then used to percutaneously drill a guide wire through the middle of the clavicle approximately 3cm from its distal end and then through the middle of the base of the coracoid. After the guide wire is over-drilled with a cannulated 4mm drill, the TightRope® suture is pulled through both holes. The suture is tied over a button on the superior surface of the clavicle after reducing the ACJ dislocation manually. At present there are no long-term results of this technique published although interim results have been presented. Clearly this technique requires healing of the coracoclavicular ligament complex to be successful; this is more likely if the dislocation is reduced and stabilized early. It is also not clear at this stage whether the reduced ACJ will become arthritic as a result of the initial dislocation, although secondary treatment of this problem is much easier than the options for reconstructing a symptomatic chronic dislocation of the ACJ. This technique is also very well suited to complex displaced fractures of the distal clavicle, particularly those involving the ACJ, which usually require surgical reduction but are very difficult to treat with conventional methods.

**Surgical treatment of chronic acromioclavicular joint dislocation**

Numerous surgical techniques have been described for the treatment of the chronic, symptomatic ACJ dislocation. It should be said that grade I and II injuries can also be troublesome for the patient and require surgery, although in the absence of significant instability, simple ACJ excision, either open or arthroscopic, is probably sufficient. It is often worthwhile excluding instability in these patients by performing a stress X-ray. Patients with a high-grade separation can complain of several different symptoms justifying surgery, such as local irritation from the prominent distal clavicle, impingement of the unstable joint in elevation, or scapular fatigue pain and weakness. Surgical procedures can be broadly grouped into those relying on a transfer of the coracoclavicular ligament based on the Weaver–Dunn procedure; autogenous tendon graft procedures (anatomic coracoclavicular reconstruction); and reconstruction using synthetic ligament and dynamic muscle transfers.

The Weaver–Dunn procedure was originally described in 1972, and has become the ‘gold-standard’ of ACJ reconstruction. The procedure essentially involves detaching the coracoclavicular ligament from the acromion and transferring it onto or into the resected distal end of the clavicle to provide stability. The original Weaver–Dunn technique is now usually modified to include augmentation of the repair to provide initial security, preventing subsequent displacement. The coracoclavicular ligament is exposed prior to detachment by either splitting anterior deltoid or detaching anterior deltoid from the clavicle and anterior acromion, although the operation can be performed arthroscopically. Detaching the ligament with a small flake of bone from the acromion may promote healing of the transfer and certainly helps to prevent cut-out of the sutures used to secure the transfer. The ligament is placed into the canalized end of the clavicle and secured in place with sutures passed through drill holes in the clavicle. Perhaps not surprisingly, this transfer in itself has little strength in the early phase of healing. There are several ways in which the initial stability of a Weaver–Dunn repair can be improved, using coracoclavicular slings or sutures. Although it is the author’s practice currently to use a PDS tape, the best biomechanical results are seen with a suture anchored into the base of the coracoid and tied through drill holes in the anterior half of the clavicle, which resists translation under a 100N cyclical load. The final construct at 246N is not as strong as the native coracoclavicular ligaments at 500N.

Increasing interest is being expressed in more anatomical reconstructions of the dislocated ACJ using tendon grafts. It has been noted that whilst a coracoclavicular ligament transfer prevents superior migration, it is less good at resisting anteroposterior translation. This is not too surprising when one remembers that the coracoclavicular ligament takes its origin from the tip of the coracoid and when transferred, inserts into the resected distal end of the clavicle. The native coracoclavicular ligaments of course arise from the base of the coracoid and insert into the undersurface of the clavicle some way from the distal end. With this in mind, surgical techniques have been described using autogenous tendon grafts including palmaris longus, flexor carpi radialis, gracilis, and semitendinosus. It has been the author’s personal experience that there are both early failures associated with anatomical reconstructions using semitendinosus (usually due to the tendon cutting out of the clavicle tunnel) and late failures (mainly seen on the coracoid side and possibly related to failure of revascularization). It is also worth mentioning that harvesting a semitendinosus reconstruction; and semitendinosus tendon graft in revisions and when it is not possible to use the coracoacromial ligament.

Artificial ligament substitutes are not widely used, given the poor results previously seen in anterior cruciate ligament reconstruction in the knee, although following work by Wallace and Neuman, the ‘Surgilig’ technique is gaining interest. The procedure uses a polyester coracoclavicular sling looped under the coracoid and then fixed to the anterior clavicle with a small fragment screw and washer. It is suggested by the Nottingham unit that this procedure can be used for both acute dislocations as well as in revision.
Other conditions affecting the acromioclavicular joint

Distal clavicular osteolysis

Distal clavicular osteolysis was first described in 1936 and was thought to be secondary to a traumatic injury. In 1982, Cahill published a series of 45 male patients with clavicular osteolysis, suggesting repetitive microtrauma as the aetiology. All but one of his patients were weightlifters. He noted the presence of microfractures in the subchondral bone in 50% of cases and proposed that repetitive overloading of the joint caused subchondral stress fractures and remodelling. There is certainly evidence of increased osteoclastic activity in many excised specimens. Patients present with pain localized to the ACJ and almost always give a history of regular and intense weight-training or overhead athletic activity. X-rays are often normal in the early part of the natural history and in cases where doubt exists as to the diagnosis, an isotope bone scan or MRI scan will be diagnostic. The condition is self-limiting with appropriate activity modification, although many young male patients are unwilling to cease their training activities. In these circumstances, Auge and Fischer have shown arthroscopic distal clavicle excision, gives good to excellent results in most patients.

Pseudodislocation of the distal clavicle

In children, the clavicle is surrounded by a thick periosteal sleeve that extends distally to the ACJ. A secondary ossification centre is present at the distal end of the clavicle that fuses with the clavicle at about the age of 19 years. Children and adolescents are much more likely therefore to fracture the distal clavicle than to dislocate the ACJ. The distal ossification centre is usually very difficult to visualize on a plain x-ray and the true diagnosis is often not appreciated. This type of injury is therefore often known as a pseudodislocation. Unless there is significant displacement, conservative management is usually recommended and there is often excellent remodelling. In markedly displaced injuries, open reduction is worthwhile, the clavicle being reduced and replaced back into the periosteal sleeve which is then repaired. Temporary stabilization is provided by a coracoclavicular screw or suture.

Rheumatoid arthritis of the acromioclavicular joint

The ACJ and subacromial bursa are said to be the primary sources of pain in 60% of patients who have rheumatoid arthritis and a painful shoulder. The symptoms as expected, consist of pain associated with swelling and tenderness over the joint. The radiological changes can be graded using the Larsen system from I to V. Treatment is best instigated by a rheumatologist initially to control the disease systemically. Localized disease in the ACJ can often be mediated by an intra-articular steroid injection and for advanced and resistant cases, ACJ excision as for degenerative arthropathy is effective.

Summary points

- Fractures and dislocations of the sternoclavicular joint are uncommon and often successfully treated non-operatively.
- There are a number of poorly defined sclerotic, sometimes inflammatory, conditions with a predilection for the medial clavicle.

Introduction

The word clavicle is derived from the Latin clavicula, ‘small key’, which refers to the musical symbol of similar shape. It describes an unusual and interesting bone in its development, function, and the disorders to which it is susceptible. It is the only human long bone that forms by intramembranous ossification. Although the central ossification centre is the first in the body to form, and is responsible for longitudinal growth in the first 5 years of life, the medial and lateral centres, which appear between 12–19 years of age, are among the latest to fuse (22–25 years).

The clavicle is the only bony connection between the upper limb and trunk, forming unusual and incongruous synovial joints at either end, each with a fibrocartilaginous intra-articular meniscus. Medially, there is a saddle-shaped sternal articulation which includes a facet with the first rib in 25% of cases. Both joints are primarily stabilized by strong extra-articular ligaments rather than capsular condensations (Figure 4.11.1). These lie some distance from the joints themselves and act as pivots, enforcing a degree of translational movement. This shearing tends to occur in the two compartments of the sternoclavicular joint with predominantly anteroposterior movements occurring between the sternum and meniscus, and superoinferior movements in the lateral compartment. At rest, the interclavicular ligament helps the superior capsular ligament to produce shoulder ‘pose’, resisting the upward force on the medial clavicle produced by the weight of the arm pulling down from laterally, across the fulcrum of the first rib and rhomboid ligaments.

![Fig. 4.11.1](image)

The sterno-clavicular joint is saddle-shaped has a fibrocartilaginous intra-articular meniscus.

The medial clavicle and its sternal articulation appear uniquely susceptible to a number of rather unusual disorders, both traumatic and atraumatic, with a very confused terminology.

Whilst subcutaneous and easily amenable to clinical examination (see Chapter 4.1), imaging is difficult. The 40-degree upwards angle "serendipity" plain radiograph is the most useful (Figure 4.11.2), but cross sectional imaging with side-to-side comparison will usually be required.
Fig. 4.11.2
Imaging is difficult. The 40-degree upwards angled ‘serendipity’ plain radiograph is the most useful, but cross-sectional imaging with side-to-side comparison will usually be required.

**Traumatic conditions (Box 4.11.1)**

Fractures and dislocations of the medial clavicle are rare, particularly by comparison with injuries to the shaft and lateral end, comprising less than 3% of injuries. Fractures are caused by high-energy compression and are almost always associated with multisystem trauma. Dislocations, however, may be entirely atraumatic anteriorly (very rarely posteriorly), especially in young adults with ligamentous laxity. In these cases, supportive treatment is usually successful, the results of open surgery poor, and the surgical risks high.

Acute anterior dislocation is caused by a blow to the front of a retracted shoulder with axial compression. Closed reduction under anaesthetic by scapular retraction over a bolster with direct pressure over the medial clavicle is usually (at least temporarily) successful, and may be maintained with a figure-of-eight sling, but redislocation is expected.

Acute posterior dislocation is much less common, caused by axial compression from a blow to the back of a protracted shoulder and may compress the structures of the neck. Closed reduction should be attempted, if necessary assisted by a towel clip, if within 7 days or so of injury, but intervention delayed longer than this is less likely to succeed and more likely to damage the adjacent vessels. Before skeletal maturity (NB 25 years!), the injury is often an occult physeal separation.

In chronic dislocations, the risks and benefits of surgery need to be carefully balanced. Preoperative imaging will include vascular studies. Excision arthroplasty is the preferred procedure with or without one of the stabilization procedures (with a thoracic surgeon on standby). Interosseous metalwork should never be used to maintain reduction in view of the risk of migration causing serious injuries including death.

**Box 4.11.1 Traumatic disorders of the sternoclavicular joint**

**Dislocation**

- Anterior:
  - Reducible
  - Likely to redislocate, but may be minimally symptomatic

- Posterior:
  - Likely to be reducible inside 1 week
  - More risk later
  - May cause neck compression

**Fracture**

- Uncommon
- High-energy compression
- Associated with multisystem trauma.

**Atraumatic conditions (Box 4.11.2)**

The investigation and diagnosis of lesions of the medial clavicle is made more difficult by the confusing descriptions and nomenclature of the very large number of eponymous and acronymous conditions beloved of rheumatologists, which are characterized by a spectrum of local and systemic inflammatory and non-inflammatory features. Having excluded tumour and hamartoma, there are four possible aetiopathologies: inflammatory (auto-immune and idiopathic), infective (acute, chronic low grade, often multifocal, and recurrent), ischaemic (Friedrich’s disease and radionecrosis), and degenerative.

**Non-inflammatory conditions**

Condensing osteitis of the clavicle was first described by Brower in 1974 and typically occurs unilaterally in women of late premenopausal years, sparing the sternoclavicular joint. It shares morphological and radiological features with osteitis of the ilium and pubis, and histologically, despite the title, there is a relative absence of inflammatory reaction. The features are often
indistinguishable from aseptic necrosis, which is more usually described in adolescents, has a similarly good prognosis, and also usually spares the sternoclavicular joint. Both disorders run a relapsing and remitting course, eventually clinically resolving. Both may be best described as a variant of osteochondrosis, and the interesting observation has been made that the clavicle, ilium, and pubis all have a fibrocartilage covering, perhaps explaining the predilection of the condition for these sites. Other suggestions have included mechanical compression and various endocrine changes.

Box 4.11.2 Sclerotic lesions of the medial clavicle

Inflammatory

- Infection
- Septic arthritis
- Osteomyelitis
- Inflammation
- Chronic recurrent multifocal osteomyelitis of Garré
- Sternocostoclavicular hyperostosis (SCCH) syndrome
- Intersternocostoclavicular ossification
- SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome
- Chronic symmetric plasma cell osteomyelitis
- Chronic sclerosing osteomyelitis
- Primary chronic osteomyelitis
- Pustulotic arthro-osteitis
- Acne-associated spondylarthropathy
- Arthro-osteitis with pustulosis palmoplantaris
- Juxtasternal arthritis and enthesitis
- Pustulotic arthro-osteitis
- Tumorous osteomyelitis.

Non-inflammatory

- Condensing osteitis
- Avascular necrosis/post-radiation
- Osteoarthritis.

Osteoarthritis tends to affect the dominant limb in perimenopausal women.

The prognosis is good for all of the listed conditions after a relapsing natural history with standard supportive measures that may include intra-articular steroid injections.

Inflammatory conditions

Arthritis

Sternoclavicular septic arthritis may occur with the same spectrum of organisms as other joints, but is characterized by an insidious onset and a tendency to abscess formation. The joint may also be involved in any of the inflammatory arthritides. Approximately 17% of patients with ankylosing spondylitis have radiological sternoclavicular changes.

Arthro-osteitis

In the presence of inflammatory changes extending into the medial clavicle, the terminology is a problem. There is a condition of low-grade inflammation of the medial clavicle that may be recurrent and multifocal (commonly symmetrical). It typically runs a relapsing and remitting course with a good overall prognosis. It was first described in children by Garré in 1893 without the help of any other investigations (just before the birth of radiography) as a chronic, relapsing, and multifocal condition, and is now considered related to a large number of other named non-suppurative inflammatory disorders (Table 4.11.1).

**PPP, Palmo plantar pustulosis.**

The sternocostoclavicular hyperostosis syndrome (SCCH) was described in middle-aged Japanese men by Sonozaki et al. as a separate entity, involving ossification of the periarticular ligaments of the sternoclavicular joint, and is probably related to diffuse idiopathic skeletal hyperostosis and ankylosing spondylitis. It has been associated with palmoplantar pustulosis in 60% of cases and also psoriasis, suggesting the connection with the SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome. It may be most appropriate to consider that the SAPHO syndrome is composed of several disorders that share some clinical, radiological, and pathological characteristics, even if the skin disorder is transient or not noticed. Even Tietze’s syndrome has been associated with similar skin lesions. Such are the diagnostic criteria that it may be fair to include many inflammatory conditions under the SAPHO heading since many have a high prevalence of associated skin disorders and therapeutic immunosuppression is reported to be of benefit. On the other hand, the prevalence of sternoclavicular pathology in patients with systemic arthritis and palmoplantar pustulosis is nearly 50% (Figure 4.11.3).

**Click to view larger**

Fig. 4.11.3

The sternocostoclavicular hyperostosis syndrome (SCCH) was described by Sonozaki et al. It has been associated with palmoplantar pustulosis.

Radiographically, mixed osteolysis with intense sclerosis is seen, often with periostitis, and the enlargement of the subcutaneous bone may become massive, suggesting a diagnosis of fibrous dysplasia, Paget’s disease, or sarcoma.

Histologically, the findings are of chronic inflammation, with mixed new bone and lysis, often with plasmacytosis. These findings are variable, and may sometimes be suggestive of bacterial osteomyelitis. The question of which conditions are caused by an infective agent either in the lesion or elsewhere, and which are best treated by antibiotics and which by immunosuppression is important and has not been answered. It is a concern that *Propionibacterium acnes*, a common skin saprophyte found in the skin lesions of severe acne, has also been isolated from the bone and joint lesions of patients diagnosed as suffering from both SAPHO and Garré’s disease, as have raised antistaphylooccin titres.

At one end of the spectrum of such disorders is frank osteomyelitis and at the other end, sternocostoclavicular hyperostosis. In between lies a less well-defined variety of musculoskeletal manifestations associated with palmoplantar pustulosis and seronegative arthropathy, perhaps best described as pustulotic arthro-osteitis.
A clinical diagnosis can often be made and biopsy is not always necessary (and in any case usually not helpful). Similarly, an isotope bone scan excludes synchronous lesions. Computed tomography is useful in delineating the extent of any hyperostosis. Magnetic resonance imaging is the investigation of choice for the sternoclavicular joint itself and the periarticular soft tissues. Laboratory tests will exclude metabolic bone disease and help with assessment of the systemic inflammatory response.

In addition to supportive measures, in the presence of inflammation, it would seem reasonable to combine rheumatological treatment of any systemic condition with a therapeutic trial of antibiotics. Although radiation therapy has been suggested for the hyperostotic syndromes it may also be a cause of the clinically similar radiation osteitis! Bisphosphonates have been used but there are few data at present on their effectiveness.

**Surgery**

In disease localized to the medial clavicle, whether traumatic, degenerative, or inflammatory, surgical excision may be expected to be curative, but symptoms are usually not sufficiently disabling for patients to undergo the procedure. Good results have been described in small series in many of the discussed conditions following resection of the medial clavicle, but emphasize the importance of either retaining or reconstructing the costoclavicular ligaments.

**Conclusion**

The medial clavicle is affected by a number of interesting and slightly unusual conditions, many of which are relatively benign and require only supportive measures. There is collection of sclerotic disorders of the clavicle that may be categorized as either inflammatory or non-inflammatory on the basis of clinical, haematological, and radiological signs. In the presence of signs of inflammation, systemic upset, or remote signs, it may be difficult or impossible to exclude infection even on biopsy. In these patients, particularly in children, a trial of antibiotics is recommended. Fortunately, surgical excision of the medial clavicle is rarely necessary, but usually successful when needed.

Disorders of the scapula

Summary points
- Sprengel's deformity causes a high riding, fixed, hypoplastic scapula
- Sprengel's deformity may be associated with Klippel-Feil syndrome
- Winging of the scapula can be caused by trapezius palsy or serratus anterior palsy
- Trapezius palsy is usually due to damage to the spinal accessory nerve
- Serratus palsy is usually caused by damage to the long thoracic nerve
- Fascio-scapulo-humeral dystrophy presents with loss of scapula control from the late teens to the late twenties
- FSHD is autosomal dominant and linked to alteration of the 4q35 gene.

Evolution and comparative anatomy

When humans assumed the erect position, the shoulder evolved with the series of complex adaptive changes exchanging stability for mobility. In our amphibian ancestry the forelimbs evolved from the longitudinal lateral folds and pectoral fins. After the migration of spinal nerves and muscle buds, the nerve fibres repeatedly divided to form a plexus and different regions of muscle tissue often combined or segmented as function evolved. Cartilage rayscalled radials arose between muscle buds to form a support structure, and the proximal portions of these radials coalesced to form basal cartilages, or basilia, of the primitive pectoral girdle. They migrated ventrally to form the ventral bar, the precursor of the paired clavicles, and projected dorsally over the thorax to form the precursor of the scapula. Articulations within the basilia developed at the junction of the ventral and dorsal segments. The basic mammalian pattern developed with articulations arising between a well-developed clavicle and sternum medially and a flat and fairly wide scapula laterally.

Four main variations of pectoral girdle are seen in mammals. Those adapted for running have lost their clavicle to mobilize the scapula further, and the scapula is relatively narrowed. Mammals adapted for swimming also lost their clavicle although the scapula is wider, permitting more varied function. The shoulder girdles modified for flying have a large, long, well-developed clavicle with a small, narrow, curved scapula. Finally, shoulders modified for brachiating (including humans) have developed a strong clavicle, a large coracoid process, and a widened strong scapula. Adaptations also seen in the erect posture were the relative flattening of the thorax in the anteroposterior dimension, leaving the scapula approximately 45 degrees to the midline and the evolution of the pentadactyl limb.

Embryological development

The limb buds, consisting of a core of mesenchyme and a covering layer of ectoderm, become visible at the beginning of the fifth week. By the sixth week of development the first hyaline cartilage models of the forelimb bones can be recognized, which will eventually form by endochondral ossification. An area, termed the interzone, which has not undergone chondrification is the precursor of the shoulder joint. The clavicle is the first bone in the body to begin to ossify. Subsequently the scapula, which at this time lies at the level of C4 and C5, also forms by intramembranous ossification. The interzone assumes a three-layer configuration, with a chondrogenic layer on either side of a loose layer of cells. At this time, the glenoid lip is discernible, although cavitation or joint formation has not occurred. The scapula undergoes marked enlargement at this time and extends from C4 to approximately T7.

Early in the seventh week the shoulder is well formed, with the middle zone of the three-layered interzone becoming progressively less dense with increasing cavitation. The scapula has now descended and spans from just below the level of the first rib and the fifth rib. The final few degrees of downward displacement occur later when the anterior rib cage drops obliquely downward. By the eighth week the upper limb musculature is well defined and the shoulder joint has the form of the adult glenohumeral joint.

Postnatal development

The postnatal development of the shoulder is mainly concerned with the appearance and progress of the secondary sites of ossification. The scapula at birth has its body and spine ossified by intramembranous ossification. The coracoid process has two, and occasionally three, centres of ossification. The first appears during the first year of life at the centre of the process with the second arising around the age of 10 years at its base. These two centres unite with the scapula around age 15 years. The acromion has two ossification centres which arise during puberty and fuse together around age 22 years. Failure of this fusion produces an os acromiale and may be present in up to 4.2% of the population. The glenoid fossa has again two ossification centres. The first appears at the base of the clavicular process around age 10 years and fuses around age 15 years. The second centre is a horseshoe shape arising from the inferior portion of the glenoid during puberty and forms the lower three-quarters of the glenoid. The vertebral border and inferior angle of the scapula each have one ossification centre, both of which appear at puberty and fuse around age 22 years.
Congenital elevation of the scapula (Sprengel's deformity)

Congenital elevation of the scapula is a rare congenital deformity first described by Eulenberg in 1863. Sprengel (1891) recognized that the deformity was caused by failure of the scapula to descend. In this condition the scapula lies high in relation to the thoracic cage and is usually rotated and hypoplastic (Box 4.12.1).

Box 4.12.1 Sprengel's deformity

- The scapula is high, rotated, and hypoplastic
- Disability is variable and relates to the degree of deformity
- Other congenital anomalies are often present: scoliosis, cervical ribs, and cervical vertebrae anomalies (Klippel–Feil syndrome)
- An omovertebral bar may be present
- Surgery is only indicated in severe cases between the ages of 3–8 years
- Techniques include extraperiosteal release, trapezius transfer, and osteotomy.

The disability is dependent on the severity of the deformity. In mild cases, the scapula is only slightly elevated and is slightly smaller than normal with minimal loss of function. In the severe cases it creates an ugly deformity with widening of the base of the neck. Occasionally the scapula can be so elevated that it almost touches the occiput and the patient's head is deviated towards the affected side. Abduction is decreased in these severe cases as the glenoid faces downwards.

Other congenital anomalies, such as scoliosis, cervical ribs, malformations of ribs, and anomalies of the cervical vertebrae (Klippel–Feil syndrome), are commonly present; rarely, one or more scapular muscles are partly or completely absent. Concomitant spine and thoracic outlet radiographs are required to identify these structural changes particularly if surgical correction is considered. An omovertebral bone together with a very straight clavicle is found in between a third and half of patients.

Surgery is only indicated in severe deformities, after consideration of the age of the patient and the severity of any associated deformities. Corrective surgery is too major to consider before the age of 3 years. However, the earlier surgery is performed after this age the better are the results, because as the child grows the operation becomes more difficult and ultimately impossible. In children older than 8 years attempts to bring the scapula inferiorly to its normal level may seriously stretch and damage the brachial plexus. Limited resection of the prominent superomedial angle may be considered after this age. It must be made clear to the parents that the results of surgery are occasionally disappointing as the deformity is never simply elevation of the scapula alone, but always complicated by malformations and contractures of the soft tissues.

Numerous methods of lowering the scapula have been described to correct this deformity. Before addressing the scapula position, consideration should be given to morcellation of the clavicle on the ipsilateral side as in severe deformities it reduces the risk of brachial plexus palsies. Many techniques of lowering the scapula have been described.

Woodward (1961) described transfer of the origin of the trapezius muscle to a more inferior position on the spinous processes. This utilizes a more cosmetic midline approach from the spinous process of the first cervical to the ninth thoracic vertebra. The patient is placed prone and draped so that the shoulder girdle and arm can be moved freely. The skin and subcutaneous tissues are undermined laterally to the medial border of the scapula. The lateral border of the trapezius is identified distally and separated by blunt dissection from the underlying latissimus dorsi muscle. Then the fascial sheath of origin of the trapezius is released from the spinous processes by sharp dissection. The origins of the rhomboideus major and minor muscles are similarly freed and separated from the muscles of the chest wall. This sheet of muscles can be retracted laterally to expose any omovertebral bone or fibrous bands attached to the superior angle of the scapula. The omovertebral bone, any fibrous band, or contracted levator scapulae are freed, taking care not to injure the spinal accessory nerve, the nerves to the rhomboids, or the transverse cervical artery. The supraspinatus part of the scapula is usually deformed and should be excised with its periosteum thus releasing the levator scapulae. The scapula can be displaced inferiorly with the attached sheet of muscles distally until its spine lies at the same level as that of the opposite scapula. With the scapula in this position, the aponeuroses of the trapezius and rhomboids are reattached to the spinous processes at a more inferior level. Postoperatively a sling or Velpeau bandage is worn for 2 weeks.

An alternative and simpler method is to lower the scapula by osteotomy. The patient is placed semiprone with the affected side uppermost. A vertical incision is made over the medial border of the scapula. The scapula is exposed by incising the periosteum along the medial part of the origin of supraspinatus and infraspinatus, which can be swept laterally. An osteotomy is made 1 cm from the vertebral border with an oscillating saw passing through the base of the spine (Figure 4.12.1). Mobility of the lateral part of the scapula is gained by removal of the medial strip of scapula above its spine. This also allows removal of fibrous bands and any omovertebral bone. Remaining fibrous bands on the inferior strip of medial scapula are also divided. The lateral part of the scapula can be protracted and lifted away from the chest wall so that a finger can be swept between subscapularis and the underlying ribs, ensuring that any adhesions or fibrous bands are divided. Once the blade of the scapula is completely mobile, the lateral portion is rotated downwards and stabilized with sutures passing through the periosteum and bone to the remaining strip. This procedure requires a longer period of immobilization in a sling for 6 weeks.
The major complication following these procedures is the significant risk of brachial plexus palsy. This risk is higher in severe deformities particularly in the presence of a straight clavicle and deformed high first rib. The other recognized complication is damage to the spinal accessory nerve on the undersurface of the trapezius.

**Winging of the scapula**

Stability of the scapula is of paramount importance to efficient shoulder function. Paralysis or weakness of the scapular stabilizing muscles causes profound loss of function.

It is of note that although we use the terms protraction, retraction, and winging, there can be few joints in the human body whose movement is so poorly defined (Box 4.12.2). We do not even have proper terms of reference regarding the range of motion of the scapulothoracic joint; somewhat surprising when we observe the remarkable range of movement maintained in patients who have undergone a glenohumeral arthrodesis. Observations are often focused on scapulothoracic rhythm, disturbance of which is a useful finding but usually reflects pathology arising from the glenohumeral or subacromial articulations rather than the scapula or its control.

**Box 4.12.2 Winging of the scapula**

- Causes profound loss of shoulder function
- May be due to trauma of the long thoracic nerve, e.g. backpackers’ shoulder
- May be involved in the postviral syndrome, neuralgic amyotrophy
- Surgical reconstruction with tendon transfers is possible.

**Loss of trapezius function**

The trapezius and levator scapulae support the entire weight of the upper extremity in the erect position (Figure 4.12.2A). In addition to their suspensory role they participate in a complicated muscle couple controlling scapulothoracic movement. The upper fibres of the trapezius and levator scapulae pull cephalad, whilst the lower fibres of the trapezius, acting with the rhomboids and the latissimus dorsi, pull the arm backwards (Figure 4.12.2B), allowing the upper fibres of trapezius to rotate the scapula.
The major cause of trapezius palsy is injury to the spinal accessory nerve (Box 4.12.2). Although the dangers of iatrogenic injury cannot be overstressed, it is important to appreciate that this palsy is commonly seen when the nerve is sacrificed during radical neck dissection for malignant disease. The ensuing disability can be so great that preservation should be encouraged if at all possible. The disability may be compounded by using the levator scapulae muscle to cover the carotid artery during this procedure. Not only is it the only other suspensory muscle, but it is also of great importance in late reconstruction of the shoulder girdle.

The spinal accessory nerve is the major nerve supply to trapezius. It exits the base of skull through the jugular foramen and passes obliquely through the sternomastoid muscle in its upper third before crossing the posterior triangle of the neck to enter trapezius. As it lies very superficially, it is vulnerable to injury and is at risk with even the simplest surgical operation in the neck region. The injury is usually not recognized at the time of surgery and the diagnosis is often delayed until the patient describes inability to abduct the arm without pain. Some of the palsies are due to neurapraxia and recover spontaneously. Electromyographic examination may be of help but if there is no recovery by 10 weeks the nerve should be explored. If the nerve is found in continuity lying in scar tissue, neurolysis may be successful, but if there is obvious discontinuity then suture or grafting is necessary. Should the repair be unsuccessful or not possible, surgical reconstruction with muscle transfers should be considered.

Reconstruction is the only option in the post-radical neck resection patients. There is a marked contrast in the subjective perception of the condition between these patients and patients with iatrogenic injury to the nerve. Many do not wish to consider further surgery and have insufficient disability to require reconstruction. The degree of disability is extremely variable which may be partly due to the dual innervation from C2 and C3 (occasionally C3 and C4) in some patients. The indications are usually not precise and depend on the activity level, age, and life expectancy of the patient.

The cause of pain in these patients may be uncertain. It is important to try and ascertain the mechanism in order to plan treatment. Pain from neurologic denervation and adhesive capsulitis may be a factor in the early phase. Ptosis of the scapula may cause discomfort by a brachial plexus traction radiculitis. More commonly the pain appears to be due to fatigue and functional impingement (Figure 4.12.3).
The procedures to restore the function of the scapulothoracic articulation must address not only the winging, but also the ptosis due to loss of the scapular suspension mechanism. The complex nature of force couples makes substitution of even one muscle acting in a single plane difficult. The Eden–Lange tendon transfer of levator scapulae and the rhomboids (Figure 4.12.4A) is probably best for near-normal. These three muscles are used to replace the upper, middle, and lower portions of the trapezius respectively.

The alternative procedures, originally used in patients with facial nerve paralysis in which the spinal accessory nerve was used as a motor for the facial muscles, have significant disadvantages. Dewar and Harris (1950) transferred the levator scapulae insertion laterally to substitute for the upper trapezius, and used a fascial sling in place of middle and lower parts of trapezius (Figure 4.12.4B). The slings were passed from the vertebral border of the scapula to the spinous processes of the second and third thoracic vertebrae. Unfortunately, these slings used in this procedure and the many variations described tend to stretch with time. If soft-tissue reconstruction fails, the only other option is limited to scapulothoracic fusion. This procedure has also been suggested as an option as a primary procedure in cases where heavy demands are anticipated. Conservative treatment has not been found successful other than treating concomitant adhesive capsulitis.

Loss of serratus anterior function

On elevation of the arm as the upper fibres of trapezius rotate the scapula, the serratus anterior assists by rotating the scapula forwards and maintaining the vertebral border of the scapula in firm apposition with the chest wall in all positions (Figures 4.12.2 and 4.12.3). Paralysis of this muscle may limit active elevation, but more frequently presents as deformity with fatigue pain on elevation of the arm. The fine tuning of scapula movement is of paramount importance in shoulder performance. In many vigorous shoulder activities the scapula is positioned so that the glenoid centre line and axis of the humeral head are closely aligned, for example, in a boxer’s punch, bench press, throwing action, and tennis shot. It is easy to demonstrate the effect of fatigue if the glenoid centre line and humerus are not aligned. Try maintaining the arm or lifting an object with the scapula deliberately retracted. With the scapula correctly protracted, the glenohumeral joint stabilizes with ease, making more muscle action available for power.

Long thoracic nerve palsy is the major cause of serratus anterior weakness. This nerve is formed from the roots of C5, C6, and C7 immediately after leaving their intervertebral foramina. It runs collaterally to the main brachial plexus and is often spared in traction lesions. The cause of long thoracic nerve palsy is often difficult to explain, but may follow viral illness, carrying objects on the shoulder, open iatrogenic injury in the axilla, lying on the operating table, and long periods of anaesthesia. It is also described after recumbency for a prolonged period of time and immunization, but these causes are rarely encountered in clinical practice. Kauppila and Vastamäki (1995) presented 27 cases of iatrogenic causes. These occurred during seven operations for first rib resection, four mastectomies with axillary clearance, two scalenotomies, two surgical procedures for spontaneous pneumothorax, and two infraclavicular plexus anaesthetic blocks. Nine occurred after general anaesthesia and one after spinal anaesthesia. Only one of these cases recovered spontaneously.

Palsies occurring after closed trauma are usually traction lesions and spontaneous recovery can be anticipated. Recovery is usually seen by 1 year. After this time the prognosis is poor, although some cases may still recover at 2–3 years.

The major problem is pain with difficulty in lifting the arm and lifting weights (Figure 4.12.5). Discomfort from the prominent scapula when sitting against a chair back is common. The shoulder may also be painful as a consequence of functional impingement within the subacromial space. There is little useful treatment; braces are uncomfortable and rarely tolerated, but may be of value in selected patients required to lift at work. Many patients learn to live with the disability and thus few come to surgery. There is no place for nerve repair and the only option is surgical reconstruction. Pectoralis major transfer with a fascia lata graft to the lower pole of scapula gives gratifying results (Figure 4.12.6).

Box 4.12.3 Loss of trapezius function

- Usually caused by damage to the spinal accessory nerve
- Surgical reconstruction is possible (the Eden–Lange transfer of the levator scapulae and the rhomboids).
Global weakness of the scapular stabilizers

Generalized weakness of the scapular stabilizers is commonly seen with many injuries and conditions affecting the shoulder. Careful examination will often demonstrate minor winging even in the absence of stiffness of the glenohumeral joint. When the weakness is severe, the imbalance as a consequence of relatively greater strength of deltoid pulling up the scapula causes winging on elevation of the arm. Duchenne showed this mechanism of winging of the scapula in his treatise *Physiology of Motion* (Figure 4.12.7). This is the situation in muscular dystrophies affecting the muscles of the scapula.
Muscle dystrophies should be suspected in cases of atraumatic onset of weakness and atrophy occurring in first and second decade. The most common type is fascioscapulohumeral dystrophy (FSHD; Landouzy–Déjerine disease) (Box 4.12.4). A positive family history is common, as this is an autosomal dominant condition with sporadic cases appearing very occasionally. Recent genetic linkage studies have mapped the FSHD gene to chromosome 4q35. On presentation it is usually unilateral, with the other side not developing until months or even years later. Involvement of the facial muscle may be detected early, with the child’s inability to whistle or blow out candles on the birthday cake. This condition has a variable muscle involvement and prognosis. There is usually good life expectancy and slow deterioration. The deltoid is spared but loses its stable origin and tilts the scapula rather than raising the humerus. The cosmetic appearance due to the selective muscle loss is characteristic and may cause difficulty with clothing (Figure 4.12.8).

**Box 4.12.4 Fascioscapulohumeral dystrophy**

- Autosomal dominant inheritance
- Unilateral presentation with slow development of both shoulders
- Scapulothoracic fusion improves function.

In this condition, muscle involvement is global, precluding muscle transfer. If the function of the deltoid muscle is preserved and the disability is severe, scapulothoracic fusion should be considered. This operation recreates the stable origin by anchoring the scapula to the fourth, fifth, and sixth ribs. This procedure was described by Copeland and Howard in 1978. There are many technical variations performed but the principles remain the same. The results in 11 shoulders were reported with an average range of 90 degrees of flexion and 100 degrees of abduction. There was no deterioration with time and the vital capacity was preserved. The most frequent complication reported is stress fracture, which is treated by immobilization in a sling.

**Scapulothoracic fusion**

The patient is initially placed supine to harvest sufficient corticocancellous bone graft from the iliac crest. The patient is then moved into the prone position with the arm free and supported on an adjustable stool.

An incision is made along the medial border of the scapula. The atrophied muscles on the deep and superficial surfaces of the scapula are stripped laterally for at least 2cm. The subjacent three ribs (usually the fourth, fifth, and sixth) are exposed by subperiosteal dissection. Retractors are placed under the ribs to protect the pleura. Corticocancellous grafts are placed between each rib and the scapula. Three to four screws are inserted taking care that they do not protrude into the pleura. Chips of bone are packed between the grafts. The shoulder should be fused and held in 50 degrees of abduction and 30 degrees of forward flexion with sufficient internal rotation to place the hand in front of the mouth.

A spica cast or shoulder brace is worn for 3 months. The abduction is reduced slowly over a week by adjusting the brace or replacing the spica with foam wedges.

An alternative method of fixation is with Luque wires through drill holes in the scapula. A pelvic reconstruction plate on the posterior surface can be incorporated to increase the strength of fixation. This method allows early mobilization and a sling rather than a spica.
Loss of the scapular suspensory mechanism

The ligamentous structures, that is, the conoid and trapezoid parts of the coracoclavicular ligaments, are important static suspensory structures and constraints to scapular movement. They not only prevent the scapula from dropping but also prevent posterior displacement of the clavicle and protraction of the scapula (Figure 4.12.1).

An injury commonly not recognized is described by Rockwood and Matsen and termed ‘scapulothoracic dissociation’. This results from violent lateral displacement of the scapula causing disruption of the soft tissues with separation of the acromioclavicular joint or fracture of the clavicle. Vessel or brachial plexus damage may occur with these injuries. There is also a more discrete type of injury in which there is stretching of the scapular stabilizers usually associated with type IV acromioclavicular joint separations and displaced clavicular fractures, particularly those of the lateral third. The increased distance from spinous processes to medial border of scapula can be appreciated on clinical examination or on the chest radiograph. Similarly, protraction of the scapula with soft-tissue stretching is seen with malunion and non-union of the clavicle. The protraction and winging can be accentuated by resisted external rotation with the arm by its side.

Restoration of the skeletal injury even with repair of the disrupted ligaments may be insufficient to correct the deformity, and specific rehabilitation of the scapular muscles must be stressed.

Pseudowinging or obligatory winging

Obligatory winging is seen following glenohumeral fusion. This is rarely of significance, with the exception of arthrodesis for brachial plexus injury. In some cases of C5 and C6 root avulsion, the upper part of serratus anterior may be denervated. This should be assessed prior to surgery.

Injuries to the upper roots of the brachial plexus during childbirth may also cause winging of the scapula. Anterior contracture and capsular tightness develops with posterior subluxation of the humeral head and stretching of the posterior capsule. The glenohumeral joint becomes fixed in abduction, so that when the shoulder is forced into adduction and external rotation, superior winging due to the contracture occurs—known as the scapular sign of Putti.

An abduction contracture of deltoid may cause secondary winging. This is not so rare and many cases are reported, so it should be looked for in clinical practice. It is often bilateral and usually affects the anterior part of deltoid. Two types occur; congenital or secondary to multiple intramuscular injections. The treatment is by release of fibrous bands and manipulation. A defect in deltoid may result and require closure by transfer of posterior deltoid anteriorly. Displacement of the scapula and pseudowinging may be seen with large subscapular osteochondromas.

Voluntary winging

Rowe (1988) described four patients with voluntary winging. A more common appearance of winging is seen in cases of habitual or voluntary glenohumeral instability. In this situation the ability to sublux the shoulder requires winging of the scapula to destabilize the glenohumeral joint. The role of the scapula in this poorly understood condition is well demonstrated by observing the persistent muscle activity of the muscles controlling the scapulothoracic movement after brachial plexus anaesthesia blocked in patients with severe dysfunction. The importance of addressing the task of re-educating these muscles is apparent.

Snapping scapula

Presentation with a tactile and acoustic clunk localized at the superomedial corner of the scapula is not infrequent. This phenomenon, termed a snapping scapula, is usually encountered in the third decade and normally only requires treatment if painful (Box 4.12.5).

Box 4.12.5 Snapping scapula

- Usually no identifiable bony bump can be found
- Muscle retraining is often beneficial
- Surgery is only rarely indicated.

A variety of causes have been reported but the condition remains poorly understood. A history of trauma is not uncommon, but fractures of the scapula and ribs are extremely rare causes. More commonly the onset is gradual. A prominent Luschka’s tubercle, excessive forward curvature of the superomedial border, exostoses, or tumours are potential skeletal causes. These identifiable causes are comparatively rare and the majority of patients present with poor posture with sagging of the shoulder girdle such that the superomedial corner descends and impinges on the chest wall.

Plain radiographs, including a carefully positioned lateral view, will exclude an exostosis or obvious bony cause. Computed tomography is of limited value and difficult to interpret. Occasionally narrowing between the superomedial corner and the chest wall can be demonstrated in comparison to the contralateral side. Magnetic resonance imaging has little place, with the exception of defining the rare cases of tumor.
The treatment is usually non-operative; careful assessment and correction of abnormal posture is essential. The snapping or grating often disappears when the scapula is passively elevated and retracted. This can be demonstrated to the patient and is helpful in increasing the patient’s understanding of the rehabilitation programme. Before abandoning these measures in favour of surgery it is important to consider the natural history and the not infrequent association with psychological stress. It is interesting to note that very few cases fail to resolve with time. However, this can be a disabling condition and can be relieved by surgical resection of the superomedial scapula. Some authors advocate arthroscopic resection, but since the surgical landmarks are few and important nerves are close by, this technique should be left to a few superspecialists.

Reverse geometry replacement

Summary points

♦ RSR provides a unique tool for patients with cuff tear arthropathy
♦ RSR is a useful tool for fractures, tumours, and revision of shoulder replacements
♦ However RSR comes with specific complications such as scapular notching and acromial fractures
♦ The 10 year results of RSR show that prosthetic loosening is no more frequent than with anatomical prostheses.

Introduction

Conventional shoulder arthroplasty has been extremely successful in many forms of arthritis. The aim is to resurface the arthritic joint, but also to restore joint biomechanics. Deficiency of the soft tissues, and in particular of the rotator cuff, is therefore a major problem. Contractures can be released, the subscapularis can be lengthened, but an irreparable cuff tear is by definition an insurmountable obstacle to restoring normal biomechanics.

Whilst a tear is the most common cause of cuff dysfunction, there are other situations where the proximal humeral anatomy is distorted and the cuff is either physically or functionally compromised. These include certain fractures and fracture sequelae, as well as certain revision situations. In all of these cases poor active elevation and an unstable centre of rotation secondary to a deficient cuff cannot be corrected by a conventional shoulder prosthesis.

Historical perspective

Neer recognized the challenge posed by arthrosis associated with massive irreparable cuff tears and suggested that it was realistic to pursue ‘limited goals rehabilitation’. The limited results of hemiarthroplasty in this setting have been confirmed by several other authors who reported inconsistent pain relief and small improvements in active elevation.

Conventional total shoulder arthroplasty fared no better, as superior eccentric loading of the glenoid component by the unstable humeral head increased the risk of premature loosening, the so-called rocking horse phenomenon.

In the early 1980s, a number of constrained shoulder prostheses were introduced. Increased constraint stabilized the centre of rotation, but at the expense of premature aseptic loosening, and most never progressed beyond the experimental. This same lesson had already been learned with excessively constrained prostheses in other joints.

In 1985, Grammont introduced a revolutionary design of semi-constrained reverse geometry total shoulder replacement (RSR). The idea of reversing the ball and the socket was not new. However, previous designs had sought to preserve the shoulder’s anatomical centre of rotation by using a glenoid component shaped like a chess pawn, with a small head offset from the glenoid base-plate by a neck. Grammont’s prosthesis, the Delta, used a large hemispherical glenoid component applied directly to the surface of the glenoid in order to minimize torsional stresses, yet stabilize the centre of rotation and optimize range of movement.

This design has progressed well beyond the experimental and its popularity has encouraged a number of imitations, each striving to ‘improve’ on the original design.

Biomechanics

Intact rotator cuff

Shoulder elevation is a rotatory movement requiring a muscular moment to overcome the moment resulting from the weight of the arm. In practice, this is provided by the deltoid and the supraspinatus, but the initial forces produced by the deltoid when the arm is alongside the body are predominantly vertical shear. It is the role of the rotator cuff to oppose this upward force and stabilize the centre of rotation, in order to convert a vertical linear force into a rotatory movement. A useful analogy is of a person standing on the edge of a cliff holding a ladder on a rope that is secured to a rung halfway down its length. If they pull on the rope, the ladder will simply slide up the cliff. However, if they place their foot on the top rung of the ladder and then pull on the rope, the ladder will swing away from the cliff.

The situation is, however, a little more complex than this. The cuff does not simply oppose the vertical component of the deltoid, but also generates compressive forces that help to stabilize the centre of rotation in the sagittal as well as in the coronal plane. Furthermore, the deltoid itself also generates compressive forces as elevation increases, and beyond 60 degrees these compressive forces exceed its vertical shear force, thus diminishing the role of the cuff.

Deficient rotator cuff

Post defined a massive rotator cuff tear as measuring 5cm or more in the sagittal plane. This is, however, a somewhat arbitrary
figure, and a massive tear is perhaps more usefully defined as one involving at least two complete tendons. In practice, this means the supraspinatus plus the infraspinatus, and/or the subscapularis. Any remaining cuff is also likely to be degenerate, and its function may be further compromised by fatty degeneration of the muscle bellies.

Without a functional cuff, the unopposed upward force generated by the deltoid muscle causes the humeral head to migrate proximally and ultimately to abut the acromion. It is still a matter of some speculation why certain patients are able to maintain useful active elevation despite this biomechanical disadvantage, yet others are not and exhibit what has been termed pseudoparalysis. An intact coracoacromial arch should provide a fulcrum to stabilize the centre of rotation, so why do some patients lose active elevation? This may sometimes be explained by pain inhibition of the deltoid, yet pseudoparalysis is often painless. In these cases, upward migration of the humerus is probably sufficient to functionally lengthen and thus seriously weaken the deltoid. Furthermore, a massive cuff tear, particularly one involving subscapularis, may destabilize the centre of rotation of the shoulder in the sagittal as well as in the coronal plane. The humeral head may therefore sublux anteriorly as well as superiorly, thus diminishing the fulcrum provided by the acromion.

A massive cuff tear is often a gradual process of cuff wear rather than a sudden catastrophic failure of the cuff. This means that the bony surfaces have the opportunity to remodel, a process which can eventually lead to acetabularization of the glenohumeral joint (Figure 4.13.1). This adaptive process has been described by Hamada in five stages:

- **Stage 1**: a balanced cuff tear with no upward migration of the humeral head (acromiohumeral distance more than 6mm)
- **Stage 2**: upward migration of the humeral head without any secondary bony changes (acromiohumeral distance 5mm or less)
- **Stage 3**: remodelling of the subacromial space with erosion of the undersurface of the acromion and the greater tuberosity
- **Stage 4**: glenohumeral narrowing in addition to stage 3, with predominantly superior erosion of the glenoid
- **Stage 5**: collapse of the humeral head in addition to stage 4 (this corresponds to true cuff tear arthropathy as described by Neer).

**Principles of reverse geometry shoulder replacement**

As mentioned earlier, previous attempts at RSR had used a glenoid component shaped like a chess pawn in order to restore the centre of rotation to its anatomical location (Figure 4.13.2A). This meant that the upward force of the deltoid was applied to the head of the glenoid component, and the neck of the component provided a lever arm. The end result was the application of excessive torsional forces to the glenoid base-plate causing early loosening. What is more, the small size of the glenoid head meant that impingement between the components limited the potential range of movement. Broström published the only series in the literature for this type of design (the Kessel prosthesis). Pain relief was achieved in 90%, but average active elevation was only 35 degrees and the reoperation rate was 26%.
The Delta RSR was originally designed for elderly patients with painful cuff tear arthrosis who had failed to respond to conservative measures. In essence this meant Hamada stages 3–5 (Figure 4.13.2B). This had the following consequences:

- The centre of rotation was medialized, thus minimizing torque on the glenoid component
- The humerus was displaced medially and distally, thus retensioning the deltoid
- Impingement between the components was minimized, thus optimizing range of movement.

Grammont was therefore facing a formidable challenge. His prosthesis needed to stabilize the centre of rotation in the absence of a functional cuff, restore a functionally weakened deltoid, optimize the range of movement allowed by the prosthesis, yet avoid premature loosening.

The crucial element of his design was a large hemispherical glenoid component applied to the glenoid without a neck (Figure 4.13.2B). This provided superior pullout strength as compared to a central peg alone, or to non-locking screws. The superior screw is therefore placed towards the base of the coracoid and the inferior one into the inferior pillar of the scapula as these represent the thickest areas of the bone in the scapula. This will be discussed later on the subject of scapular notching.

Medialization of the centre of rotation

The use of a hemispherical component applied directly to the glenoid means that the centre of rotation is at the bone–prosthesis interface. There are therefore no rotational forces applied to this interface as there were with designs that used a neck to preserve a more anatomical (lateral) centre of rotation (Figure 4.13.2C).

Displacement of the humerus

The humeral component articulates under the glenoid hemisphere, which means that the humerus is displaced medially and distally relative to its normal position. In the normal shoulder the middle fibres of the deltoid course around the greater tuberosity, giving the shoulder its rounded contour. The tuberosity effectively acts as a cam, increasing the tension in the deltoid muscle as well as altering the angle at which it acts on the humerus. Medial displacement of the humerus removes this cam effect and the deltoid has a more linear course between the acromion and its humeral insertion, effectively lengthening the muscle. It is therefore vital that the humerus is also displaced distally, not only to restore the deltoid tension that was lost as a result of the deficient cuff (and the consequent upward migration of the humeral head), but also to compensate for this effective lengthening of the deltoid. Clinical measurements have demonstrated that mean lengthening of the upper limb following RSR is 1.5cm.

Component impingement

As has been well documented in hip arthroplasty, rotation around a small sphere is typically limited by impingement between the components. In the shoulder, scapular rotation can compensate to a degree for limited glenohumeral movement, but the use of a large glenoid hemisphere maximizes component excursion. Furthermore, in the absence of a neck on the glenoid component, a larger hemisphere also reduces the risk of impingement between the humeral cup and the inferolateral aspect of the scapula. This will be discussed later on the subject of scapular notching.

Minimizing aseptic loosening

The most important factor in minimizing the risk of premature loosening of the glenoid is medialization of the centre of rotation and the attendant abolition of torsional forces at the bone–prosthesis interface. However, particularly during the earlier stages of elevation, the glenoid component is nevertheless subjected to significant shear forces that may also jeopardize glenoid fixation.

Grammont’s first design for the glenoid component was a monoblock which fitted over and around the glenoid like a barrel and was fixed with cement. However this was rapidly abandoned in favour of the current design which provides superior fixation in the limited bone stock of the scapula and greater resistance to shear forces. The glenoid component now has two parts: the metaglene and the glenosphere.

The metaglene is a circular baseplate with a central pillar and a hydroxyapatite coating. Its fixation to the glenoid is augmented by two divergent screws whose heads lock into the plate, as well as two non-locking screws. Not only is the bone-stock limited by the shape of the scapula, but in many of these elderly patients the bone itself is of poor quality. The locking plate configuration therefore provides superior pullout strength as compared to a central peg alone, or to non-locking screws. The superior screw is aimed at the base of the coracoid and the inferior one into the inferior pillar of the scapula as these represent the thickest areas of bone in the scapula medial to the glenoid.

The hemispherical glenosphere fits over the metaglene and is fixed with a peripheral morse taper and a central countersunk screw.

Massive irreparable cuff tear

The Delta RSR was originally designed for elderly patients with painful cuff tear arthrosis who had failed to respond to conservative treatment.
measures. In essence this meant Hamada stages 3–5 (Figure 4.13.3). However, patients without bony changes (Hamada stage 2) who fail to respond to simpler surgical procedures such as arthroscopic debridement and biceps tenotomy may also benefit from RSR.

![Fig. 4.13.3](image)

Cuff tear arthrosis treated with Delta RSR. A) Stage 4 cuff tear arthrosis. B) Glenoid component positioned low with slight inferior overhang. C) No notch at 18 months.

Whilst most authors agree that RSR should be reserved for patients over the age of 70 years, most series do include a number of patients who are younger than this. Those who still have active elevation above shoulder height despite cuff-tear arthrosis may obtain good results with a conventional hemiarthroplasty. In the presence of painful pseudoparalysis, the case for RSR in a patient under the age of 70 becomes stronger, but both surgeon and patient should be aware of the uncertain long-term results, and each case should be judged on its individual merits.

**Revision surgery**

RSR is indicated for revision cases where there is either significant distortion of the proximal humeral bony anatomy or a deficient rotator cuff. The most common situation where this is encountered is in a fracture hemiarthroplasty that has failed because of tuberosity non-union or malunion.

**Fracture sequelae and acute fractures**

Painful malunion or non-union of a three- or four-part proximal humeral fracture is another difficult surgical situation. Hemiarthroplasty alone cannot restore cuff function unless combined with osteotomy of the tuberosities, but the results of this are often disappointing and there is a high rate of tuberosity non-union. RSR offers a solution without the need for tuberosity osteotomy (Figure 4.13.4).

![Fig. 4.13.4](image)

Four-part fracture non-union treated with Delta RSR. A) Non-union with very poor bone quality. B) Delta RSR.

In the acute displaced four-part fracture, hemiarthroplasty remains the treatment of choice, but accurate and durable reconstruction of the tuberosities around the prosthesis can present a considerable challenge. Malposition, non-union, or migration of the
tuberosities are significant risks and can seriously compromise results. RSR has been suggested as an alternative, particularly if the tuberosities are comminuted or osteoporotic as is often the case in the elderly.

**Results**

Cuff tears have a high prevalence in the elderly, but few cause sufficient symptoms to warrant a RSR. Furthermore even the original RSR, the Delta, is still quite a new prosthesis. Most series are therefore relatively small and follow-up is at best short to medium term.

Only five series with more than 20 patients have been published for the Delta RSR to date (Table 4.13.1). As one might expect, the results for primary reverse arthroplasty are significantly better than for revision surgery. In the largest series to date (Wall et al., 2007), elevation improved from 76 degrees to 142 degrees in the CTA group, but from 58 degrees to 118 degrees in the revision group. Constant score improved from 27.7 to 65.1 in the former versus 19.7 to 52.2 in the latter.

* Age adjusted Constant score;

** but 0% in the CTA group. *, degrees; CTA, cuff tear arthrosis; FS, fracture sequelae; rev, revision.

In the only published review of acute three- or four-part fractures treated with RSR, mean active elevation was 97 degrees despite secondary displacement of the tuberosities in 53%. Mean age/sex adjusted Constant score was 66%. Unlike hemiarthroplasty, clinical results were not influenced by tuberosity healing.

Whilst RSR has been shown to restore active elevation, active external rotation is not significantly improved. The main determinant of postoperative active external rotation is therefore the preoperative condition of the posterior cuff. Latissimus dorsi transfer has been described in association with RSR. Active external rotation did not improve significantly with the arm at the side, but functional external rotation in the Constant score did. The authors argued that this resulted in a better ability to position the hand in space and thus superior function.

Survivorship analysis of a multicentre series of 80 cases demonstrated 10-year survival of 91% for revision and 84% for glenoid loosening, but only 58% for ‘absolute Constant score <30’ as an end point. Confidence intervals were, however, wide.

**Complications**

Reported complication rates range from 19–50%, but rates vary considerably between primary and revision cases. In the largest series to date, a complication rate of 13% was reported for primary surgery as opposed to 37% for revision cases. This large difference has been confirmed by others.

As well as the complications that affect conventional shoulder arthroplasty, there are three that appear to be a particular problem with the reverse design, namely notching, instability, and acromial fracture.

**Notching**

Whilst the absence of a neck on the glenoid component conveys great benefits, the reduced offset between the humerus and the scapula can also have a significant detrimental effect: impingement between the superomedial aspect of the humeral component and the lateral pillar of the scapula just below the glenoid. This commonly results in damage to the humeral cup and the appearance of a notch on the scapula. This has been reported in 44–68% of cases.

In many cases the notch is small and does not extend as far as the inferior screw, but it can extend to and even beyond this screw.
in up to 28% of cases (Figure 4.13.5). These larger notches are difficult to explain on the basis of physical impingement alone, and are probably due to osteolysis induced by polyethylene wear particles released from the damaged humeral cup.

![Click to view larger](image)

Fig. 4.13.5

The risk of notching may be reduced by inserting the glenoid component with a slight inferior overhang relative to the glenoid in order to minimize the physical impingement (Figure 4.13.3). This has been confirmed in a cadaveric study and also a retrospective clinical study.

Despite the high prevalence of notching, loosening of the glenoid component has not been a significant problem to date, even with very large notches. It should be noted, however, that there are no long-term reviews in the literature and notching is arguably the greatest threat to long-term survival of RSR. Because of this, most authors recommend that RSR should be reserved for patients over the age of 70 at present.

**Instability**

In the absence of a functional cuff, a semi-constrained reverse prosthesis depends on deltoid tension to maintain compression between the congruent joint surfaces. Inadequate tension can cause instability that may be addressed by increasing the thickness of the humeral cup or adding a neck extension under the cup in order to increase deltoid tension.

**Acromial fracture**

At the other end of the spectrum, excessive deltoid tension can cause a fracture of an acromion that may have been eroded and weakened preoperatively by the action of the humeral head (Figure 4.13.6). However, such fractures are often asymptomatic and may present as incidental radiological findings.

![Click to view larger](image)

Fig. 4.13.6

The future of reverse geometry shoulder replacement

The Delta RSR has proved to be extremely popular as it offers a unique solution to a difficult orthopaedic problem. It has therefore encouraged a number of imitations with a variety of purported improvements. Several of these prostheses are very close to the Delta with small changes designed essentially to improve ease of implantation. Only time will tell whether any of these small changes have any unforeseen side effects.

There are, however, some new reverse designs that have moved further away from the Delta concept, mainly in an effort to reduce notching. The danger is that these changes may sacrifice the principles which have made the Delta RSR successful. For example, one proposed solution has been to use a glenoid component that is between a sphere and a hemisphere. This may reduce the risk of impingement between the humeral component and the scapular neck, but it does so by lateralizing the centre of rotation relative to the bone–prosthesis interface, in effect reintroducing a neck onto the glenoid component (Figure 4.13.3C). Although the offset is not as great as on older unsuccessful reverse designs, it remains to be seen whether it creates sufficient torsional forces at the glenoid component–bone interface to induce premature loosening.

The Delta itself needs longer follow-up in order to determine whether notching is a threat to its survival. Furthermore, whilst it has been shown retrospectively that a low position of the metaglene is associated with a reduced incidence of notching, prospective studies are required to confirm that this can be reliably achieved and that notching can indeed be avoided or at least minimized.

Conclusion

Modern RSR has proved itself as a useful tool in the treatment of a number of conditions where conventional shoulder arthroplasty offers limited and uncertain results because of deficient cuff function. It has been shown to provide reliable pain relief and also to restore active elevation, though active external rotation often remains limited. However, it is important to remember that only short-to medium-term results are available at present. Early loosening has not been a problem, but notching could potentially lead to failure in the longer term. Careful patient follow-up is therefore essential.

Further reading

Summary points

- History: presenting complaint; past medical history.
- Examination: inspection; palpation; movement; special tests.

Introduction

In the assessment of elbow problems a detailed history is essential. This should include information regarding the patient’s age, sex, hand dominance, and occupation. In addition, a full description of the presenting complaint, previous elbow problems, the patient’s hobbies or sporting activities, and previous medical history must also be recorded.

Presenting complaint

Most patients presenting with elbow disorders report pain usually associated with localized tenderness and/or reduced range of movement. They may also describe the inability to perform specific activities. It is important to document the duration of symptoms and exacerbating or relieving factors. The nature of the pain is important to document, whether this radiates or if there are any associated symptoms. These may include swelling, locking, or reduced range of movement. These symptoms usually occur in combination. The patient should be asked specifically about previous elbow problems and whether there is any history of trauma or surgical procedures. Pain in other joints is also relevant as the elbow may be part of a systemic illness, such as inflammatory arthropathy.

In common with other upper limb presentations it is important to ask about neck symptoms and any neurological symptoms in the upper limbs.

Past medical history

This should include a general past medical history to assess whether the patient would be suitable for surgery if this is required. It is also important to ask about current medication as this often indicates medical comorbidities that the patient may not initially have mentioned. Any family history should be noted as this may bring to light problems such as haemophilia or osteochondromatosis.

A social history must include details of the patient’s occupation, sporting activities and hobbies, together with details of their alcohol intake and smoking history. All of these may impact on the underlying diagnosis, treatment options, and rehabilitation.

Examination

Inspection

The whole of both upper limbs must be exposed in order to compare the symptomatic and contralateral sides.

Before the patient is asked to do anything the posture of the upper limbs should be noted. At this stage it is also sensible to examine the axilla for scarring which may impact on upper limb function. The elbow should then be inspected for scars (traumatic or surgical), or obvious swelling which may be caused by inflammatory arthropathy, acute injury, or neoplastic lesions. There may also be evidence of psoriasis or paper-thin skin indicative of Ehlers–Danlos syndrome. Examination of the hands for evidence of intrinsic muscle wasting that may indicate ulnar nerve pathology is also essential.

Palpation

A systematic approach to palpation of the elbow will avoid missing relevant signs (Box 5.1.1).

Box 5.1.1 Palpation of the elbow

- Lateral:
  - Lateral supracondylar ridge
  - Lateral epicondyle and common extensor origin
  - Infracapsular recess
  - Radiocapitellar joint
• Radial head

♦ Posterior:
  • Olecranon bursa
  • Bony anatomy
  • Triceps

♦ Medial:
  • Ulnar nerve
  • Medial epicondyle and common flexor origin
  • Medial supracondylar ridge

♦ Anterior:
  • Brachioradialis
  • Biceps tendon
  • Lacertus fibrosis
  • Brachial artery.

Palpation is most easily performed with the patient sitting and the elbow at 90 degrees. Palpation of the lateral and anterior aspect is best carried out standing in front or to the side of the patient. Palpation of the medial and posterior aspect of the elbow is more comfortably undertaken by standing behind the patient with the shoulder slightly abducted.

It is suggested that palpation of the elbow begins on the lateral side. However, if the examiner feels that this may cause pain it is better to start on the medial side to prevent the patient becoming apprehensive and therefore making further evaluation of the elbow difficult. The lateral supracondylar ridge should be palpated and any tenderness noted. Progress should be made down the ridge to the lateral epicondyle onto the common extensor origin and then down onto the lateral ligament complex.

The extensor carpi radialis longus can be assessed by resisted wrist extension with radial deviation and the extensor carpi radialis brevis by resisted wrist extension in neutral. Any pain reproduced may point the clinician towards a diagnosis of lateral epicondylitis. The infracondylar recess (recess between lateral condyle and radial head) should be palpated looking for an effusion (fluctuant swelling) or synovial hypertrophy (boggy swelling). The radiocapitellar joint should be palpated in conjunction with pronation and supination of the forearm, and flexion and extension of the elbow looking for subluxation or dislocation of the radial head, or radiocapitellar crepitus.

Palpation should then progress to the olecranon. Any tenderness or swelling may be indicative of an olecranon bursa. The relationship between the tip of the olecranon and the epicondyles should be assessed in both flexed and extended positions. In the extended position the condyles and the olecranon should form a straight line. With the elbow at 90 degrees these bony landmarks form an isosceles triangle (Figure 5.1.1). Any abnormality in this may indicate a previous fracture or congenital abnormality. Whilst palpating posteriorly the triceps should be examined under resistance in order to assess for a partial or complete rupture.

![Click to view larger](image)

Fig. 5.1.1

With the elbow flexed the two epicondyles and the tip of the olecranon form an isosceles triangle. When the elbow is extended they form a straight line if the elbow is normally located.

Moving towards the medial side the ulnar nerve should be palpated behind the medial epicondyle. Its presence should be noted and if it cannot be easily palpated in its usual location then palpation anterior or over the medial epicondyle may reveal a subluxed ulnar nerve (present in 10% of patients). Flexion and extension of the elbow whilst palpating the ulnar nerve may make this more
obvious. Tinel’s sign may be positive in cases of ulnar neuritis and if palpation does indicate ulnar nerve pathology at the elbow the examiner should carry out a neurological examination of the hand.

Palpation of the medial epicondyle and common flexors may reveal signs of medial epicondylitis (tenderness and reproduction of pain on resisted wrist flexion). Careful palpation may distinguish this from pronator syndrome, which would be indicated by tenderness over the belly of pronator teres.

Anteriorly the brachioradialis muscle, the biceps tendon, and lacertus fibrosis can be palpated. Palpation of a normal biceps tendon is relatively easy but after a rupture there may be quite a lot of swelling and tenderness which makes palpation more difficult. If this diagnosis is suspected then resisted flexion and resisted supination should be assessed. The lateral hook test involves the examiner’s index finger being hooked under the distal biceps from the lateral side. In a normal tendon this is possible but in the ruptured tendon it is impossible to hook the tendon.

Movement

Movement of the elbow is best assessed with the patient standing. It is essential to compare both upper limbs.

With the arms by the side, alignment should be assessed with the elbow in full extension looking for any valgus or varus deformity (Figure 5.1.2). The carrying angle is on average 10 degrees in males and 15 degrees in females. A varus deformity is always abnormal and if present is usually the result of a childhood supracondylar fracture. A valgus deformity is due to loss of height of the lateral column which may be secondary to a previous fracture of the distal humerus or avascular necrosis of the capitellum. If a valgus deformity is present the ulnar nerve should be assessed as the patient may have tardy ulnar nerve palsy.

If there is longstanding valgus or varus deformity then stability of the elbow should be assessed as instability secondary to attenuation of the ligaments may be present.

In a normal elbow, the carrying angle is valgus in extension but becomes varus in full flexion.

If the patient does not have any problems with the shoulders, elbow flexion and extension is best assessed with the shoulder at 90 degrees of abduction and with the forearm in full supination. The patient is then asked to fully extend and flex the elbow (Figure 5.1.3). This method will pick up even quite subtle loss of movement when compared to the normal elbow. To document the range of movement full extension is recorded as 0 degrees with full flexion being approximately 140 degrees. Hyperextension of up to 10 degrees is normal and is recorded as a negative integer; i.e. −10 degrees to 140 degrees.
If hyperextension is observed then the examiner should look for other signs of generalized ligamentous laxity and document this by recording the Beighton score.

Forearm rotation is assessed with the arms adducted to the side of the body and with the elbows at 90 degrees. If the patient is asked to extend the thumb then this can be used to gauge the range of movement. Normal supination is around 85 degrees with pronation around 80 degrees. If there is any discrepancy, the wrist must be examined as problems at the distal radioulnar joint may present with abnormal pronation and supination.

It is important to record both active and passive ranges of movement.

The power of different muscle groups around the elbow should be documented using the Medical Research Council grading system.

### Provocative tests

The choice of provocative tests will be determined by the patient’s history and examination (Box 5.1.2). After a complete examination of the elbow an examination should be carried out of the neck as this may be the source of radicular pain experienced around the elbow. Neurological examination of the upper limb should also be performed.

#### Box 5.1.2 Provocative tests for elbow disorders

- Lateral epicondylitis: resisted wrist extension
- Medial epicondylitis: resisted wrist flexion
- Posterior elbow impingement: passive forced extension
- Anterior elbow impingement: passive forced flexion
- Instability: tests as described in Chapter 5.3.

### Lateral epicondylitis

Tenderness just anterior and superior to the lateral epicondyle around the origin of extensor carpi radialis brevis is suggestive of lateral epicondylitis. To confirm this, the examiner should ask the patient to extend the wrist against resistance (Figure 5.1.4) and also extend the middle finger to resistance. Both of these manoeuvres should reproduce pain around the lateral aspect of the elbow if lateral epicondylitis is present. Passive volar flexion of the wrist with the elbow in full extension and the forearm pronated may also cause pain in the same region. It is often found that pinch grip is uncomfortable and may be weak. If the signs are positive for lateral epicondylitis a small amount of local anaesthetic can be injected around the origin of extensor carpi radialis brevis and resolution of the pain will confirm the diagnosis. Care must be taken not to inject the elbow joint as an intra-articular pathology may then be missed.

![Fig. 5.1.4](image1.png)

**Click to view larger**

**Fig. 5.1.4**

Provocative test for lateral epicondylitis. Resisted wrist extension results in localized pain over the extensor origin.

### Medical epicondylitis

There is tenderness localized to the origin of the common flexors at the medial epicondyle. The examiner should test flexion of the wrist against resistance (Figure 5.1.5) which should produce pain. Passive extension of the wrist with the elbow in extension may also reproduce symptoms.
Impingement

Anterior and posterior impingements are usually caused by osteophytic change on the coronoid and olecranon processes respectively. This can be tested by asking the patient to extend to just a few degrees short of the patient’s full extension and then the examiner passively, gently but quickly, extends the elbow to the limit of the patient’s range. If positive this produces pain posteriorly. A similar manoeuvre done with the patient’s elbow in flexion will reproduce anterior impingement pain.

Elbow instability

Significant progress has been made in the understanding of elbow instability over the last few years. It is discussed in detail in Chapter 5.3 and therefore no further mention will be made here.
Summary points

- Most common in middle age.
- Classically ECRB affected laterally, Pronator teres and FCR medially.
- Histology is angiofibroblastic hyperplasia-tendinosis, not inflammation.
- Treatments include physical and injection therapy, as well as surgery.
- Concomitant ulna neuritis medially reduces success of surgery.

Introduction

Lateral and medial epicondylitis of the elbow are commonly referred to by the terms tennis and golfer’s elbow respectively. Although originally described in tennis players and golfers, the overall incidence in the population is between 1–3%. This peaks in the fifth decade, affecting 10% of women and up to 15% of men. Only half of these will ever seek medical help.

The pathology of both lateral and medial epicondylitis involves the origins of the muscles, so the term ‘epicondylitis’ is inaccurate. On the lateral side, extensor carpi radialis brevis (ECRB) is the site of the classical lesion, but sometimes the anteromedial edge of extensor communis and the deep surface of ECRL are involved. Medial epicondylitis usually involves the origin of pronator teres and flexor carpi radialis, but can occasionally affect flexor carpi ulnaris and even palmaris longus.

The classical report from Goldie in 1964 was the first to identify the pathology within the tendinous insertions of the lateral epicondyle, but the excised tissue showed no evidence of inflammatory activity. Subsequent analyses of excised specimens commonly showed both fibroblastic and vascular granulation tissue infiltration of normal tendon tissue. Similar histological changes have been identified in flexor carpi radialis and pronator teres on the medial side of the elbow. This has led to the term ‘angiofibroblastic hyperplasia tendinosis’. As the degenerative process continues to affect the tendons, tears within the tendon substance can occur. Macroscopic tears are found in up to one-third of surgically treated cases. Complete tendon ruptures are rare.

The aetiology of epicondylitis is predominantly overuse of the forearm muscles. Lateral epicondylitis is related to activities that increase the tension, and thus the stress, of the wrist and finger extensors. Electromyographic studies in tennis players have revealed high levels of activity in ECRB during both the acceleration and early follow-through phases in ground strokes and during the cocking phase of the serve. The backhand stroke appears the more problematic, though only when executed with a single-handed action (two-handed strokes appear protective). Medially it is the overactivity of the wrist flexor and pronator muscles, as in golf and baseball pitching. Again, electromyogram recordings report high activity within the common flexor muscles at the point of contact with the golf ball.

History and clinical examination

The history of a suspected epicondylitis should include evaluation of sporting and occupational activity. Duration of symptoms, treatments received to date, and pre-existing comorbidities, such as cervical spondylosis, should be established. There is a significant incidence of concurrent lateral and medial epicondylitis, approaching 25% in those patients whose medial symptoms are treated surgically. Any history of morning stiffness or ‘locking and catching’ should alert the examiner to possible intra-articular pathology. Symptoms radiating into the extensor muscles of the forearm, provoked by supination and (less often) pronation, suggest radial tunnel syndrome or posterior interosseous nerve (PIN) entrapment.

Examination should establish the site of tenderness over the epicondyle, or more commonly just anterior to the prominence of the epicondyle, distal to the insertion of the tendon. Laterally, radiocapitellar pathology may be suspected if pain occurs when the forearm is rotated with a gripped hand (such as using a screwdriver). Tenderness over the course of the radial nerve, or pain on resisted forearm rotation suggests a PIN lesion. Five per cent of patients may have concurrent lateral epicondylitis and PIN entrapment.

Box 5.2.1 Histological changes in lateral and medial epicondylitis

- Fibroblastic change
- Vascular granulations
- ‘Angiofibroblastic hyperplasia tendinosis’.

Medial epicondylitis is associated with ulnar nerve neuropraxia in 23–61% of patients. Over half of those undergoing surgery for
medial epicondylitis may have suffered with ulnar nerve symptoms. Less common is medial collateral ligament injury or insufficiency. Clearly the history is important as this may reveal sports such as baseball pitching or javelin throwing. Intra-articular pathology, such as post-traumatic or primary osteoarthritis, is an occasional cause of medial elbow pain.

### Investigation

If clinical examination is not felt to be sufficiently diagnostic, various investigations may be used to help clarify the condition. Plain radiographs show abnormal calcification in up to 20% of patients undergoing surgery for lateral epicondylitis. Diagnostic ultrasound may detect abnormalities within the ECRB tendon. Magnetic resonance imaging has also been shown to correlate well with a degenerate ECRB tendon as found at surgery. It may also detect subtle tears in the lateral ligament complex and subsequent posterolateral instability. Interestingly, infrared thermography appears to be a highly sensitive investigative tool, with specificity of between 94–100% for the assessment of unilateral and bilateral tennis elbow.

### Treatment options

There are both non-operative and operative options available for treatment of epicondylitis.

#### Non-operative interventions

Non-operative interventions include rest, brace, physiotherapy, non-steroidal anti-inflammatory drugs, and injection therapy. It has been claimed that a combination of these treatments may offer a cure in up to 90% of patients with tennis elbow. However, significant inconsistencies exist in the literature with some authors claiming less than 25% success at 1 year.

**Rest**

Cessation of any painful or aggravating activity, the alteration of technique or equipment, or modification of workplace ergonomics may all help.

**Brace**

This is used to counteract the muscle forces of both contraction and tension. Braces ultimately reduce the tensile forces within the tendon and thus protect the damaged area. They must be non-elastic and are worn on the upper part of the forearm.

**Physiotherapy**

Classical deep friction manipulation over the extensor tendon and Mills manipulations, as described by Cyriax in the 1930s, continue to be offered as a means of treatment. They, however, prove of little long-term benefit to the majority of patients, with approximately 70% of patients suffering recurring symptoms. In comparative studies of corticosteroid injection versus physiotherapy versus ‘wait and see’ treatment, results based on patient satisfaction scores showed similar outcomes at 1 year for the conservative groups. The injection group had both a delayed recovery time and higher recurrence rates. Physiotherapy was superior to injection and ‘wait and see’ treatment at 6 weeks, but no difference was found at 1 year. The amount of time off work and the number of other treatments tried by the physiotherapy group was less over the study period.

Both low-power laser and high-voltage stimulation appear to be ineffective in providing a long-term cure. Ultrasound, whilst useful for diagnosing and tracking pathology in the tendons, appears to offer little therapeutic difference from placebo treatments.

**Non-steroidal anti-inflammatory drugs**

There are no studies to show these to be of use in the treatment of epicondylitis.

**Injection therapy**

Corticosteroid injections currently remain a popular choice for many physicians. The initial results are usually good, but the benefit may not last. It is important to emphasize that the pathology of tendinosis does not involve inflammatory cells, and it has been postulated that much of the benefit of the injection results from the disruption of fibrin within the tendon by the insertion of the needle. ‘Dry needling’, however, appears to have little increased therapeutic effect over placebo.

Recent reports suggest autologous blood injection or plasma spun down from a patient’s own blood, has a significant effect on tendon healing and resolution of symptoms. The important components appear to be transforming growth factor beta and fibroblast growth factor. The technique is, however, time consuming and there are increased costs and greater potential exposure to blood products. One group reported 22/28 benefited from autologous blood injection at a mean follow-up of 9.5 months.

#### Operative interventions

**Lateral epicondylitis**

Surgical treatment falls into three basic categories:

- Release of the common extensor origin
- Resection of the degenerate or ruptured tendon with repair of the defect
Thermal disruption of the diseased tissue within the tendon. Release of the extensor tendon origin can be performed using either an open, percutaneous, or arthroscopic technique. Approximately 80% of patients report good results following an open procedure and over 90% success is reported for a percutaneous release. Synovial fistulas from both the percutaneous and arthroscopic releases remain a concern (2% reported).

Box 5.2.2 Non-operative interventions: conservative treatment

- Rest
- Brace
- Physiotherapy
- NSAIDs
- Corticosteroid injections
- Autologous blood injections.

Resection of the degenerative part of the ECRB tendon with repair was described by Coonrad and Hooper in the 1970s and by Nirschl in the 1990s. Results match those obtained in the release studies and are successful in 77–85%.

Thermal disruption of the degenerative tendon has recently been reported to be beneficial. The procedure, however, should not be performed under a local anaesthetic, as patients can experience considerable pain during the application of the probe’s impulse whilst within the tendon (personal communication).

Medial epicondylitis

Surgical treatment falls into two categories:

- Release of the common flexor origin
- Resection of the degenerative tendon and repair.

There is no safe way to percutaneously release the common flexor origin because of the proximity of the ulnar nerve, so it is recommended to always release the origin through an open approach.

Results appear to be comparable from both procedures, with reported success rates between 87–97%. It is noted that concomitant ulnar neuritis decreases the chances of a successful surgical outcome to around 60%, leading some surgeons to recommend decompression of the ulna nerve as part of the operation. Transposition, however, should be reserved for cases where there is evidence of subluxation. Despite these considerations, symptomatic ulnar neuritis may persist in almost two-thirds of cases.

Postoperative rehabilitation following surgery

Postoperative management following surgery for lateral and medial epicondylitis varies from early mobilization as pain allows, to resting in a plaster backslab for 2 weeks. Progressive rehabilitation and grip strengthening is then undertaken. Some patients can return to sporting activities at 8–10 weeks, but most need longer to fully recover and rehabilitate. The average rehabilitation period is 4–6 months, although it is not uncommon for improvement to continue for a year.

Box 5.2.3 Operative interventions: surgical treatment

- Release of common extensor/flexor origin
- Resection of degenerate tendon and repair
- Thermal disruption of the degenerate tendon*

* Applies to the treatment of lateral epicondylitis.

Failure of operative treatment is uncommon, and other potential sources of pain and dysfunction should be considered if a patient fails to make a good recovery from surgery. Intra-articular causes such as secondary osteoarthritis, osteocartilaginous loose bodies, or synovial plicae may be present. Laterally, posterior nerve entrapment should be considered.

Complications are rare, and apart from local wound sensitivity, infection, and complex regional pain syndrome, the most common is instability, due to damage to the lateral ligament complex. Percutaneous and arthroscopic procedures have been associated with synovial fistulae.

Chapter: Chronic instability of the elbow

Author(s): Amir Salama and David Stanley

Summary points

♦ Posterolateral rotatory instability is the commonest following elbow dislocation
♦ Diagnosis is mainly clinical and by examination under anaesthesia
♦ Surgical treatment is the mainstay.

Introduction

Elbow instability is relatively uncommon in the general population. However, in the past few years it has received a lot of attention as the mechanism of elbow dislocation and types of elbow constraint have become much better understood.

Biomechanics of elbow dislocation

Elbow dislocations or subluxations typically occur as a result of a fall onto the outstretched hand. The elbow experiences an axial compressive force as the hand hits the ground and the elbow starts to flex. The body then rotates internally on the elbow (forearm rotates externally on the humerus) resulting in a supination moment at the elbow. A valgus moment also occurs as the mechanical axis passes through the lateral side of the elbow. This combination of valgus, supination, and axial compression during flexion is the mechanism responsible for subluxation or dislocation of the elbow (Box 5.3.1). It can be divided into three stages. In stage 1 the ulnar part of the lateral collateral ligament is disrupted. This results in posterolateral rotatory subluxation of the elbow, which reduces spontaneously. With additional disruption, the capsule tears anteriorly and posteriorly. The elbow in stage 2 instability is capable of an incomplete posterolateral dislocation in which the medial edge of the ulna rests on the trochlea such that a lateral radiograph gives the impression of the coronoid being perched under the trochlea (Figure 5.3.1A). This can be reduced readily with minimal force or by the patient self-manipulating the elbow. In stage 3, the coronoid and radial head are fully posterior to the trochlea and capitellum, respectively. Depending on the severity of tissue disruption in stage 3 (A, B, or C) the elbow will be stable in valgus (stage 3A), unstable in valgus (stage 3B), or grossly unstable except when flexed greater than 90 degrees after reduction (stage 3C). In stage 3C, the entire distal aspect of the humerus is stripped of soft tissues, rendering the elbow extremely unstable even in a cast (Table 5.3.1). The pathoanatomy of these stages of elbow dislocation represent a circle of progressive soft tissue disruption from the lateral to the medial aspect of the elbow (Figure 5.3.1B).

LUCL, lateral ulnar collateral ligament; MUCL, medial ulnar collateral ligament.

Constraints to elbow instability

The elbow has both static and dynamic constraints (Figure 5.3.2). The three primary static constraints are the ulnohumeral articulation, the medial collateral ligament, and the lateral collateral ligament, especially the ulnar part (the lateral ulnar collateral ligament). The secondary constraints include the radial head, the common flexor and extensor origins, and the capsule. The dynamic stabilizers include the muscles that cross the elbow joint and produce compressive forces across the joint. The anconeus, triceps, and brachialis are the most important muscles in this regard. If the coronoid process is fractured, the radial head becomes a critical stabilizer and must not be excised if the coronoid and the ligaments cannot be securely repaired.

Classification of elbow instability

Five criteria should be considered when evaluating elbow instability in order to help plan appropriate treatment:

1. The articulation(s) involved (ulnohumeral, radiohumeral, proximal radioulnar, or a combination)
2. The direction of displacement (posterolateral rotatory, valgus, varus, anterior, or varus posteromedial)
3. The degree of displacement (subluxation or dislocation)
4. The timing (acute, chronic, or recurrent), and
5. The presence or absence of associated fractures.

Articulation(s) involved

Two categories of elbow instability exist according to the articulation(s) involved: the hinge joint (the radius and ulna as a unit articulating with the humerus) and the proximal radioulnar joint leading to subluxation or dislocation of the radial head from the ulna. Dislocation of the radial head from the ulna is usually traumatic and often part of a Monteggia fracture-dislocation. Instability can also involve both joints in a combined fashion.
Posterolateral rotatory instability

In posterolateral rotatory instability (PLRI) the radius and ulna rotate externally in relation to the distal humerus, leading to posterior displacement of the radial head relative to the capitellum. Here, the proximal radioulnar joint is intact and both forearm bones rotate as a single unit. This differentiates PLRI from isolated dislocation of the radial head, where the proximal radioulnar joint is disrupted and the ulnohumeral articulation is intact. It is usually posterolateral rather than direct posterior so that the coronoid can pass inferior to the trochlea. The main static constraints to posterolateral laxity are the lateral ligament complex, the radial head, and the coronoid process, with a smaller contribution from the common extensor origin.

Traumatic: as the lateral ligament is the first to be disrupted, PLRI is the most common instability seen following elbow dislocation. It represents a spectrum of instability (see Figure 5.3.1). The Horii circle (stage I to III) represents the soft-tissue disruption that occurs in a circular fashion from lateral to medial when the elbow dislocates. The lateral ligament is usually avulsed from its humeral origin. Radial head and capitellar fractures can contribute to loss of height on the lateral side of the elbow, loss of congruity, and slackening of the lateral ligament complex. Therefore every attempt should be made to preserve the radial head and capitellum in good alignment following fractures, and when excision is necessary, arthroplasty should be considered.

Damage to the lateral ligament complex may also be due to chronic attenuation or iatrogenic injury.

Iatrogenic: PLRI can occur following a lateral epicondyritis release, or may result from surgical approaches to the lateral side of the elbow joint and radial head.

Chronic attenuation of the lateral ligament complex may occur in long-standing cubitus varus and secondary to overuse, such as in patients with poliomyelitis who use crutches to walk. In these chronic conditions the ligament stretches, losing its normal tension. In addition, the direction of pull of triceps is altered and exerts an external rotatory moment on the ulna which is an important component of PLRI. The lateral ligament complex may be inherently lax in conditions of generalized ligamentous hyperlaxity, for example, Ehlers–Danlos syndrome.

Valgus

Valgus instability is seen in one of two varieties: post-traumatic or chronic overload. Post-traumatic valgus instability implies rupture of the medial collateral ligament. It may be associated with disruption of the common flexor and pronator origin. Valgus instability is usually found in patients with radial head fractures that are associated with tears of the medial collateral ligament, or in patients with stage III elbow dislocations. The medial collateral ligament usually heals after elbow dislocation, perhaps because of the vascularity of the surrounding muscles.

In the throwing athlete, valgus instability can occur from repetitive microtrauma or overload that leads to attenuation or rupture of the anterior band of the medial collateral ligament.

Varus

Varus instability is attributable to disruption of the lateral collateral ligament complex and can be shown acutely in patients with elbow dislocations and in many patients with recurrent or chronic instability when this ligament fails to heal. As the forces across the elbow are principally valgus because of the anatomic alignment, it is not often subjected to varus stress and this pattern of instability may not be obvious.

Anterior

Anterior instability of the elbow is rare and typically is seen in association with fractures of the olecranon.

Varus posteromedial

Varus posteromedial rotatory instability occurs when a varus and internal rotation moment is applied to the elbow during axial loading of the elbow in flexion. It is usually associated with an anteromedial facet fracture of the coronoid process. Due to the varus force the radial head remains intact and there is usually an avulsion of the lateral collateral ligament. This instability pattern is clinically noticed with the shoulder in 90 degrees of abduction and the elbow in 90 degrees of flexion. This is a significant injury as it results in ulnohumeral joint incongruity and medial loading of the elbow, which can lead to premature arthritis. It is therefore recommended to internally fix the anteromedial coronoid fact even when the fracture fragment is small. This injury can be subtle and can pass unrecognized in the acute phase and a high index of suspicion is needed particularly when there is an isolated fracture of the coronoid without a fracture of the radial head. The implications of not recognizing this varus posteromedial rotatory instability are potentially devastating, as subsequent reconstructive options are difficult.

Degree of displacement

PLRI can be considered a spectrum consisting of three stages according to the degree of soft tissue disruption (see Figure 5.3.1). Each stage has specific clinical, radiographic, and pathological features that are predictable and have implications for treatment.

Timing

Elbow instability can be acute, chronic, or recurrent. Acute instability occurs with acute elbow dislocations or fracture-dislocations.
All patterns of instability can occur acutely with PLRI being the most common. Traumatic valgus instability implies rupture of the medial collateral ligament and, usually, a fracture of the radial head. It is a distinct problem, separate from dislocation. Recurrent instability occurs when soft tissue healing after elbow dislocation is incomplete and is almost always PLRI. Chronic elbow instabilities present to the clinician as either chronic unreduced dislocations or fracture dislocations. Chronic dislocations, whilst infrequently seen in the developed world, are unfortunately still common in some developing countries and their management is challenging.

**Associated fractures**

When an elbow dislocation is associated with an elbow fracture(s) it is referred to as a complex dislocation. Fracture-dislocations most commonly involve the coronoid and radial head and are referred to as a terrible triad. This name has been coined since it often results in persistent instability, non-union, malunion, and proximal radioulnar synostosis. Other fractures include avulsion fractures of the lateral collateral ligament, impression fractures of the radial head or the posterior part of the capitellum, and olecranon fractures. The goal of management of fracture-dislocations of the elbow is to restore the osseous-articular restraints and convert the injury to a simple dislocation. This has been demonstrated to have a generally favourable long-term prognosis. The recognition of an anteromedial facet fracture of the coronoid as a distinct and important type of coronoid fracture makes an important addition to the Regan and Morrey classification, which is based on fragment size alone.

**Box 5.3.2 Injury patterns in elbow instability**

- Posterolateral rotatory: rupture of the ulnar part of the lateral collateral ligament
- Valgus:
  - Rupture of the medial collateral ligament
  - Often radial head fracture
- Varus: rupture of the lateral collateral ligament
- Varus posteromedial:
  - Anteromedial facet fracture of the coronoid process
  - Avulsion of the lateral collateral ligament

**Evaluation of recurrent elbow instability (Box 5.3.2)**

**Posterolateral rotatory instability**

PLRI is the commonest pattern encountered in clinical practice. In this type of instability patients may present with a spectrum ranging from vague symptoms in the elbow to frank recurrent posterolateral dislocation. Symptoms include: lateral elbow pain, recurrent clicking, popping, snapping, or locking of the elbow. The elbow position most typically associated with symptoms is approximately 40 degrees of flexion with the forearm in supination. The subluxation reduces on pronation. Symptoms are often brought on by activities such as pushing up with the arms when rising from an armchair or doing press-ups. These activities place the elbow in an unstable position of external rotation of the forearm with valgus and axial loading of the elbow. This in the presence of a previous history of dislocation or even an injury without dislocation suggests PLRI. A history of surgery on the lateral side of the elbow and a family history of ligamentous laxity should be sought. A thorough examination to identify signs of previous trauma or surgery, cubitus varus deformity, and range of movement is essential. Several clinical tests for PLRI have been described (see Table 5.3.1 and Figures 5.3.3–5.3.7). All these place the elbow in a position of maximal instability, with a combination of external rotation of the forearm, valgus, and axial loading, which try to reproduce either the symptoms or displacement of the radial head. It is important to look for coexistent valgus or varus instability as well as generalized ligamentous hyperlaxity.
Fig. 5.3.4
Patient performing his own drawer test. With the elbow flexed 40 degrees, anteroposterior force is applied to the radius and ulna with the forearm in external rotation. This aims to sublux the forearm away from the humerus on the lateral side, pivoting on the intact medial ligaments. Under general anaesthesia the radial head is seen dislocating, whereas with the patient awake apprehension occurs.

Fig. 5.3.3
Lateral pivot shift (O’Driscoll). Patient supine, affected limb overhead. With forearm supinated, valgus and axial loading applied, elbow is flexed from full extension. In posterolateral rotatory instability as the elbow is flexed the radial head subluxes/dislocates and is seen as a prominence posterolaterally. With flexion beyond 40 degrees the radial head suddenly reduces with a palpable and visible clunk. The test is best done under general anaesthesia for radial head dislocation and relocation to be seen. When this manoeuvre is performed with the patient awake, the test is positive in presence of apprehension.

Fig. 5.3.7
Table-top test (Arvind). (A) Patient performs a press-up on the edge of a table with the forearm in supination. In the presence of instability, apprehension occurs. (B) Relocation test. The manoeuvre is repeated while the examiner’s thumb presses on the radial head, preventing subluxation. The test is positive if thumb pressure relieves apprehension.

Valgus instability

Valgus stress testing is performed with the forearm fully pronated so that PLRI is not mistaken for valgus instability. Forced pronation prevents PLRI because the intact medial soft tissues are used as a hinge or fulcrum. Clinical examination may elicit point tenderness distal to the medial epicondyle along the ulnar collateral ligament. The location of tenderness is important to differentiate ulnar collateral ligament injury from medial epicondylitis and flexor–pronator mass strains. Flexing the wrist and pronating the forearm to decrease traction on the flexor–pronator mass can assist in differentiating these entities although they may coexist. Palpating with the elbow in 50–70 degrees of flexion moves the flexor mass anterior to the ulnar collateral ligament, allowing direct palpation of the ligament. The milking manoeuvre (Figure 5.3.8) is performed by abducting the shoulder and flexing the elbow to 90 degrees and the thumb is pulled posteriorly to create a valgus stress on the elbow. Comparison is then made with the opposite elbow. Medial opening and pain signify a positive test.
Fig. 5.3.5
Floor push-up test (Regan). Patient pushes off the floor with elbows flexed 90 degrees, forearms supinated, and arms abducted. The test is positive if apprehension or radial head dislocation occurs as the elbow is extended.

Fig. 5.3.6
Chair push-up test (Regan). Patient pushes off from sitting position; causes apprehension or radial head dislocation on extension.

Fig. 5.3.8
The milking manoeuvre.

**Varus instability**

Varus stress testing is easiest to perform with the shoulder fully internally rotated. Both valgus and varus stress testing are
performed with the elbow in full extension and in 30 degrees of flexion which unlocks the olecranon from the olecranon fossa.

**Investigations (Box 5.3.3)**

Plain radiographs of the elbow are often normal but occasionally demonstrate an avulsion fracture of the origin or insertion of the lateral ligament complex. The presence of fractures of the radial head, coronoid process, and capitellum can be demonstrated as well as the presence of degenerative changes. Impression fractures of the radial head or the posterior part of the capitellum may also be seen. The drop sign—an ulnohumeral distance greater than 4mm on the plain lateral film of the unstressed elbow—may be present on immediate post-reduction lateral radiographs but usually disappears after muscle loading with mobilization. Concern is warranted only when the sign is still present on follow-up radiographs as it can be indicative of residual instability following elbow dislocation. It has been shown that properly performed magnetic resonance imaging (MRI) is sensitive and specific in demonstrating lateral collateral ligament pathology. However, PLRI is a clinical diagnosis, and the MRI should not be relied upon to make the diagnosis. Arthroscopic examination of the elbow may show posterior displacement of the radial head, an elongated lateral ligament complex, or widening of the lateral joint space. The diagnosis of PLRI remains a clinical entity with a combination of the history, active and passive apprehension tests, and examination of the elbow under anaesthesia. Apprehension is usually all that can be elicited when the patient is awake and general anaesthesia is needed to demonstrate displacement of the radial head and/or dimpling of the soft tissue.

With the patient under general anaesthesia, examination should be performed for valgus and varus instability as previously described. Testing for valgus instability with the forearm in supination may give a false positive result in the presence of PLRI, and so this should be performed with the forearm in pronation. Inability to demonstrate varus instability does not imply that the lateral ligaments are intact, as the ulnohumeral articulation is the main constraint to varus. PLRI is tested using the pivot shift and posterolateral drawer tests. If these fail to demonstrate instability the elbow should be screened using the image intensifier and the test repeated to detect dislocation or subluxation of the radial head (Figure 5.3.9).

**Management**

Recurrent posterolateral rotatory instability

Treatment depends on the severity of the patient’s symptoms. The ligament does not become stable over time, except possibly when a patient is seen in the very early stages. Conservative treatment by avoiding provocative activities and bracing to limit supination and valgus loading may be offered to some patients if surgery is declined. Surgical management is the standard and aims at reattaching, retensioning, or reconstructing the lateral ligament complex together with treating any bone deficiency of the radiocapitellar and ulnohumeral articulation by replacement of the radial head or coronoid reconstruction, and correcting any varus deformity of the humerus by osteotomy prior to ligament reconstruction. One or a combination of these may be necessary, depending on individual assessment and the underlying pathology.

Reattachment and retensioning of the lateral ligament complex with imbrication and advancement have been used, but reconstruction with a graft usually provides a more reliable construct. A tendon graft is used, with fixation achieved by bone tunnels, anchor sutures, or interference screws. The docking technique provides a stable construct and allows tensioning of the graft. Although an autograft of palmaris longus is commonly employed, the use of a strip of triceps tendon, semitendinosus, gracilis, plantaris, and synthetic ligaments have also been used. The latter is worth considering in cases of generalized ligament hyperlaxity. If both medial and lateral ligaments need to be reconstructed, a circumferential graft can be used and attached to both sides of the ulna. Arthroscopically-assisted repair of the avulsed lateral ligament complex has been described. Arthroscopic electrothermal shrinkage of the lateral ligament complex as the sole treatment for posterolateral elbow instability has also been used.

Valgus instability is usually treated in a similar fashion to ligament reconstruction procedures on the medial side of the elbow.
Results of surgery for ligament reconstruction

Generally if there is no degenerative arthritis and if the radial head is intact, approximately 90% of patients have a satisfactory outcome with no subsequent recurrent subluxation. If the radial head is excised or if there is degenerative arthritis of the ulnohumeral joint, the outcome is less satisfactory at between 67–75%. The results are not good in patients with generalized ligamentous laxity.

Box 5.3.3 Investigations for elbow instability

- Radiographs: fractures particularly anteromedial coronoid
- MRI: often reveals ligament injury
- Examination under anaesthesia:
  - Valgus instability
  - Varus instability
  - Pivot shift for posterolateral instability
  - Arthroscopic examination: reveals widening of lateral joint space and/or posterior subluxation of the radial head.

Simple elbow dislocation and fracture dislocations

O’Driscoll described an algorithm that helps in decision-making once the elbow is reduced (Figure 5.3.10).

Subluxation or dislocation must be detected by careful examination throughout the comfortable range of motion and by radiographic examination, with anteroposterior and lateral radiographs made initially after the reduction and every 5–7 days for the first 3 weeks.

When the elbow is stable to valgus stress only with the forearm in pronation (that is, a stage-3A dislocation), the injury is treated immediately in a cast-brace that allows unlimited flexion and extension and holds the forearm in full pronation.

The presence of fractures usually changes the management, and almost always these fractures should be treated surgically. In general, the approach to the unstable elbow is to fix the bones internally and then repair the ligaments (particularly on the lateral side) so that early motion can be commenced.

Coronoid process fractures that are type I and type II (those involving 50% of the height of the coronoid process or less) should be fixed if the joint is subluxated or dislocated. Type III fractures (those involving more than 50% of the coronoid process) cause instability and must always be fixed.

Fractures of the radial head are best managed by internal fixation when technically possible. When the radial head is comminuted and has to be excised, prosthetic replacement is indicated if the elbow is unstable and cannot be rendered stable by ligament reconstruction alone.

Repair of an acute ligament injury is indicated in all fracture-dislocations requiring internal fixation of the radial head or the coronoid process, or both, and following reduction of a dislocation if gross instability does not allow early protected motion in a cast-brace without subluxation.

Rheumatoid arthritis of the elbow

Summary points

- 50% of RA patients have elbow involvement
- Females affected 3 times more than males
- Peak incidence 60-70 years of age
- Radiological severity assessed using the Larson radiological grading system
- No single test used to diagnose RA
- The management of RA requires a multidisciplinary approach
- Anti-TNF drugs are used when disease-modifying agent combinations have failed to control symptoms
- Intra-articular and intramuscular cortisone is an effective way of controlling flare-ups
- Total elbow arthroplasty is indicated in severe RA where there is failure of medical management to control symptoms
- 10 year survival rates of total elbow replacement between 80% (unlinked) and 92% (linked).

Introduction

Rheumatoid arthritis (RA) is the most common form of inflammatory arthritis and affects 3% of women and 1% of men. The classification criteria developed by the American Rheumatism Associated require four of the following:

- Morning stiffness
- Symmetrical arthritis
- Arthritis of three or more areas
- Arthritis of hand joints
- Rheumatoid nodules
- Positive rheumatoid factor
- Radiographic findings typical of RA.

The elbow is involved in 20–50% of patients with rheumatoid disease and, in the majority of cases, it is bilateral. Women are affected three times more commonly than men. The elbow is the first joint to be affected by RA in only 2.1–3% of cases. In the early stages, the synovitis causes pain and tenderness, especially over the radiohumeral joint line, with associated loss of elbow extension. Later, the whole elbow may become swollen and stiff. Finally, when bone destruction is severe, instability and capsular rupture result in a flail elbow (see Figure 5.4.1). Ulnar collateral ligament incompetence may cause valgus ulnar humeral instability and ulnar nerve dysfunction. Annular ligament incompetence can lead to radial head subluxation.

Fig 5.4.1
An example of a 72-year-old female patient with severe rheumatoid arthritis (Larsen grade 5) who has a painless elbow with a functional range of motion.
The aetiology in RA is unknown. The genetic predisposition, the involvement of activated immune cells, and the response to immunosuppressing therapy, all suggest the disease is immune mediated. The cell-mediated immune response (T cells that incite an inflammatory response) is initially against soft tissue (synovitis) and later, against cartilage (chondrolysis), and then bone (periarticular bone resorption). The pathological spectrum of RA spans across early disease when joints exhibit active synovitis without structural damage, to late disease when the joints may be mechanically damaged, mal-aligned, and unstable without persistent active synovitis.

RA is a rare disease in men under the age of 30 years. The incidence rises to peak at 60–70 years. In women, the prevalence of disease increases from the mid twenties to a fairly constant level at 45–75 years with a broad peak at 65–75 years. The genetic contribution in RA is around 15–20% and this can exert a significant effect on disease expression. The risk of RA in first-degree relatives is almost double that amongst the general population.

Radiological grading

The standard radiographic assessment of RA was proposed by Larsen and colleagues in 1977. He grades the disease into six stages (Figure 5.4.2).

- Grade 0: normal
- Grade 1: slight abnormality—one or more of the following changes are present:
  - Periarticular soft tissue swelling
  - Periarticular osteoporosis and slight joint space narrowing
- Grade 2: definite early abnormality erosions (an obligatory sign and joint space narrowing is noted)
- Grade 3: medium destructive abnormality; erosions and joint space narrowing is more marked
- Grade 4: severe destructive abnormality; marked erosion, joint space narrowing, bone deformation is also present
- Grade 5: mutilating abnormality. Original articular surfaces have disappeared, gross bone deformation is present.

Biomechanics

An understanding of the function and biomechanics of the elbow is important when considering the design and features of total elbow replacement. The main role of the elbow joint is to position the hand in space but a full range of movement of the elbow is not required for many activities of daily living. It has been shown in normal volunteers that most tests can be carried out with a 100-degree arc of flexion between 30–130 degrees, and a 100-degree arc of forearm rotation equally divided between pronation and supination. In patients with elbow RA the flexion arc is often well preserved until a late stage in the disease.

The other main role of the elbow joint is to act as a fulcrum for the forearm lever, and this stability is essential for normal strength and function. Increasingly, severe erosion of the subchondral bone of the elbow joint, due to RA, gives rise to varus/valgus and anteroposterior instability and thus weakness, because of the loss of the elbow joint as a stable fulcrum.

Many RA patients are unable to carry out the more demanding activities of daily living because of pain and weakness caused by reflex inhibition of adjacent muscles. One group found the average flexion strength of the elbow in rheumatoid patients tested at 90 degrees, was approximately 50% of the normal young adult. The activities of daily living, such as eating and dressing, can apply compressive loads of up to half of the body weight to the elbow and may be as high as three times body weight with certain actions, such as pushing up out of a chair or lifting heavy weights.
When assessing the elbow in a patient with RA, it is important to perform a thorough evaluation of the cervical spine, shoulder, wrist, and hand in both upper limbs, to determine if the patient’s complaints are limited to the elbow or are more diffuse in nature. The age, occupation, hand dominance, and age of onset of RA should be assessed.

Isolated elbow involvement in RA is rare. It should be noted that associated wrist (distal radioulnar joint) pathology can contribute to loss of forearm rotation and limited shoulder abduction can prevent the ability to compensate for loss of pronation. Specific elbow problems that require assessment are pain, stiffness, swelling, instability, and ulnar nerve symptoms.

Pain arising in the joint is often diffuse in nature. It is commonly felt on the lateral side initially. To gauge the level of pain in the elbow an assessment of night and rest pain should be made together with the number of anti-inflammatory painkillers taken per day. In addition, an assessment of whether there is pain on certain specific activities of daily living is made, including washing, dressing, and lifting simple household objects, for example, the ability to lift a mug, kettle, or a pan.

Mild stiffness may hardly be noticed. If it is severe, it can be very disabling. The patient may be unable to reach to the mouth (loss of flexion), or to the perineum (loss of extension). Limited supination makes it difficult to carry large objects. It is very important to consider the function of the whole arm as a unit as well as the patient’s age, occupation, and overall condition prior to forming a treatment plan.

An in-depth medical history is taken of age at onset of the RA, current drug treatment relating to anti-inflammatory drugs, disease modifying drug therapies, and specifically whether the patient is taking prednisolone or anti-tumour necrosis factor (TNF) therapies. An assessment of the extra-articular complications of RA should be made, specifically relating to pulmonary and cardiac symptoms and the neurological effects of peripheral entrapment of the ulnar nerve. It is important to assess the effects of the RA on other joints, particularly in the lower limb, and whether the patient has had or is awaiting total hip, total knee, or forefoot arthroplasty surgery. If surgery is being contemplated a general medical history must be taken to assess fitness for anaesthesia (diabetes, ischaemic heart disease, use of warfarin, lung pathology).

Finally, a social history is useful in noting where the patient lives (flat, a bungalow, or two storey house), who the patient lives with, the need for social service support and an assessment of mobility, particularly the use of walking aids.

**Box 5.4.1 Rheumatoid elbow symptoms that require assessment**

- Instability
- Ulnar nerve dysfunction.

**Examination (Box 5.4.2)**

General considerations include a rapid assessment of the patient’s habitus and whether walking aids or a wheelchair are being used. The patient should be asked to undress to reveal the whole of the upper limb. Screening examination of the neck and shoulders should be made to assess range of movement and pain. Rheumatoid involvement of the neck or shoulder may make examination of the elbow difficult because of pain and stiffness.

**Look**

With both upper limbs exposed, the patient holds their arms by the side of the body with palms forward; this enables varus or valgus deformity at the elbow to be assessed. The patient then holds the arm out sideways at right angles to the body with palms upwards and elbows straight. An assessment of muscle wasting, swelling, lumps (Figure 5.4.3), surgical scars, and skin colour can be made.
Feel

The back of the elbow joint is palpated for warmth, subcutaneous nodules, synovial thickening, and fluid. Laterally, the joint line can be palpated for swelling and crepitus. The radial head should be assessed for tenderness, and to make sure it is properly aligned and not subluxed or dislocated. The ulnar nerve can be palpated behind the medial epicondyle and assessed for sensitivity and Tinel's test for cubital tunnel syndrome.

Move

Flexion and extension are compared on the two sides. Pronation and supination can be measured and compared with the elbows tucked into the sides and flexed to a right angle.

Rheumatoid nodules (Figure 5.4.3) occur in 30% of patients with progressive seropositive disease. These are most commonly subcutaneous and occur on the extensor surface of the elbow and especially around the olecranon. They are usually mobile but can be fixed to deeper tissues. In addition, they can be found in the spine, occiput, and other areas exposed to mechanical pressure. Nodules have a characteristic histology in that they are made up of a central area of fibrinoid necrosis surrounded by an area of palisading epithelial cells and fibrocytes.

Investigations (Box 5.4.3)

There is no single test to diagnose RA. Instead, the diagnosis is based upon many factors, including the characteristic signs and symptoms, the results of blood tests, and the results of radiographs. Laboratory studies are performed to help with the diagnosis, to monitor the progress and complications of the disease, and to assess the side effects of drugs. Blood tests include a full blood count to measure haemoglobin (anaemia is a common presenting feature of RA), white blood cell count and platelet count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), rheumatoid factor, antinuclear antibodies, liver enzymes, and renal function.

Box 5.4.2 Examination of the rheumatoid elbow

♦ Look:
  • Scars
  • Deformity
  • Muscle wasting
  • Rheumatoid nodules
  • Swelling

♦ Feel:
  • Rheumatoid nodules
  • Swelling
  • Tenderness
  • Ulnar nerve irritation
Rheumatoid factor (immunoglobulin M) is detected by the Rose–Waaler assay and is positive in approximately 80% of RA patients. Rheumatoid factor may also be positive in a number of other conditions.

The ESR and CRP are non-specific markers of inflammation. A high ESR and CRP suggest the presence of inflammation, but they do not indicate the cause of this inflammation. The anticitrullinated peptide antibody test is more specific than rheumatoid factor for diagnosing RA. It may be positive very early in the course of the disease. The test is positive in 50–90% of patients with RA. Between 30–40% of people with RA have autoantibodies called antinuclear antibodies (ANAs). However, many healthy people also have a positive ANA test.

Plain anteroposterior and lateral radiographs are an important measure of disease progression (see Fig 5.4.1C). In established RA, radiographs are used to classify and monitor disease progression from osteoporosis, soft tissue swelling, periarticular cysts, joint space narrowing, alteration of joint architecture, and finally, gross joint destruction. About 15–30% of patients with RA will have radiographic changes in the first year. However, after the first 2 years of RA, more than 90% of people have changes on radiographs.

Magnetic resonance imaging (MRI) scans are more sensitive than radiographs for detecting the cartilage damage caused by RA. Therefore, MRI scans may be more effective than radiographs for detecting the early changes of RA.

In patients where the elbow joint is the first joint to present, aspiration of the joint for microscopy, Gram staining, crystals, and culture, may aid in the diagnosis by excluding other conditions that may cause a swollen elbow. These include infection, gout, pseudogout, and other connective tissue diseases.

Box 5.4.3 Investigations in the diagnosis and assessment of the rheumatoid patient

  - Anticitrullinated peptide antibody
  - Antinuclear antibody
  - CRP
  - Liver and renal function

- Radiographs:
  - Elbow
  - Cervical spine

- Elbow aspiration:
  - Occasionally indicated.

**Treatment**

The therapeutic goals are the control of synovitis and pain, maintenance of joint function, and the prevention of deformities. The management of RA requires a multidisciplinary team approach, usually headed by a rheumatologist and may involve the use of drugs, physical therapy, and sometimes surgery (Table 5.4.1).

Education by a clinical nurse specialist plays a vital role in helping patients understand their disease, and associated drug therapy. The management of RA has changed substantially over recent years with the emphasis now being on early diagnosis and aggressive early intervention with disease-modifying antirheumatic drug (DMARD) therapy. This approach has been shown to make a long-term difference to prognosis. Anti-TNF drugs are indicated in patients not responding to conventional DMARDs. The aim of initial drug therapy is to prevent disease deterioration as well as to alleviate pain.

A multidisciplinary team should be involved early and throughout the course of the disease. This involves specialist nurses who can take patients through the details of drug regimens, side effects, and monitoring requirements, and physiotherapists who can help with non-pharmacological pain relief, introduce appropriate exercise, and discuss the balance between activity and rest. Occupational therapists provide resting splints for painful joints, and aids which maintain function, independence, and employment.

The key role of all professionals in early RA is education. Evidence exists that educating patients with early RA is an independent predictor of good disease control.

Non-steroidal anti-inflammatory drugs (NSAIDs) represent first-line treatment in all types of arthritis, acting to decrease the synovial reactivity and alleviate pain and swelling. Disease-modifying drugs such as sulphasalazine, methotrexate, and azathioprine are used in mild, moderate, and severe disease. Some patients with mild disease may respond with symptom control to a single disease-modifying drug while those with poor prognosis disease may need early aggressive combination drug strategies (Box 5.4.4).

Box 5.4.4 Poor prognostic indicators in rheumatoid arthritis

- Young age
- Female
- Slow onset of disease
- Symmetrical upper extremity disease
- High level of disability at presentation
- Rheumatoid nodules present
- High titres of rheumatoid factor
- High ESR/CRP
- Early erosive changes on radiograph.

Methotrexate is now the most commonly used disease-modifying drug with a relatively high rate of response. Its risk of toxicity is reduced by the co-prescription of folic acid.

Unlike NSAIDs, the use of steroids slows the course of the disease. Over the short term, they exert a profound effect on the symptoms of RA but their long-term use is contraindicated due to their significant side effects.

TNF is a key cytokine in RA inflammation and damage. Over the past 5 years, drugs that block this cytokine (adalimumab, etanercept, and infliximab) have been introduced into clinical practice. Two of the drugs, adalimumab and etanercept are subcutaneous injections that can be self-administered; infliximab is given intravenously every 8 weeks after initial induction. These drugs have made a huge difference to the management of many patients with active disease who have failed to respond to conventional treatments. It is estimated that up to 5% of all RA patients may require such therapy. In the United Kingdom, anti-TNF
therapies are restricted to patients with ongoing active disease who have failed to respond to at least two conventional disease-modifying drugs, where one is methotrexate.

It is important in early RA to monitor treatment response and modify therapy accordingly (Table 5.4.2). This requires a combination of subjective and objective assessment using a disease activity score, which is an amalgamation of the number of tender and swollen joints, the ESR, and a visual analogue score of the patient’s overall health.

Surgical intervention

Surgery is indicated when appropriate non-surgical management has failed, giving rise to functional limitations due to pain or loss of motion (Table 5.4.3). It is important when surgery is being contemplated to preoperatively assess the cervical spine with radiographs and to be certain that the patient will be compliant with postoperative rehabilitation.

Table 5.4.3 Summary of surgical indications

| Early RA (Larson 1, 2); joint space preserved | → Conservative treatment (NSAIDs—anti-TNF; DMA—physical Rx; steroids) | → Painful radial head | → Synovectomy + radial head excision (open/closed) |
| Loss of joint space, good bone stock (Larson 3, 4) | → Conservative treatment (NSAIDs—anti-TNF; DMA—physical Rx; steroids) | → Rest pain loss of function | → Arthroplasty linked or unlinked |
| Larson vs flail arm | → Conservative treatment (NSAIDs—anti-TNF; DMA—physical Rx; steroids) | → Pain | → Linked arthroplasty |

ADLs, [TBC]; DMA, disease modifying agents; NSAIDs, non-steroidal anti-inflammatory drugs; TNF, tumour necrosis factor.

The primary aim of surgery on the elbow is to relieve pain and/or restore joint function.

- **Pain**: pain is the most common primary indication for elbow surgery. The pain relief is most predictable and complete after total elbow replacement.
- **Stiffness**: a range of movement of less than 100 degrees that does not allow the patient to reach the mouth or perineum is an indication for surgical intervention. In most instances, prosthetic joint replacement is effective at restoring a functional arc of motion.
Instability: instability often causes severe disability and pain. A linked total elbow replacement is effective treatment.

Weakness: total elbow replacement may improve strength by virtue of its elimination of the reflex inhibition associated with pain. This is a secondary benefit of surgery.

Synovectomy

Synovectomy with radial head excision is an accepted procedure for the early stages of RA (Larsen grades 1 and 2), with chronic synovitis and pain. Following synovectomy, the synovium initially regenerates normally, but with time it will generate back into rheumatoid synovial tissue.

Excision of the radial head was recommended by most authorities in the past but today the radial head is preserved if it is not severely involved in the disease process or causing pain with pronation or supination. The negative effect of radial head resection is to increase the loading of the ulnar compartment of the joint. In addition, resection of the radial head results in deterioration of the postoperative outcome from 70% to 45% during a 6-year period.

Previous synovectomy does not affect the results of total elbow replacement and can therefore be considered in the early, painful stages of rheumatoid destruction of the elbow joint. A lateral approach to the elbow is used and if the radial head is excised there is excellent exposure of the anterior compartment for synovectomy.

Lee and Morrey have reported arthroscopic elbow synovectomy results similar to those achieved by open synovectomy.

Review of the literature suggests up to 90% excellent pain relief for the first 2–5 years after surgery, with late results demonstrating deterioration over time with the success rates falling to 60% at 5–10 years. The largest study reviewed 171 rheumatoid elbows with synovectomy and radial head excision with failure defined as the need for revision surgery or significant pain. The study reported a 1-year survival rate of 85% and a 6.5-year survival rate of 45%.

Ulnar nerve compression at the elbow may at times also be an indication for synovectomy of the elbow, with or without neurolysis and nerve transposition.

Interpositional arthroplasty

Although at one time popular in Europe, this procedure is now rarely carried out in patients with RA. It is contraindicated in patients with significant joint destruction and gross loss of bony architecture. The primary indication is a young, active patient without an inflammatory arthritis, who has a severe post-traumatic arthritis associated with severe pain and limited motion, and is too young or active for total joint arthroplasty. The disadvantage of resection interposition arthroplasty in patients with RA is the risk of progressive bone loss with accelerated instability. This loss of bone may, in the long run, be such that reoperation by prosthesis is rendered impossible. The method has slowly lost ground in the light of the improved results with prosthetic surgery.

Total elbow arthroplasty

Total elbow replacement is indicated for elbows with severe pain, limited range of motion, and pronounced loss of articular cartilage. The patient must agree to postoperative limitations of lifting no more than 2.5–5kg (5.5–11lb). The contraindications to total elbow arthroplasty are sepsis, the need for soft tissue coverage, severe muscle weakness or paralysis, and a non-compliant patient.

There are two types that are commonly used: unlinked (Figure 5.4.4) and linked (Figure 5.4.5). In addition, more recently convertible implants have been designed which can be inserted as either unlinked or linked prostheses.

![An unlinked Souter–Strathclyde elbow arthroplasty.](Click to view larger)
In an unlinked total elbow replacement, there is no linkage between the humeral and ulnar components, with a metal on polyethylene articulation. It relies on the ligaments and muscles for joint stability, with the theoretical advantage of decreased loading at the bone–cement interface. However, it carries a greater risk for instability. Significant pain relief has been reported in 79–94% with an 80%, 12-year survival for the Souter–Strathclyde implant with revision as the end point and a 90%, 16-year survival for the Kudo implant. An improved final arc of flexion has also been reported of 32 degrees to 136 degrees.

In a linked prosthesis, there is a sloppy hinge with a metal on polyethylene articulation that allows limited rotational varus/vaeger motion between the humeral and ulnar components, to decrease the bone–cement interface loading. However, there is stress concentration at the hinge, which can lead to polyethylene wear, debris, osteolysis, and component loosening. The outcome of surgery in linked total elbow replacement is significant pain relief in 76–92%, with an improved final arc of flexion/extension of 29 degrees to 131 degrees. The 10–15-year survival of linked total elbow replacements with revision surgery as an end point is 92%.

A recent study compared three groups of consecutive patients who had undergone prosthetic elbow arthroplasty with the Souter–Strathclyde, Kudo, or Coonrad–Morrey implant for the treatment of RA. There were 33 elbows in each group. Clinical function was assessed on the basis of pain relief and the range of flexion. The study showed that this was similar in each group and that the component linkage with the Coonrad–Morrey implant prevented dislocation without an increased risk of loosening. Survivorship was assessed with use of a life-table method, with revision surgery and radiographic signs of loosening as the end points. Survival of the Coonrad–Morrey implant was better than that of the other two implants. The 5-year survival rates, with revision and radiographic signs of loosening as the end points, were 85% and 81% for the Souter–Strathclyde implant, 93% and 82% for the Kudo implant, and 90% and 86% for the Coonrad–Morrey implant. While radiographic evidence of loosening of the Coonrad–Morrey implants was less common, they noted focal osteolysis adjacent to 16% of the ulnar components and half of these cases progressed to frank loosening.

A discussion regarding the risks and benefits of elbow replacement should take place on several occasions prior to surgery. This should include the consequences of continued non-operative management together with discussion of the potential complications.

The complication rate following total elbow replacement is relatively high due to poor soft tissue coverage, the proximity of the ulnar nerve to the elbow joint, and the use of immunosuppressive drug therapy in patients with RA. The predominant complication is ulnar nerve damage, which, as a rule, is usually transient and reversible with permanent ulnar nerve damage uncommon. Deep infection is probably more common after elbow replacement compared to other joints and is reported to be from 2–11%. Wound healing has been a problem in 3–5% of patients, yet 75% of these required no additional surgical procedure.

Instability is a unique complication of the unlinked prosthesis and usually occurs soon after surgery. Inadequate soft tissue balance, either from the collateral ligaments or dynamically from the pull of the biceps, is the basic cause. The incidence of instability is less than 5%.

Intraoperative fracture has been reported in up to 5%, and if this occurs during an unlinked total elbow replacement, may require on-table revision to a linked prosthesis.

Aseptic loosening at 5 and 10 years requiring revision has been reported for the Souter–Strathclyde at 96% and 85% respectively. The longest follow-up of the Kudo implant gives a survivorship of 90% at 16 years. Twelve-year survivorship for the linked Coonrad–Morrey implant is 92%.

Summary
Fifty per cent of patients with RA have involvement of the elbow joint, usually bilaterally. Women are affected three times more commonly than men. There have been significant advances in the medical management of RA with the development of the disease-modifying agents. These are now used earlier in the disease, often in combination with each other. Anti-TNF drugs are used when disease-modifying agent combinations have failed to control symptoms. Intra-articular and intramuscular corticosteroids is an effective way of controlling flare-ups.

Synovectomy with or without excision of the radial head can be used earlier in the disease process when there is failure of medical management to control the symptoms of synovitis, particularly symptomatic radiocapitellar joint problems. The occasion for this procedure is diminishing with the advance of medical therapies.
Total elbow arthroplasty is indicated in severe RA where there is failure of medical management to control symptoms, particularly pain and loss of function. This gives good pain relief and restores a functional range of movement. When there is good bone stock a linked or an unlinked prosthesis can be used. When there is significant bone loss a linked prosthesis is used. However, there is a higher complication rate compared to lower limb arthroplasty, particularly ulnar nerve damage and wound healing problems. There are now published results of total elbow replacement beyond 10 years showing survival rates of between 80% (unlinked) and 92% (linked).

Summary points

- Symptomatic, primary osteoarthritis of the elbow usually occurs in young men involved in heavy manual labour.
- Common causes of secondary osteoarthritis of the elbow are trauma, infection, bleeding disorders and neuropathic conditions.
- Clinically, the commonest presenting symptom is loss of motion. Patients can also complain of pain, locking and ulnar nerve symptoms.
- Plain X-rays are usually sufficient for diagnosis. They show reduction in joint space and osteophytes at the tip of olecranon and coronoid processes. Loose bodies are also frequently seen.
- Symptoms in early stages of arthritis are controlled by non-operative means. Steroids are rarely used in clinical practice.
- In advanced cases, numerous operative treatments including arthroscopic and open procedures are available.
- Total Elbow replacement (TER) for primary degenerative arthritis of the elbow is only to be considered as the last option and when stringent pre and post-operative requirements are followed.

Introduction

Osteoarthritis is defined as a ‘non-inflammatory disorder of movable joints characterized by deterioration and abrasion of articular cartilage with formation of new bone at the joint surfaces’. Involvement of the elbow with this condition was once thought to be rare, although more recently its prevalence has been shown to be more common.

Prevalence and aetiology of primary osteoarthritis

The prevalence of symptomatic primary osteoarthritis of the elbow is around 2% and occurs most frequently in men involved in heavy manual labour. An increased incidence of osteoarthritis of the elbow in the dominant arms of middle-aged men in association with arthritis of the hip, knee, and metacarpophalangeal joints has been reported.

The use of pneumatic drills as an aetiological factor in the development of elbow osteoarthritis has been debated for a long time. However, a study has failed to show a direct relationship between the use of this type of equipment and the development of the condition.

Primary arthritis of the elbow has been shown to begin at the radiocapitellar joint as part of the normal ageing process with later involvement of the ulnohumeral articulation. It has been postulated that this may be due to the radiocapitellar joint performing a combined rotation and hinge movement as compared to the purely hinge motion in the ulnohumeral articulation. It is known that forces up to three times the body weight cross the elbow joint during strenuous lifting and up to six times during dynamic loading such as throwing or pounding.

Aetiology of secondary arthritis of the elbow (Box 5.5.1)

The most common cause of secondary osteoarthritis of the elbow is trauma. Intra-articular fractures of the distal humerus and radial head fractures can lead to the development of osteoarthritis. Management of this group of patients can be difficult due to loss of bone stock, presence of deformities, and previous surgeries.

Box 5.5.1 Causes of osteoarthritis of the elbow

- Primary (begins at radiocapitellar joint):
  - Heavy manual work
- Secondary (can begin at any part of the joint):
  - Trauma
  - Infection
  - Bleeding disorders
  - Neuropathic pathologies

Other causes of secondary arthritis of the elbow include: infection, bleeding disorders, and neuropathic pathologies.
Infection within the joint will result in destruction of the articular cartilage and should be treated with prompt washout and appropriate antibiotic therapy.

The commonest cause of haematologic arthritis is haemophilia. Recurrent bleeds with haemosiderin deposition and release of proteolytic enzymes results in destruction of the articular cartilage. Chronic arthropathy in the early stages can be managed well with a specifically designed regimen of exercises to maintain a functional range of elbow motion. In the later stages, synovectomy and total elbow replacement remains the mainstay of treatment.

Neuropathic arthritis predominantly occurs as a result of syringomyelia, tabes dorsalis, diabetes mellitus, congenital indifference to pain, and surgical denervation. The joint is subjected to repeated traumatic episodes not recognized by the patient due to loss of protective joint nociception and proprioception resulting in formation of a Charcot joint. As pain is rare, surgery is rarely considered and protective splinting remains the mainstay of treatment.

Clinical presentation (Box 5.5.2)

Although secondary osteoarthritis can occur in either sex and at any age, primary osteoarthritis is predominantly seen in men rather than women by a ratio of 4:1. The disease usually presents in the fifth decade of life with the dominant extremity most commonly involved. The symptoms and signs include:

- **Loss of motion**: loss of extension is the commonest presenting feature and although flexion may also be restricted, the patients usually maintain a functional range of motion. Forearm rotation is less frequently affected.

**Box 5.5.2 Clinical presentation**

- Loss of motion
- Pain
- Locking
- Ulnar nerve symptoms.

- **Pain**: the patient usually presents with aching discomfort which may be mild to moderate in nature. Acute pain is usually associated with episodes of locking. Pain is more evident in terminal extension (extension impingement) and less common in terminal flexion (flexion impingement). In advanced cases, the pain can be present throughout the arc of motion.

- **Locking**: single or multiple loose bodies can be found in up to 50% of cases. Patients may present with an acutely painful elbow with a loose body interposed in the joint. The elbow may spontaneously unlock or can be unlocked by gentle manipulation.

- **Ulnar nerve entrapment**: patients with arthritis of the elbow may also present with symptoms of ulnar nerve irritation. Osteophytes around the medial aspect of the joint cause compression of the ulnar nerve.

Investigations

Plain anteroposterior and lateral radiographs are usually sufficient to make the diagnosis and no other investigations are normally required. Radiographs typically show osteophytes at the tip of olecranon and coronoid processes. The olecranon and coronoid fossae also reveal ossification and osteophytes. There is reduction in the joint space and loose bodies are often present (Figure 5.5.1). Recently a radiographic classification system for primary osteoarthritis of the elbow has been proposed. Rettig and colleagues also propose that this classification system has validity in predicting postoperative outcomes.

![Click to view larger](Fig. 5.5.1)

A) Anteroposterior radiograph of an osteoarthritic elbow. It shows reduced radiocapitellar joint space with ossification and loose bodies in the olecranon fossa. B) Lateral radiograph of an osteoarthritic elbow. It shows osteophytes over the tip of olecranon and coronoid process with ossification and loose bodies in the anterior compartment.

Occasionally a computed tomography scan can be useful in locating loose bodies or delineating the extent of osteophytes prior to surgical planning.
Nerve conduction studies should be performed in cases of ulnar neuritis.

**Treatment**

**Non-operative treatment**

Symptoms in the early stages of arthritis can be controlled by lifestyle modifications, analgesics, and anti-inflammatory medication (Box 5.5.3). Although intra-articular steroids have been shown to be of some symptomatic relief, they are rarely used in practice due to their short-term benefits.

**Box 5.5.3 Non-operative treatment options**

- Analgesics
- Non-steroidal anti-inflammatory drugs
- Intra-articular steroid injection
- Sodium hyaluronate injection.

Splinting and physiotherapy are of use in post-traumatic elbows but are of little value once the degenerative process becomes established.

Viscosupplementation has been used to treat arthritic conditions around the knee and, more recently, the elbow. A study by Van Brakel and Eygendaal involved giving a series of three injections of sodium hyaluronate within a 4-week period for treatment of post-traumatic arthrosis of the elbow. It was seen to provide slight, short-term pain relief but no benefit was observed after 6 months. The authors did not recommend this treatment for post-traumatic arthritis of the elbow.

**Operative treatment**

A number of surgical options are available for the treatment of elbow arthritis (Box 5.5.4) which can broadly be divided into arthroscopic and open procedures. The exact choice of procedure depends upon the patient’s symptoms, the radiological evaluation, and the surgical expertise.

**Box 5.5.4 Operative treatment**

- Arthroscopic debridement
- Outerbridge–Kashiwagi procedure/ulnohumeral arthroplasty
- Tsuge procedure
- Column procedure
- Interposition arthroplasty
- Total elbow arthroplasty.

**Arthroscopy**

The elbow is the most congruous joint in the body. Degenerative changes further reduce the intra-articular space making instrument manipulation more difficult. This in association with the close proximity of the major neurovascular structures makes elbow arthroscopy a technically demanding procedure with a steep learning curve. Surgeon experience and familiarity with elbow arthroscopy is essential in preventing complications during arthroscopic debridement.

Originally elbow arthroscopy was used for the removal of loose bodies but later it was also appreciated that osteophytes could also be excised. Recent studies have established elbow arthroscopy as an important tool in performing debridement, osteophyte and loose body removal, and capsular releases. Adams and colleagues described the results in 42 primary osteoarthritic elbows treated by arthroscopic osteophyte resection and capsulectomy with a minimum of 2 years’ follow-up. They had 81% good to excellent results with minimal complications. However, like other studies, this review does not establish that an arthroscopic procedure is superior to open debridement, has improved outcomes, or results in earlier return to function. Additionally, radial head excisions can also be performed successfully arthroscopically, especially in post-traumatic arthritis. Radial head excision is not often required in primary degenerative arthritis unless the patient experiences predominantly lateral-sided pain or has significant pain on forearm rotation.

**Open procedures**

**Joint debridement procedures**

These procedures are useful when conservative measures fail to provide adequate symptomatic relief.
Outerbridge–Kashiwagi procedure.

Kashiwagi described a joint debridement procedure which he attributed to Outerbridge and called the Outerbridge–Kashiwagi or OK procedure. This is a simple technique allowing the removal of loose bodies and excision of osteophytes. It is performed using a posterior surgical approach. If indicated, the ulnar nerve can also be decompressed at the same time.

Technique of OK procedure: the procedure can be undertaken either in a supine position with a sandbag under the scapula or in a lateral decubitus position with the arm supported by a bolster. Under tourniquet control, a midline central incision is made over the posterior aspect of the elbow joint approximately 8cm above the tip of the olecranon. The triceps is split in the line of its fibres and the posterior capsule of the joint is exposed. The capsule is incised and any loose bodies in the posterior compartment removed. Osteophytes around the tip of the olecranon are excised. A bone burr is then used to fenestrate the floor of the olecranon fossa providing an opening into the anterior compartment of the elbow. Loose bodies from the anterior compartment are identified and removed at the fenestration by flexing and extending the elbow. The tip of the coronoid process is then brought into view by flexing the elbow and coronoid osteophytes removed using a fine osteotome. Osteophytes around the coronoid fossa can be removed using a Kerrison rongeur. This also partially releases the anterior capsule. The finger can then be passed through the fenestration to confirm the adequacy of resection (Figure 5.5.2). The joint is then thoroughly lavaged and closed in layers over a suction drain. The drain is removed at 24 hours and mobilization commenced with the help of therapists.

Ulnohumeral arthroplasty.

The OK procedure was modified by Morrey (1992) and termed the ulnohumeral arthroplasty (UHA). Morrey elevates the medial half of the triceps rather than performing a triceps split. He believes this causes less blood loss and less swelling. He also uses a bone trephine to create the fenestration into the anterior compartment rather than a burr since he feels that this provides a more predictable and cleaner resection and creates less bone debris. The placement of the trephine is vital so as not to compromise the integrity of the trochlea, capitellum, or lateral and medial columns. Morrey also uses a more aggressive postoperative regimen. This involves the use of a brachial plexus block with a catheter for 2–3 days together with continuous passive motion and the use of splints to maximize the operative gain.

Results: Minami and Ishii (1986) presented their initial results showing good pain reduction and improvement in motion. Their subsequent study showed some deterioration of the results with time. Recurrence of symptoms was seen in 20% of cases at 10 years and recurrence of radiographic changes in up to 50% at 5 years. Morrey’s study (1992) highlighted similar conclusions.

Several other studies have shown good mid- to long-term results of open UHA confirming its durability as a good procedure for this condition. Antuna et al. (2002) reported good or excellent results in 34 of 46 patients at an average of 80 months after surgery. To avoid postoperative ulnar nerve complications, they recommended decompression or mobilization of the nerve in patients who had preoperative ulnar nerve symptoms. Wada et al. (2004) reported satisfactory results in 85% of patients at an average of 121 months after surgery. They also found that 76% of their patients returned to preoperative strenuous labour after surgery. None of the elbows in these discussed studies converted to total elbow replacement in spite of the follow-up being up to 13 years in some cases.

Tsuge debridement procedure.

Tsuge and Mizuseki (1994) advocated a more extensive surgical procedure especially in young patients with more aggressive disease. The procedure involved isolation and protection of the ulnar nerve followed by reflection of the extensor mechanism medially. The radial collateral ligament together with the posterior portion of the medial collateral ligament was then divided and the joint dislocated. Loose bodies were removed, the capsule released, and all osteophytes around the olecranon and coronoid excised. The olecranon and coronoid fossa were then deepened and, if required, the radial head reshaped. Continuous passive motion was then continued for 7 days postoperatively. The authors reported reduced pain and improved motion in most of 29 of their cases at a mean of 64 months.

Column procedure

Some patients with osteoarthritis of the elbow present predominantly with symptoms of loss of motion. They develop progressive loss of extension with a reasonably pain-free mid arc of motion. This confirms a predominantly extrinsic contracture involving periarticular capsule ligamentous structures. The column procedure is useful in such patients in order to gain a functional range of motion especially if the extension deficit exceeds 20 degrees. The procedure involves a lateral Kocher incision with elevation of the brachioradialis and extensor carpi radialis brevis in order to gain exposure to the anterior aspect of the joint. The anterior capsule is
then excised with removal of loose bodies and osteophytes. The triceps is then elevated to gain access to the posterior aspect of the joint and a similar procedure is repeated posteriorly. Continuous passive motion is instituted postoperatively to maintain the surgical gain. The Mayo clinic experience showed excellent pain relief and a substantial gain in range of motion following this procedure in spite of an heterogeneous group of pathologies.

**Interposition arthroplasty**

This technique involves reshaping of the distal humerus and proximal ulna, interposition of a membrane between the elbow joint surfaces, and suturing it to the humeral side. Skin, fascia, and Achilles tendon allograft are most commonly used as interposition tissue. Collateral ligaments are either repaired primarily or reconstructed. A unilateral hinged fixator keeps the joint slightly distracted and allows early active range of motion. The procedure is suitable in young patients (under 60 years old) suffering from incapacitating pain due to traumatic or primary degenerative arthritis affecting the elbow and who have failed to respond to joint debridement procedures. Recent sepsis, an unfused epiphysis, and grossly unstable elbows are contraindications for this procedure. The technique also does not guarantee enough stability for heavy manual work. Larson and Morrey in 2008 updated the Mayo experience of 69 consecutive elbows that underwent interposition arthroplasties using achilles tendon allograft and a hinged fixator. Three fourths of the patients suffered from post-traumatic arthritis. They concluded that this is a good salvage procedure for young active patients with severe inflammatory or post-traumatic arthritis, especially with limited elbow motion. They emphasized to exercise caution when using this procedure in patients with instability or severe pain.

**Total elbow replacement**

The indications for total elbow replacement are constantly evolving. It is an established and effective treatment in patients with inflammatory arthritis but its role in young patients suffering from primary degenerative arthritis is still limited. It is particularly unsuitable in patients planning to undertake manual work after replacement surgery. It is recommended that after total elbow replacements patients do not lift more than 4–5 kg with the operated arm as a single event or more than 1 kg repeatedly. Currently, total elbow arthroplasty is only indicated in patients with primary osteoarthritis of the elbow who are older than 65 years of age, are retired, have low activity levels, experience pain throughout the range of motion, or who have substantial deficits in motion in whom all other interventions have failed. In addition the patients must be happy to comply with postoperative restrictions which are essential after such a procedure.

Espag et al treated 10 patients with primary osteoarthritis of the elbow using an unlinked total elbow replacement. At a mean of 68 months after surgery, one had loosened and needed revising and a further two showed radiographic signs of loosening but 9 out of 10 were satisfied with the procedure.

### Summary

Osteoarthritis of the elbow is a common condition. Patients present with symptoms of pain and stiffness and occasionally complain of locking due to the presence of loose bodies. Ulnar nerve symptoms may also coexist. Xrays are usually diagnostic and often no other investigations are required.

Conservative treatment is a good option in the early stages but surgical treatment may become necessary. Arthroscopic and open procedures are both effective in removal of loose bodies, capsulectomy, and osteophyse excision. The choice of procedure depends upon the patient symptoms, radiological appearances, and surgical expertise.

Interposition arthroplasty is only rarely performed. Total elbow replacement is also rarely indicated in this group of patients as they are often young and involved in manual work.

Elbow arthroscopy

Summary points

- Indications relate to experience
- Neurovascular considerations are paramount
- Elbow Arthroscopy is an evolving technique.

Introduction

Burman reported a cadaveric study of elbow arthroscopy as early as 1932, but it was not until recent times that the technique became popular for treating elbow disorders. Advances in instrumentation as well as arthroscopic skills are the most probable reasons for the increase in use of the arthroscope in and around the elbow joint.

Elbow arthroscopy remains a technically challenging procedure. The reported complication rate is ten times higher than that of shoulder or knee surgery and careful attention to detail is required to help avoid iatrogenic neurovascular complications. The purpose of this chapter is to explore the current indications and contraindications for the procedure, give a description of preoperative planning, patient positioning, and the portals available, and review the results reported in the literature.

Indications

The original indications for elbow arthroscopy were for diagnosis and for removal of loose bodies. As surgeons became more proficient in this procedure, however, the range of pathology dealt with by arthroscopy has expanded. An example of its application is the osteoarthritic elbow where arthroscopy can be used after non-operative treatment has failed, as an intermediate step before arthroplasty. Indication is closely allied to experience and the indications have been related to five stages of surgical experience by Savoie as below:

- Stage I: beginning elbow arthroscopy:
  - Diagnostic arthroscopy before open surgery

- Stage II: limited experience with elbow arthroscopy/experienced arthroscopist with other joints:
  - Diagnostic arthroscopy
  - Confirmation of instability before open repair
  - Loose body removal
  - Spur debridement
  - Excision of posterolateral plica
  - Arthroscopic irrigation/debridement of contaminated joints

- Stage III: experienced elbow arthroscopist:
  - All stage II surgeries
  - Arthrofibrosis (open nerve protection)
  - Extensor carpi radialis brevis (ECRB) debridement for lateral epicondylitis
  - The arthritic elbow: synovectomy, spur excision, radial head excision, and ulnohumeral arthroplasty
  - Complete management of osteochondritis dissecans
  - Fractures: non-displaced or minimally displaced
  - Olecranon bursa removal
  - Synovectomy for rheumatoid arthritis, chronic infectious arthritis, or other arthritides

- Stage IV: advanced elbow arthroscopist:
  - ECRB repair
  - Varus/posterolateral rotatory instability reconstruction
  - Displaced intra-articular fractures
  - Triceps tendon repair
  - Ulnar nerve release

- Stage V: experimental—the future:
Debridement of the arthritic elbow and removal of loose bodies remain the most common indications for elbow arthroscopy, but simultaneous debridement of impinging osteophytes (Figure 5.6.1) and release of capsular contracture can also be performed. In fact, a three-dimensional computed tomography scan prior to the operation in order to identify all potential osteophytes needing debridement has been recommended.

Debridement of ECRB in the treatment of lateral epicondylitis (tennis elbow) can be effectively performed arthroscopically. Instability, osteochondritis dissecans, and fractures are more recent additions to the indications of elbow arthroscopy.

If debridement/synovectomy is entertained in the deformed rheumatoid elbow, this should be performed by an experienced arthroscopist as the risk of neurovascular injury is particularly high.

With regards to the paediatric population, Micheli et al. (2001) have reported a series of 47 patients aged 3.5–17 years who underwent elbow arthroscopy for osteochondritis dissecans, arthrofibrosis and joint contracture, synovitis, acute trauma, and posterior olecranon impingement syndrome. Using a modified Andrews elbow scoring system (MAESS), 85% of these patients had a good to excellent result with 90% returning to sports free of any limitations. They concluded that elbow arthroscopy was both safe and effective in the paediatric and adolescent population as long as there was a careful selection process and the arthroscopist was experienced.

**Contraindications**

Disordered anatomy caused by trauma, arthritis (including rheumatoid disease), previous surgery (especially ulnar nerve transposition), or an overlying cellulitis may be regarded as contraindications. Congenital conditions may be a relative contraindication. Biceps tendon injury and isolated radial tunnel syndrome are also relative contraindications.

**Preoperative preparation (authors’ practice)**

On the day of the operation the patient is seen on the ward and placed in the position for surgery. This is because the skin around the elbow is very mobile and will alter in position with changes in patient position. The medial and lateral epicondyles, radial head, subcutaneous olecranon tip, ulnar nerve, and area of interest are then marked with a permanent marker. Whilst identifying these structures the authors go through the procedure and the structures at risk, to reinforce informed consent.

**Anaesthesia**

General anaesthesia allows full muscle relaxation and enables the patient to be positioned as required without discomfort (especially if the patient is positioned in the lateral decubitus or prone position). We routinely use additional regional blocks for postoperative pain relief although these do not allow for immediate postoperative exclusion of nerve injury.

**Patient positioning (Box 5.6.1)**

Supine

Positioning: the patient is positioned supine at the edge of the operating table. The affected limb is suspended by overhead traction of 5–10lb (2.25–4.5kg) (e.g. ‘Chinese finger traps’). The shoulder is abducted to 90 degrees and the elbow flexed to 90 degrees.

Advantages: since the elbow is held in an anatomic position, orientation of the structures is made easier for the arthroscopist. Excellent visualization of the anterior joint can be achieved. This is particularly useful for fixation of anterior radial head or coronoid fractures. Importantly, it also allows for maximal airway exposure if there are any anaesthetic concerns.

Disadvantages: it is more difficult to access the posterior compartment. In addition, an assistant is required to prevent the arm from swinging when instrumented. This can be partly overcome by modifying the position—having the shoulder flexed to 90 degrees thereby suspending the forearm over the chest. A secondary advantage of this modification is that the anterior neurovascular structures are pulled away from the working area by the force of gravity.

Prone

Original description: Poehling et al. (1989).

Positioning: the patient is positioned prone with the shoulder abducted 90 degrees. The upper arm is placed in a holder allowing 90 degrees of elbow flexion.

Advantages: gravity pulls the neurovascular structures further anteriorly, away from the working area. Full extension to near full flexion of the arm can be produced. The entire elbow is readily accessible.

Disadvantages: patient needs intubation for airway protection.

Lateral decubitus (author’s preference)

Box 5.6.1 Patient positioning

- Supine
- Prone
- Lateral decubitus.

Positioning: the patient is placed in the lateral position with the affected side up. The upper arm rests on a padded support. The table is tilted 20 degrees towards the operating surgeon to avoid potential antecubital fossa compression and minimize patient roll-back (Figures 5.6.2).

Advantages: the position allows excellent access to the anterior and posterior aspects of the elbow without some of the disadvantages of the positions mentioned earlier, particularly regarding anaesthesia implications.

Disadvantages: access to the medial side is limited but can be improved by positioning the elbow higher than the shoulder.

Instrumentation

- A high arm tourniquet
- Fluid management system: the authors use pressure fluid distension for the procedure—we advise experimenting with this preparatively
- 4-mm 30 degree scope with 2.7-mm arthroscope available: most cases can be performed with the 4-mm 30 degree scope. A 2.7-mm scope may be needed in the case of a tight lateral compartment or smaller elbows, for example, in the paediatric group.

Portal positioning
Of all the joints, arthroscopy of the elbow arguably carries the greatest risk of iatrogenic neurovascular damage. It is therefore essential to have a thorough knowledge of the anatomy of the available portals (Box 5.6.2) and their precise locations as margins for error are very small. The distance to the nerves from each portal has been elegantly documented by a number of cadaveric studies.

**Box 5.6.2 Portal positions**

- Anterolateral
- Proximal anterolateral
- Mid lateral
- Anteromedial
- Proximal anteromedial
- Posteroanterior lateral
- Direct posterior
- Posterior retractor portal
- Accessory lateral portal.

We regard it as essential to distend the elbow prior to making the entry portal. This is achieved by using 20–30mL of arthroscopic fluid (Figure 5.6.3A). Capsular distention pushes the neurovascular structures further away from the initial portal site and allows for easier entry into the joint. The site of injection is the centre of a triangle formed by the lateral epicondyle, subcutaneous olecranon tip, and radial head. This site is known as the ‘soft spot’ or infracondylar recess.

In establishing a portal, care must also be taken to minimize the risk of injury to the superficial cutaneous sensory nerves. Only the skin is incised, with a small blade and then a haemostat is used for blunt dissection in the pericapsular tissue. A blunt arthroscopic trochar and cannula are next inserted aiming towards the subcutaneous olecranon tip. Saline issuing from the cannula confirms intra-articular placement.

The authors begin by establishing the anterolateral portal followed by the anteromedial portal using a within-out technique. However, some prefer to begin with the anteromedial portal.

Steinmann (2003) has given an excellent account of the described portals in his review of elbow arthroscopy (Figures 5.6.3B,C). Due to an unacceptably high risk of injury to the ulnar nerve, there are no posteromedial portals.

**Anterolateral portal**

*Position:* 3cm distal, 1cm anterior to lateral epicondyle. The trochar is aimed towards the centre of the elbow joint and passes through ECRB and supinator. Clearly, the precise measurement will depend on body habitus and will need to be modified appropriately.

*Structures at risk:* radial nerve (1.4mm away on average) and posterior antebrachial nerve (7.6mm away on average).

*Function:* passing all instruments through this port minimizes the risk of injury to the radial nerve. Used to scope the anterior trochlea, coronoid fossa, coronoid process, proximal radioulnar joint, and radiocapitellar joint.
Proximal anterolateral portal

Position: 2cm proximal, 1cm anterior to lateral epicondyle.

Structures at risk: radial nerve (9.9mm) and posterior antebrachial nerve (6.1mm).

Function: preferred by some surgeons to the anterolateral portal due to its greater distance from the radial nerve. However, scoping the coronoid fossa or medial trochlea may be more difficult.

Mid or direct lateral portal

Position: the centre of a triangle formed by the lateral condyle, subcutaneous olecranon tip, and radial head (the soft spot).

Structures at risk: lateral antebrachial nerve (between 6–16mm in 90 degrees elbow flexion and mid pronation).

Function: scoping the intra-articular olecranon tip and fossa, posterior trochlea, olecranon articular surface, posterior capitellum, radial head, and radioulna articulation. May be of particular use in osteochondritis dissecans of the capitellum and for the removal of loose bodies.

Anteromedial portal

Position: 2cm distal, 2cm anterior to medial epicondyle. The trochar is aimed at the centre of the elbow joint and passes through the brachialis and common flexor origin.

Structures at risk: medial antebrachial cutaneous nerve (1mm away). Median nerve 7–14mm away with the elbow flexed at 90 degrees. The ulnar nerve is, on average, 20mm away in 90 degrees of flexion but it should be palpatated prior to making the portal, checking for any possible subluxation from the cubital tunnel. Needless to say, particular caution is due in the case of a prior ulnar nerve transposition—in which case the surgeon would be advised to avoid this portal.

Function: good visualization of the anterolateral capsule, radiocapitellar, and ulnohumeral joints. Useful as an accessory portal when working in the medial gutter.

Proximal anteromedial portal

Position: 2cm proximal to the medial epicondyle, immediately anterior to the intermuscular septum. The trochar is aimed towards the radial head gliding across the anterior distal humerus.

Structures at risk: medial antebrachial cutaneous nerve (2.3mm average), ulnar nerve (12mm average), and median nerve (12.4mm average). The same considerations regarding the ulnar nerve apply with this portal as described earlier.

Function: good visualization of the radial head, lateral capsule, and coronoid (Figure 5.6.4) but poor visualization of the radiocapitellar joint and radial fossa. Useful as a retractor portal.

Posterolateral portal

Position: lateral joint line level with the tip of the olecranon with the elbow in 90 degrees elbow flexion. Trochar aimed at centre of olecranon fossa.

Structures at risk: average distances at 90 degrees of flexion—medial brachial cutaneous nerve 22mm, posterior antebrachial cutaneous nerve 22mm, and ulnar nerve 26mm. The ulnar nerve is palpated before portal placement.

Function: excellent visualization of the posterior elbow (Figure 5.6.5) including the olecranon fossa and tip, medial and lateral gutters, and the posterior radiocapitellar joint where loose bodies are frequently missed.

Fig. 5.6.4
View of coronoid tip from anteromedial portal.
Direct posterior portal

Position: 3cm proximal to the tip of the olecranon. Sometimes a scalpel may be needed to penetrate the elbow joint due to the bulk of triceps. Trocar aimed at centre of olecranon fossa.

Structures at risk: average distances at 90 degrees flexion:—medial brachial cutaneous nerve 15mm, posterior antebrachial cutaneous nerve 30mm, and ulnar nerve 20mm. The ulnar nerve is palpated before portal placement.

Function: debridement of the posterior elbow joint. As an accessory portal to the posterolateral portal.

Posterior retractor portal

Position: 2cm proximal to direct posterior portal.

Function: a Howarth elevator can be passed to elevate the joint capsule allowing better visualization of the olecranon fossa.

Accessory lateral portal

The author (S.M.H.) also uses an accessory lateral portal positioned on the radiocapitellar joint line directly between the anterolateral and the direct lateral portals. It has proven very valuable for debridement of osteochondritic lesions and removal of posteriorly placed loose bodies.

Results

Osteoarthritis

Adams et al. (2008) have recently published their results of arthroscopic osteophyte resection and capsulectomy. Forty-one patients with primary osteoarthritis in 42 elbows showed significant improvements in mean flexion, extension, supination, and Mayo Elbow Performance Index scores with 81% good to excellent results. Pain decreased significantly. Complications were rare and included heterotopic ossification and ulnar dysesthesias.

Cohen et al. (2000) have compared the results of arthroscopic debridement with an open Outerbridge–Kashiwagi (OK) procedure (Figure 5.6.6). Overall they found no difference between the two procedures although arthroscopic intervention provided better pain relief, whereas open debridement resulted in an improved flexion range.
Savoie et al. (1999) have reported a series of 24 patients with osteoarthritis treated with arthroscopic debridement, partial resection of the coronoid and olecranon processes, and fenestration of the olecranon fossa. Eighteen of the 24 patients had arthroscopic radial head excision. They report significant pain reduction and an improvement of average arc of motion of 81 degrees. The paper records a complication rate comparable to open ulnohumeral arthroplasty.

Kelly et al. (2007) have reported a series of 24 patients with elbow joint osteoarthritis treated with arthroscopic ulnohumeral arthroplasty, leaving the radial head intact. Debridement of the radial head, anterior and posterior osteophytes, and capsular release alone was performed. Their results showed 14 patients with an excellent result, seven good, three fair, and one poor. The average flexion–extension arc improved by 21 degrees. Twelve patients had no limitations in their daily activities, and 12 experienced occasional problems. No surgical complications were reported. They concluded that resecting an arthritic radial head was not essential.

Rheumatoid arthritis and synovectomy

The rheumatoid elbow presents a particular challenge to the elbow arthroscopist mainly caused by deformity, obscured vision, and synovial hypertrophy (Figure 5.6.7).

Lee et al. (1997) have reported a series of 14 elbows in 11 patients with good 3–4-year results (93% excellent/good) but with subsequent rapid deterioration.

Horiuchi et al. (2002) have reported results of arthroscopic synovectomy in 29 elbows (27 patients). They graded preoperative radiographs from 1–4 using the system of Larsen et al. (1977) forming three groups: 1/2, 3, and 4. They found only elbows with Larsen grade-1 or 2 arthritis had a favourable long-term result with regard to total function. The postoperative results were unsatisfactory for Larsen grade-4 elbows.

Arthrofibrosis

Nerve injury is the predominant concern when performing arthroscopic release of arthrofibrosis. Phillips et al. (1998) reported a series of 25 patients with elbow arthrofibrosis treated with arthroscopic debridement. At 18 months, all patients demonstrated increased motion and decreased pain, although one patient had a reoperation due to continued symptoms. They found that patients with post-traumatic arthritis tended to have greater contractures preoperatively, compared to those patients with degenerative arthritis, but had greater improvement postoperatively. This series reported no perioperative or postoperative complications and concluded that arthroscopic release and debridement of arthrofibrotic elbow joints achieved equal improvement to that of open techniques, with less morbidity and earlier rehabilitation.

Jones et al. (1993) have reported a series of 12 patients with good results, although one patient had residual posterior interosseous nerve palsy.

Radial head excision

Menth-Chiari et al. (2001) have reported a series of 12 patients who underwent arthroscopic excision of the radial head either due to post-traumatic arthritis after fracture of the radial head, or due to rheumatoid arthritis. All except one patient had significant pain relief and complete relief of mechanical symptoms. There were no infections or neurovascular injuries reported.

Lateral epicondyritis

Owens et al. (2001) have reported a series of 16 patients with recalcitrant tennis elbow who underwent arthroscopic surgical debridement of ECRB. There was only 75% follow-up data due to patients’ military reassignment, but the group found that all patients had an improvement with an average return to unrestricted work at 6 days.
Peart et al. (2004) report a series of 87 patients, 54 treated with an open and 33 with an arthroscopic procedure. No significant difference in outcome was noted although an arthroscopic release led to an earlier return to work and required less postoperative therapy.

A systematic review of the literature found similar results in endoscopic, percutaneous, and open procedures.

**Osteoarthritis dissecans**

Rahusen et al. (2006) reported a series of 15 patients with osteoarthritis dissecans treated with arthroscopic debridement (Figure 5.6.8). Their results showed no significant improvement in range of motion, but use of the MAESS showed a significant improvement from 65.5% (poor) to 90.8% (excellent). There was a reduction in pain level and the average return to work occurred 3 months postoperatively.

![Click to view larger](image)

Fig. 5.6.8
Debridement of osteochondritic capitellum.

The role of drilling or microfracture of the capitellum remains unproven.

**Miscellaneous**

There are a number of reports of novel use of the arthroscope in managing conditions of the elbow such as osteoid osteoma and treatment of posterolateral elbow impingement in professional boxers. The treatment of throwers’ elbow/plica has also seen an increasing role of the arthroscope, and the author (S.M.H.) reports arthroscopic removal of a silastic radial head replacement. These are indications of the developing nature of the technique.

![Click to view larger](image)

Fig. 5.6.7
Synovitis.

**Complications**

Kelly et al. (2001) have reported the complications of elbow arthroscopy in 473 patients. Four (0.8%) had a complication classified as major (septic arthritis). Minor complications occurred in 11%, which included prolonged drainage from, or superficial infection at, a portal site after 33 procedures, 12 transient nerve palsies (five ulnar, five superficial radial, one each of posterior interosseous, medial antebrachial cutaneous, and one anterior interosseous palsy). Rheumatoid arthritis followed by contracture was the most significant risk factor for temporary nerve palsy.

This study found no permanent nerve injuries. It also reports the findings of The Arthroscopy Association of North America who conducted two separate surveys. Of the 1648 elbow arthroscopies in both surveys, only one nerve injury was documented.
The authors of this comprehensive study of complications suggest that the use of retractors was the single most important technical step in preventing serious nerve injuries especially when performing synovectomy or capsulectomy. The second factor was arthroscopic/open identification of the nerve when performing a capsulectomy around nerves.

With regards to prolonged portal drainage, Kelly and colleagues found that all were from lateral portals and recommended the use of a locked horizontal mattress suture to minimize the risk of this complication.

### Conclusion

As with many areas of arthroscopic surgery, the technique of elbow arthroscopy, its indications, and its success has evolved considerably in recent years. However, it is a technically demanding and a dangerous procedure for which a detailed working knowledge of the surrounding neurovascular anatomy is essential. It remains the preserve of the experienced arthroscopist and we strongly concur with Savoie (2007) that graduated progression where indication is titrated against experience remains the mandatory approach.

Bursitis of the elbow

Summary points

- Inflammation of the bursa
- Non-Septic or Septic
- Repetitive Micro-traumata
- Bloods, XR, USS, MRI, Aspirate
- Splintage, NSAID, Antibiotics, I+D
- 85% Staph. aureus

Introduction

A bursa (Latin for purse or bag) is a small fluid-filled sac lined with synovial membrane providing a gliding plane and/or a cushioning effect between tendon, muscle, and bone. Several deep and superficial bursae around the elbow have been described; however, only a few are of clinical relevance.

Bursitis is the inflammation of a bursa through either mechanical irritation (non-septic bursitis) or infection (septic bursitis).

Inflammation of the lateral and medial epicondylar bursae are rare sequelae of tennis elbow or a subluxing ulnar nerve and respond to treatment of the underlying pathology. The bicipital radial bursa is often the cause for symptoms deep in the cubital fossa. Differentiation of this from tendinitis, a partial tear of the distal biceps tendon, and secondary compression of the posterior interosseous nerve can be difficult and requires magnetic resonance imaging for exact diagnosis and treatment. The clinically most significant elbow bursa is the superficial olecranon bursa (Box 5.7.1).

Box 5.7.1 Bursae around the elbow

- Lateral epicondylar bursa
- Medial epicondylar bursa
- Bicipital radial bursa
- Superficial olecranon bursa*

* Clinically most important.

History and clinical examination

Olecranon bursitis has a male predominance with a mean age of 45 years, a prevalence of 3:1000, and an incidence of 1:1000 which is seasonal with the peak in summer. The olecranon bursa develops only after the age of 7 years and increases in size thereafter. In up to 54% the history includes a precipitating trauma but other risk factors need to be considered:

- Macrotrauma (occupational or recreational)
- Repetitive microtraumata (overuse, leaning on elbow)
- Immunosuppression (alcoholism, chronic obstructive pulmonary disease, systemic corticosteroid therapy, diabetes mellitus)
- Systemic inflammatory disease (gout, rheumatoid arthritis, psoriasis)
- Previous posterior elbow surgery
- Structural abnormalities (olecranon spur).

The clinical examination should begin with a routine elbow assessment including range of motion, nerve function, and pre-existing elbow pathologies (osteoarthritis, rheumatoid arthritis, and post-traumatic disorders). Localized clinical features of olecranon bursitis include: swelling, erythema, increased skin temperature, fluctuance, and tenderness.

Attention should be given to scarring in the elbow region (previous surgery, healed sinuses, haemodialysis) and areas of possible skin breakage (open or healed).

It is important to differentiate between non-septic (more than 60%) and septic bursitis (Box 5.7.2) since early diagnosis is essential for appropriate treatment.

Box 5.7.2 Regional and systemic signs of septic olecranon bursitis
Induration
Spreading cellulitis
Lymphangitis
Lymphadenitis
Fever and shivering.

Septic arthritis of the elbow must be considered in the differential diagnosis and when present there is usually a painful reduction of joint movement. Aspiration of the elbow will normally confirm the diagnosis.

**Investigations**

If the bursa contains sufficient fluid, an aspiration is recommended in order to exclude or confirm infection. This can guide fast and efficient treatment. Aspiration also enables microscopic examination of the fluid for crystal formation. The extent of further investigations is dependent on the presenting symptoms and may require:

- Blood screening tests (inflammatory parameters including full blood count, erythrocyte sedimentation rate, and C-reactive protein)
- Radiographs of the elbow (pre-existing underlying bony pathology, effusion, osteomyelitis)
- Ultrasonography (soft tissue oedema, joint effusion)
- Magnetic resonance imaging (fluid collection, joint effusion, intra-articular pathology, reactive tissue changes).

Staphylococcus aureus is the most common organism found in septic olecranon bursitis (85%). Other organisms that may be present include Gram negatives, mycobacteria, as well as fungi. It has been suggested that the clinical spectrum of septic olecranon bursitis differs when it is caused by organisms other than Staphylococcus aureus.

**Treatment options**

Most cases of olecranon bursitis do not require hospitalization and can be treated ambulatory (Box 5.7.3).

**Box 5.7.3 Treatment of olecranon bursitis**

- **Non-septic:**
  - Splintage
  - NSAID
  - Intrabursal steroid injections
- **Septic:**
  - Splintage
  - Antibiotics—oral/intravenous
  - Surgical excision.

**Non-septic olecranon bursitis**

This can be successfully treated with splintage, reducing elbow movements and thereby resting the overlying soft tissues. This should be combined with oral, non-steroidal anti-inflammatory drug (NSAID) treatment. Whilst intrabursal corticosteroid injections can be a very effective treatment option, the concern over local long-term effects remains. Any associated underlying systemic disease such as gout or rheumatoid arthritis must also be addressed if treatment is to be effective. The symptoms in patients with non-septic olecranon bursitis resolve more slowly when compared to septic bursitis.

**Septic olecranon bursitis**

Early treatment involves a combination of elbow splintage and oral antibiotic therapy. However, once the clinical picture shows advanced signs (Figure 5.7.1) such as local cellulitis, lymphangitis, and lymphadenitis or systemic effects with shivering and fever, the antibiotic therapy should be administered intravenously. The duration of therapy is guided by the response to treatment but prolonged treatment courses are not uncommon.
The typical features of a traumatic, septic olecranon bursitis: scab over entry wound, swelling, induration, and spreading cellulitis.

If the olecranon bursitis remains refractory to conservative treatment or a bursal collection with septicaemia develops, surgical excision of the bursa should be performed. Although normally the initial response to such treatment is good, the complication rate remains a concern for the treating clinician. Recurrence, a chronic discharging sinus, and wound breakdown are common (up to 25%) along with worrisome complications. In order to reduce such problems, several surgical techniques have been described:

- Skin incision skirting the tip of the olecranon
- Postoperative immobilization in 45 degrees of elbow flexion
- Application of a compression bandage postoperatively
- Wound drain.

If the extent of the bursa is difficult to determine, the use of methylene blue and hydrogen peroxide staining can be used. In an attempt to prevent wound healing problems following resection of the bursa, endoscopic techniques with excellent results have more recently been described.

A chronic discharging sinus can initially be treated non-operatively with regular changes of wound dressing in the outpatient department. If signs of infection develop, antibiotic therapy is required and is based on the culture and sensitivity report.

Should the sinus remain refractory to such treatment, revision surgery should be contemplated. The use of talcum powder in revision surgery has shown favourable results. For chronic and recurrent wound breakdown, more advanced reconstructive soft tissue techniques, such as local and free flap, may be required.

Assessment and investigation of chronic wrist pain

Summary points

♦ A careful history and a thorough physical examination is of paramount importance in the diagnosis of chronic wrist pain
♦ The mechanism of injury and the position of the wrist when injured is crucial information
♦ The localization of swelling and local tenderness can be invaluable in diagnosis
♦ Imaging of the wrist is often helpful in diagnosis, with plain radiography standard
♦ Fluoroscopy, nuclear medicine, CT and MRI scans, arthrography and arthroscopy can also help with diagnosis
♦ The choice of imaging technique and its interpretation depend upon clinical information derived from the history and physical examination

Introduction

Advances in the understanding of the anatomy, biomechanics, and pathology of the wrist over the last few years have greatly increased the number of diagnoses that the upper limb surgeon must consider in the management of wrist disorders. At the same time, new methods of investigation are able to demonstrate wrist pathology with increasing accuracy. The aim of this chapter is to give an overview of the techniques of clinical assessment and diagnostic investigations that are useful in the management of chronic wrist pain.

Clinical assessment (Box 6.1.1)

Of paramount importance in the diagnosis of chronic wrist pain are a careful history and a thorough physical examination. Attention must be paid to the position of the wrist at the time of injury and the location of pain. Swelling and local tenderness are noted and the ranges of motion and grip strength of the injured and uninjured side are measured.

Box 6.1.1 Clinical assessment

This is paramount in assessment. In particular:

♦ Position of wrist at injury
♦ Site of pain
♦ Swelling and local tenderness
♦ Specialist clinical tests
♦ Grip strength.

History

The mechanism of injury and the position of the wrist at the moment of impact can give useful information on likely injuries. Was the wrist flexed or extended? Was it the thenar or hypothenar eminence that struck first? The latter is particularly important when considering the possibility of intercarpal ligament damage. The magnitude of the force is also informative. Injuries that involve sudden transmission of body weight through the wrist are liable to cause fracture or intercarpal ligament damage. However, pain that follows a blow to the side of the wrist on a hard surface is unlikely to represent a serious injury.

The precise location of pain is most valuable. All too often, however, patients are unable to localize the pain and the best that can be achieved is localization to a specific area, for example, the radial or ulnar aspect of the radiocarpal joint or the distal radioulnar joint.

An indication of the severity, frequency, and duration of pain is useful in determining the management. Constant severe pain suggests infection or tumour. The activities that aggravate intermittent wrist pain should be ascertained. Persistent swelling would suggest an arthropathy. Mechanical symptoms (snapping, clicking, and so on) may be due to carpal instability.

Physical examination (Box 6.1.2)

The localization of swelling and local tenderness can be invaluable. Loss of motion can have a significant effect on the patient’s function and the plane of principal loss can suggest potential diagnoses, for example, restricted or painful ulnar deviation in ulnar impaction or radial deviation with dorsiflexion in dorsal rim arthritis.
Osteoarthritis and other pathology of the first carpometacarpal joint can be detected by eliciting pain on the simple manoeuvre of applying traction to the thumb and pressing downwards over the base of the first metacarpal. More proximally, pathology of the scaphotrapeziotrapezoidal joint can be reproduced by balloting the distal pole of the scaphoid. It should be remembered, however, that osteoarthritis of this joint can be associated with inflammation of the adjacent flexor carpi radialis tendon. As a consequence, resisted flexion and radial deviation will reproduce the pain.

Tenderness in the anatomical snuff box is said to be pathognomonic of fractures of the scaphoid bone. However, pressure in this area may be uncomfortable in the normal wrist, so the opposite side should be examined for comparison. Stability of the scapholunate joint can be demonstrated by two means. Firstly, the joint can be balloted using the thumb and index fingers of both hands. Secondly, Watson’s manoeuvre is performed by applying pressure to the palmar aspect of the distal pole of the scaphoid as the wrist is moved from ulnar deviation into radial deviation (Figure 6.1.1). If an audible or palpable painful clunk is produced, the test is deemed positive. In the normal wrist, the scaphoid flexes along with the lunate as the wrist moves into radial deviation. If the scapholunate joint is unstable, pressure from the examiner’s thumb prevents flexion of the scaphoid and allows dorsal displacement of the proximal pole as the wrist moves from ulnar to radial deviation.

In de Quervain’s syndrome there is usually swelling and local tenderness over the tendons of the first dorsal compartment. Finkelstein’s test is useful confirmatory evidence. The ‘intersection syndrome’ produces pain, swelling, and local tenderness over the radial wrist extensor muscles as they run under the muscles of the first dorsal compartment. Tendon disorders are characterized by a longitudinal distribution of tenderness and swelling, extending proximal and distal to underlying joints. In joint conditions, these signs are more typically orientated transversely and can be elicited on all surfaces of the joint.

On the dorsal surface, point tenderness may be seen in cases of ‘occult’ ganglion. Simple ballottement of the lunotriquetral joint will reproduce symptoms due to instability or other pathology at that site. The lunate is grasped between the index finger and thumb of one hand of the examiner. The examiner’s opposite thumb and index grasp the triquetrum and pisiform. The examiner then attempts to displace the lunate and triquetrum in a palmar/dorsal direction, looking for pain and/or instability, and comparing the findings with the contralateral normal wrist. Midcarpal joint instability is often manifest by clicking or voluntary clunking of the wrist. The provocative manoeuvre used to confirm this diagnosis is performed by applying an axial load to a pronated and slightly flexed wrist, which is then brought into ulna deviation. This may reproduce the painful click.

Volarly pisotriquetral pathology can be identified by compressing the pisiform onto the triquetrum both ulnarily and radially as well as from proximal to distal. This manoeuvre is helped by flexing the wrist. Firm ulnar deviation of the wrist may produce ulnar-sided wrist pain in the unocarpal impaction syndrome, which results from impingement between the lunate and triquetrum distally and the triangular fibrocartilage complex and ulnar head proximally. More distally, affictions of the carpometacarpal joints such as a carpal boss have been demonstrated by direct ballottement of the each joint. A particularly effective manoeuvre is to flex the appropriate metacarpophalangeal joint to 90 degrees (thus tightening the collateral ligaments) and then to rotate the metacarpal by radial and ulnar deviation of the flexed finger. Reproduction of the pain at the carpometacarpal joint is highly suggestive of pathology at that site.

The distal radioulnar joint and ulnocarpal area are responsible for many cases of wrist pain. Pathology of the distal radioulnar joint, such as osteoarthritis and osteochondral defects, can be demonstrated by direct ballottement, which can be undertaken by compressing the articular surface or by producing a shear force in the anteroposterior plane (it appears clinically that the distal
ulnar moves but this is fixed and in fact it is the distal radius that moves). The latter can also be used to demonstrate instability, but comparison with the contralateral wrist is essential. Finally, it is also important to be aware of the possibility of inflammation or tendinitis affecting the extensor carpi ulnaris and flexor carpi ulnaris tendons. Localized tenderness here is quite specific and pain is reproduced by resisted extension or flexion in the appropriate plane.

Limitation of the range of motion strongly suggests intra-articular pathology. The flexion/extension and radial/ulnar deviation ranges can be measured directly with the use of a goniometer and compared with the contralateral side. Pronation and supination are performed with the elbow flexed to 90 degrees so as to prevent rotation at the shoulder. Pain on active resisted motion suggests a disorder of tendon or tendon sheath.

Grip strength can help to evaluate the level of disability experienced by the patient. The measurements are made with a dynamometer with the elbow flexed and the forearm and wrist in neutral. Clinical estimation of grip strength is unreliable. Grip strength should diminish with fatigue on repeated testing. Rapid alternating tests between normal and abnormal hands may reveal an increase in strength (from an initial low level) on the abnormal side in patients whose symptoms are modified by psychological factors. The plot of grip strength against width of grip should show a bell-shaped curve with maximal strength at the middle position. A flat plot suggests that the voluntary effort is submaximal.

Imaging

Imaging of the wrist is often very helpful. The mainstay is plain radiography, with the addition of stress views when necessary. Specific clinical problems can be further examined with isotope bone scanning, ultrasound, arthrography, computed tomography (CT), or magnetic resonance imaging (MRI). The choice of imaging modality and the interpretation of the results depend upon knowledge of the clinical information derived from the history and physical examination.

Plain radiography

The standard radiographic assessment of the wrist comprises posteroanterior (PA) and lateral views of the wrist. The films are taken with the wrist in the neutral position with regard to flexion/extension and pronation/supination, so that measurements of intercarpal angles and relative radioulnar length are reproducible.

Special views may be required when particular diagnoses are suspected. An oblique view may show degenerative arthritis of the pisotriquetral joint. Fractures of the hook of the hamate may be seen on the carpal tunnel view.

Stress views are valuable in the assessment of carpal instability. All carpal instabilities are abnormal movements of the proximal row. The proximal row receives no tendon insertions and depends for its stability on the ligaments that bind the bones to each other, to the distal row and to the radius and ulna. Abnormal movement between two of the proximal row bones is termed carpal instability dissociative. Abnormal movement of the whole proximal row is termed carpal instability non-dissociative. Scapholunate dissociation is an example of dissociative carpal instability; midcarpal instability is non-dissociative.

PA radiographs in ulnar and radial deviation, and clenched fist views in PA and lateral projections, apply load to the proximal carpal row and may show displacement that is not evident on static films. Stress views increase the sensitivity in the diagnosis of ligamentous injury. On PA views the scapholunate gap should be no greater than the lunotriquetral gap, normally not more than 3mm. A larger gap suggests scapholunate dissociation or scapholunate ligament rupture (Figure 6.1.2), although there is considerable normal variation and comparison views of both wrists have been suggested. In the presence of scapholunate ligament disruption, forces acting on the wrist may cause flexion of the scaphoid, with an increase in the angle between the scaphoid and the lunate on the lateral radiograph. The normal angle is between 30–60 degrees. Angles of 80 degrees or greater indicate rotatory subluxation of the scaphoid. If, in addition, the lunate is dorsally angulated on the radius the appearances is termed dorsal instability (dorsal intercalated segment injury) scapholunate angle of less than 30 degrees indicates volar intercalated segment injury, which usually results from disruption of the ulnotriquetral ligament complex.

Fig. 6.1.2
Scapholunate dissociation due to scapholunate ligament rupture. The gap between the scaphoid and lunate is greater than the
Chronic scapholunate ligament rupture leads to flexion of the scaphoid decreasing the contact area and thus increasing the load in the radioscaphoid joint, leading to radioscaphoid osteoarthritis with proximal migration of the capitate and the subsequent involvement of the scaphocapitate and hamate/lunate joints. This degenerative pattern is known as the scapholunate advanced collapse (SLAC) wrist and may occur naturally as well as after trauma (Figure 6.1.3). Other common patterns of primary degenerative arthritis are of the scaphotrapeziotrapezoid joint and the first carpometacarpal joint. Less commonly, arthritis may involve the triquetrolunate, radiolunate, or pisotriquetral joints.

Fluoroscopy

Fluoroscopy enables wrist movement to be viewed dynamically and shows the abnormal movements occurring in instability. Recording the examination on videotape allows replay in slow motion. Fluoroscopy may show dynamic instabilities which cannot otherwise be demonstrated. It is especially useful in assessing the ‘catch-up clunk’ that can occur in scapholunate and midcarpal instabilities. In radial deviation, the proximal carpal row is normally flexed with respect to the distal row but moves smoothly into extension during ulnar deviation. In unstable wrists, the proximal row remains in flexion initially but makes a sudden movement or ‘clunk’ into extension as the joint is taken into ulnar deviation. The clunk may be painful and palpable, and may occur in reverse during radial deviation.

Wrist arthrography

Wrist arthrography was the principal means of diagnosing tears of the intrinsic ligaments of the wrist, the scapholunate and lunotriquetral ligaments, and the triangular fibrocartilage prior to the development of arthroscopy and MRI. The wrist comprises three anatomically separate compartments: the distal radioulnar joint, the radiocarpal joint, and the midcarpal joint. In wrist arthrography, radio-opaque contrast is injected into the radiocarpal joint. The contrast is usually mixed with local anaesthetic and is injected away from the site of expected abnormality to avoid obscuring the area with extravasated contrast material. The joint is distended. If there is a perforation of the scapholunate ligament or the lunotriquetral ligament, contrast may be seen to flow through the tear into the midcarpal compartment. A triangular fibrocartilage tear may be identified as contrast passes through it into the distal radioulnar joint (Figure 6.1.4). The injection of contrast should be visualized with fluoroscopy, as the route by which it reaches the midcarpal joint may not be apparent from postinjection radiographs. Standard radiographs after injection are PA (in neutral and with radial and ulnar deviation), lateral, and both obliques.
Unfortunately the demonstration of a communication between the wrist joint compartments does not necessarily imply a traumatic tear or that the abnormality is the cause of symptoms. Communications are common in asymptomatic wrists. Degenerative perforations of the triangular fibrocartilage are present in 40% of cadavers in the fifth decade. Abnormal arthrograms are found in the opposite asymptomatic wrist in most patients with wrist pain and abnormal arthrograms. Given this and the fact that arthrography has a relatively low accuracy when compared with arthroscopy the use of this investigation has declined.

**Nuclear medicine**

Three-phase isotope bone scanning using $^{99m}$Tc-MDP is a useful technique in assessing chronic wrist pain, particularly where a cause is not initially evident. Bone infection and tumour, osteonecrosis, fracture, and arthritis usually appear as areas of increased uptake on bone scans. In chronic wrist pain, bone scanning is most likely to be helpful in the diagnosis of occult fractures and osteonecrosis of the carpal bones. Osteoid osteomas, occasionally found in the wrist, show intensely increased uptake. Bone scanning is best used in patients with chronic wrist pain where there are no definite diagnostic signs on clinical or radiographic assessment. It is not useful in the diagnosis of carpal instability.

**Tomography**

Standard or trispiral tomography is useful in the diagnosis of occult fractures of carpal bones and in the assessment of fracture healing. Indications for tomography are broadly similar to those for CT, which has largely superseded it.

**Computed tomography**

CT shows excellent bony detail but is less useful in the investigation of soft tissue abnormalities. It is the technique of choice in the assessment of occult fractures, and in the assessment of position or healing of a known fracture when this cannot be achieved with plain radiographs (Figure 6.1.5). The examination must be tailored to the likely diagnosis e.g. thin slices (1–2mm) in the long axis of the scaphoid for assessment of union. CT scanning is also the preferred method for demonstrating healing of bone grafts and bone invasion by a soft tissue mass. Axial CT images of the symptomatic and opposite normal distal radioulnar joints in pronation and supination can be used to detect subluxation, which may be evident only in extremes of rotation.
Computed tomography arthrography

Arthrography is accurate in the detection of scapholunate ligament tears, but does not show the exact size and position of the tear. These can be accurately visualized using CT arthrography and, where this information will influence treatment, the technique is useful. CT arthrography is performed after standard arthrography; thin-section axial and coronal scans are taken through the wrist.

CT arthrography is more accurate than current MRI scanners in visualizing the scapholunate ligament. It is useful in demonstrating carpal fractures occurring in association with ligamentous injuries, but it is less likely to be helpful in triangular fibrocartilage or lunotriquetral ligament tears. The technique may also be helpful in detecting loose bodies in the wrist.

Ultrasound

Ultrasound is a quick, cheap, and simple method of imaging the wrist. It allows the examiner to assess the wrist clinically at the same time and does not involve the use of ionizing radiation. However, it is operator dependent. Ultrasound waves do not penetrate bone, precluding its use in bony and some deep soft tissue assessment. The major uses of ultrasound are in the assessment of tendon pathology and in the assessment of palpable swellings. Tendon ruptures and other pathology, especially tenosynovitis, can readily be diagnosed with ultrasound. The advantage over MRI scanning is that the patient can be clinically assessed by the operator at the time of scanning. Ultrasound is also useful in the assessing of lumps and masses around the hand. It is most useful in assessing ganglia; as in other areas of the body any mass that might signify aggressive or malignant pathology should be initially assessed with urgent MRI scanning where possible. Ultrasound has also proved useful in the assessment of occult foreign bodies, and is increasingly used to help in the diagnosis of early inflammatory arthritis. It can also be used to ensure accurate placement of injections.

Magnetic resonance imaging

MRI has developed into an invaluable imaging tool in the diagnosis of chronic wrist pain. Its main advantages are the excellent contrast discrimination between different soft tissues and the ability to image in any plane. It is non-invasive and does not use ionizing radiation. Cortical bone does not return a signal but MRI is sensitive to bony abnormalities because of the signal returned by marrow fat. Fractures that are occult on plain radiographs can be seen on MRI, where on T1-weighted images they show a low signal line through the normally high signal marrow fat with surrounding marrow oedema. MRI is the most sensitive technique in the diagnosis of early avascular necrosis. On T1-weighted MRI, avascular necrosis shows loss of the high signal of marrow fat (Figure 6.1.6). Later changes, including cyst formation, bone collapse, and osteosclerosis, are also well seen.

MRI has an accuracy of about 90% in the diagnosis of triangular fibrocartilage tears. Tears are characterized by a gap across the triangular fibrocartilage containing high signal; the normal triangular fibrocartilage shows as a low-signal disc (Figure 6.1.7). Degenerative perforations of the triangular fibrocartilage are common over the age of 40 years and thus a tear may not be the cause of a patient's symptoms. The scapholunate ligament and lunotriquetral ligament are not always visible, and so MRI is not entirely reliable in demonstrating tears. Tears may appear as absence of the ligament or high-signal fluid crossing the ligament. MRI is not as sensitive as arthrography in the detection of scapholunate ligament and lunotriquetral ligament perforations, and as with the triangular fibrocartilage the functional significance of a perforation may be uncertain.
Fig. 6.1.7
A) Coronal T1-weighted MRI scan shows a high-signal defect in the normally low-signal triangular fibrocartilage, indicating perforation of the central portion of the triangular fibrocartilage, in a patient with abutment of the long ulna against the carpus. B) The normal triangular fibrocartilage of another patient is shown for comparison. (Courtesy of the Department of Radiology, Nuffield Orthopaedic Centre, Oxford.)

MRI shows tendon pathology clearly. In tendinitis the tendon is enlarged. Tendon oedema and fluid within the tendon sheath return a high signal on T2-weighted images. These conditions are most commonly seen in de Quervain’s syndrome. Rupture of the tendon may be obvious. In arthritis, cartilage loss can be seen and erosions are said to be identifiable earlier than on radiograph. Joint fluid can be distinguished from pannus because the latter enhances after intravenous gadolinium.

MRI is valuable in the diagnosis of both cystic (Figure 6.1.8) and solid masses in the wrist and hand.

Fig. 6.1.8
Axial MRI image shows a small high-signal occult dorsal wrist ganglion. (Courtesy of the Department of Radiology, Nuffield Orthopaedic Centre, Oxford.)

Increasingly MRI is performed with injection of contrast medium particularly to look for ligament/triangular fibrocartilage complex (TFCC) tears. As with standard arthrography, the presence of a tear does not of necessity mean it is traumatic nor that it is the cause of the patient’s symptoms.

**Box 6.1.3 Investigations**

- Plain radiography: the mainstay and usually diagnostic
- Fluoroscopy: for dynamic assessment
- Nuclear medicine: useful for non-specific localization
- CT scan: best for bone problems
- MRI: best for soft tissues
- Arthrography: best for ligament/TFCC tears. Usually done with CT or MRI
- Arthroscopy: the gold standard assessment.

Arthroscopy
Arthroscopy has recently assumed the position of pre-eminence in the investigation of chronic wrist pain. Arthroscopy can provide information about the altered mechanics and pathology of the wrist, and can identify pathologies that would otherwise remain undetected. However, interpretation is sometimes difficult, not least because of the high prevalence of asymptomatic wrist lesions such as TFCC perforations.

In patients with symptoms suggestive of a scapholunate interosseous ligament tear but with normal radiographs, instability can be established by dynamic manoeuvres undertaken during radiocarpal and midcarpal arthroscopy.

**Conclusion**

There is no single clinical sign or investigation that can lead to an accurate diagnosis in cases of chronic wrist pain. The wide range of diagnostic investigations now available has revealed many pathological abnormalities in the painful wrist, although these changes are also seen in asymptomatic wrists. It is therefore essential to correlate the clinical information with the results of diagnostic studies before making decisions on management.

An initial section covers physical examination of the wrist. The description of plain radiography includes instability as well as normal variants.]

Degenerative arthritis of the wrist

Summary points

- The multiple joint compartments of the wrist show very different susceptibility to degenerative arthritis
- Secondary, not primary, degenerative arthritis of the radiocarpal joint is more common, and non-operative treatment is often sufficient
- Scaphoid-trapezoid-trapezium osteoarthritis is common and often asymptomatic or only mildly symptomatic, non-operative treatment is usually sufficient
- Pisiform-triquetral osteoarthritis is uncommon and often asymptomatic
- Range of movement, features of pain and radiography are important in diagnosis

Introduction

A strong, stable, mobile and painless wrist is the key to function of the hand. The multiple joint compartments of the wrist show very different susceptibility to degenerative arthritis. The frequency of involvement of joints of the wrist determined from study of 210 radiographs was radoscaphoid (RS) joint 55%, scaphoid-trapezoid-trapezium (STT) joint 26%, both RS and STT joints 14%, and other joints 5%. The fact that either the proximal or distal surface of the scaphoid was affected in 95% of cases emphasizes that bone's importance in the function of the wrist.

Radiocarpal osteoarthritis (Box 6.2.1)

Aetiology

Primary osteoarthritis of the radiocarpal joint is uncommon but may be associated with calcium pyrophosphate crystal deposition disease (CPDD) and with haemochromatosis. Most cases are secondary to conditions that damage articular cartilage or to injuries that increase surface pressure on articular cartilage by altering loading and joint contact areas. The causes of secondary degenerative arthritis are listed in Box 6.2.2.

Box 6.2.1 Causes of secondary degenerative arthritis of the radiocarpal joint

- Intra-articular fractures of the distal radius
- Scaphoid non-union, malunion, and avascular necrosis
- Scapholunate instability
- Kienböck’s disease
- Preiser’s disease (idiopathic osteonecrosis of the scaphoid)
- Lunate fracture.

Box 6.2.2 Radiocarpal arthritis

- Cause:
  - Primary arthritis is uncommon
  - Mostly secondary, especially related to scaphoid problems (SLAC and SNAC wrist)
- History:
  - Pain
  - Stiffness
  - Reduced grip strength
  - Previous injury
- Examination:
  - Swelling
  - Tenderness
Degenerative arthritis of the radioscaphoid joint is the final common pathway for several disorders that alter the mechanics of the wrist. The path of motion of the scaphoid in the elliptical radioscaphoid joint is controlled by ligamentous attachments to the radius and to the lunate. The scaphoid flexes during radial deviation and extends during ulnar deviation. The radiocarpal load is shared 60:40 between scaphoid and lunate. Injuries that destabilize the scaphoid, either by ligament disruption or by scaphoid fracture, affect the radioscaphoid joint in three ways: excessive scaphoid flexion; decreased articular surface contact; and increased radioscaphoid loading. The articular cartilage that is in contact with the unstable scaphoid (or, in the case of a scaphoid fracture, the unstable distal fragment) deteriorates rapidly in the face of this mechanical challenge, while the spherical and relatively unloaded radiolunate joint is preserved. Later, the capitolunate joint is affected. This characteristic pattern of degeneration is referred to as the Scapholunate Advanced Collapse (SLAC) wrist (Figure 6.2.1).

Clinical features

In the early stages, activity-related pain is experienced intermittently on the dorsoradial aspect of the wrist. As the process extends to the midcarpal joint, pain generally increases and is associated with loss of wrist motion and with loss of strength. In some cases, however, pain correlates poorly with the radiographic appearance and function remains good.

Radiography

The first sign of radioscaphoid osteoarthritis is beaking of the radial styloid. Loss of height of articular cartilage in the radioscaphoid joint and subchondral sclerosis follow. The changes are most marked along the dorsal rim of the radioscaphoid joint and may be associated with osteophytes that are best seen on oblique radiographs (Figure 6.2.2). Chondrocalcinosis may be seen in cases resulting from CPDD (Figure 6.2.3).
Non-operative management

Modification of activity, splintage, and analgesic medication are appropriate for modest symptoms. Steroid injection can give useful medium-term relief in patients who prefer to avoid operative treatment. Modest loss of wrist motion is consistent with good function. About 70% of normal daily activities can be accomplished within the range of 40° extension, 40° flexion, and 40-degree radial/ulnar deviation. Many patients adjust to their disability and do not require operative management.

Operative management

Wrist pain that persists despite non-operative management may require operative treatment (Box 6.2.3). The options are as follows:

Box 6.2.3 Treatment of radiocarpal osteoarthritis

- Non-operative (usually adequate):
  - Activity modification
  - Non-steroidal anti-inflammatory
  - Splint
  - Steroid injection
- Operative:
• Denervation
• Proximal row carpectomy
• Partial fusion
• Total fusion
• Arthroplasty.

Proximal row carpectomy

Excision of the proximal row of the carpus requires intact articular cartilage on the head of the capitate and the lunate fossa of the radius (Figure 6.2.4). The wrist is immobilized for 3–6 weeks. Strength and mobility improve over at least 12 months. A review of 22 cases after a minimum of 10 years found 14 patients very satisfied, four satisfied, and four failures requiring arthrodesis.

![Fig 6.2.4](image)
Proximal row carpectomy. The head of the capitate articulates with the lunate fossa of the radius. The tip of the radial styloid may require excision to prevent impingement against the trapezium.

Scaphoid excision and midcarpal arthrodesis

The preservation of the spherical radiolunate joint in the late stages of the SLAC wrist allows it to be used as the sole articulating surface. Radial-scaphoid impingement is relieved by excision of the scaphoid and the midcarpal joint is stabilized by arthrodesis (capitolunate or capitate-lunate-hamate-triquetrum) (Figure 6.2.5). Several studies have shown that proximal row carpectomy fares at least as well as scaphoid excision/midcarpal arthrodesis with regard to range of motion (ROM) and strength, and does not have the disadvantages of fixation-related complications, prolonged immobilization, and risk of non-union. However, scaphoid excision and midcarpal arthrodesis is the only alternative to total wrist arthrodesis when damage to the head of the capitate precludes proximal row carpectomy.

![Fig 6.2.5](image)
Scaphoid excision and midcarpal fusion for SLAC wrist.
Radiocarpal arthrodesis

Arthrodesis of the radiocarpal joint is indicated for osteoarthritis confined to the radioscaphoid and/or radiolunate joints. Intra-articular fracture of the distal radius is the most common cause.

Total wrist arthrodesis

Wrist arthrodesis is the definitive and durable solution for osteoarthritis of the wrist. The joint is fused in 15–25 degrees of extension and 0–15 degrees of ulnar deviation. Plate fixation has significantly a higher fusion rate than other techniques and is the method of choice for degenerative and post-traumatic arthritis (Figure 6.2.5). The arthrodesis must include the radioscaphoid and midcarpal joints, but inclusion of the third carpometacarpal joint is controversial. In most cases, sufficient cancellous bone graft can be obtained from the distal radial metaphysis, obviating the need for iliac crest graft.

Total wrist arthroplasty

Wrist arthroplasty is indicated mainly for severe rheumatoid arthritis. Patients who wish to maintain dexterity for low-demand activities of daily living may be suitable for wrist arthroplasty, but they must be willing to accept permanent restrictions in activity. Many patients with degenerative arthritis are young and active, and not suitable for wrist arthroplasty.

Wrist denervation

Division of multiple nerve branches that supply the wrist joint has been used to reduce pain from osteoarthritis and other painful disorders, either on its own or combined with other procedures. So-called total denervation requires multiple incisions around the wrist. Partial denervation, usually comprising the terminal branches of the posterior and anterior interosseous nerves through a dorsal approach, is also used. Preoperative diagnostic nerve blocks are believed to be helpful in predicting the effect of denervation.

Scaphoid-trapezoid-trapezium osteoarthritis (Box 6.2.4)

Aetiology

Osteoarthritis of the scaphoid-trapezoid-trapezium (STT joint) may be idiopathic, associated with CPDD, associated with trapeziometacarpal osteoarthritis, or secondary to trauma (intra-articular fractures and, possibly, ligament injury).

Clinical features

Pain on the dorsoral aspect of the wrist is the characteristic symptom but the severity of pain is variable and asymptomatic. STT osteoarthritis is frequently seen on radiographs taken for another purpose. Local tenderness may be present over the dorsal and/or palmar surfaces of the STT joint. Loss of wrist motion is usually slight. Synovial fluid tracking from the STT joint along the
flexor carpi radialis (FCR) tendon sheath may form a ganglion cyst just proximal to the wrist crease. STT osteoarthritis should be suspected when a ganglion cyst is seen at this site in an older individual. Rarely, osteophytes at the margins of the scaphotrapezial joint irritate the flexor carpi radialis tendon or flexor pollicis longus tendon, causing tendinitis or rupture.

**Radiography**

Loss of articular surface height in the scaphotrapezial and/or scaphotrapezoid joints is the earliest sign of STT osteoarthritis. Later, subchondral sclerosis, osteophytes and cysts appear (Figure 6.2.6). Oblique views are useful in showing the scaphotrapezial and trapeziometacarpal joints.

**Non-operative management**

Splintage and analgesic medication are the first line of treatment. Steroid injection may be given through dorsal or palmar approaches, and be guided by fluoroscopy if necessary. Non-operative treatment is sufficient for most cases.

**Operative management**

Arthrodesis of the STT joint is appropriate for isolated STT osteoarthritis. The joints are approached through a dorsoradial incision, avoiding branches of the superficial radial nerve. The alignment of the scaphoid and the spatial relationship of the three bones should be preserved, so as to avoid distortion of surrounding joints. Cancellous bone graft from the distal radius is packed between the decorticated surfaces and the bones are fixed together with pins, screws, or staples (Figure 6.2.7). If pins are used, their ends should be left under the skin and removed later under local anaesthesia, to avoid the risk that pin-track infection will lead to septic arthritis. Good pain relief is usually achieved. However, complications are frequent (20–30%), including superficial radial neuroma, pin-track infection, and non-union. The postoperative range of wrist motion is approximately 75% of normal. Excision of the distal scaphoid is an alternative but the long-term results are unknown.

When both STT and trapeziometacarpal joints are involved, the trapezium should be excised. It may also be useful to undercut the scaphotrapezoid joint to minimize the risk of persistent pain from the scaphotrapezoid joint.
Pisotriquetral osteoarthritis

Aetiology

The pisiform is a sesamoid bone that lies within the flexor carpi ulnaris tendon and articulates with the triquetrum. Pisotriquetral osteoarthritis may be idiopathic or due to fractures of the pisotriquetral articular surfaces or instability of the pisotriquetral joint. It may also be associated with loose bodies in the pisotriquetral joint and with entrapment or irritation of the ulnar nerve.

Box 6.2.5 Pisotriquetral osteoarthritis

- Uncommon
- Often asymptomatic
- Examination:
  - Local tenderness
  - Positive shear stress test
- Treatment:
  - Non-operative: steroid injection
  - Operative: excision.

Clinical features

Pain over the palmar/ulnar surface of the wrist is the hallmark of pisotriquetral arthritis. Pain is frequently aggravated by flexion or ulnar deviation of the wrist. Local tenderness is present over the pisiform. Pain and crepitus may be elicited by compression and mediolateral movement of the pisiform against the triquetrum. Signs of ulnar nerve entrapment should be sought.

Radiography

Sclerosis of the pisiform may be apparent as an increase in density on the PA radiograph, but the joint is shown best on a 20-degree supinated oblique view or via computed tomography (CT). Osteophytes, sclerosis, and loss of articular cartilage height are seen on the underside of the pisiform and the adjacent surface of the triquetrum (Figure 6.2.8).

Non-operative management

Steroid injection through an ulnar approach can reduce pain substantially, though the effect may be short-lived.

Operative management

Excision of the pisiform is effective in relieving pain. It should be performed through a palmar or ulnar approach, protecting and, if necessary, decompressing the ulnar nerve and preserving the continuity of the flexor carpi ulnaris tendon. Excision does not appear to reduce wrist function significantly.
Further reading

Kienböck’s disease

Summary points

- Uncommon but well recognised
- Cause – avascular necrosis
- Probably related to ulna positive variance
- History and examination may be suggestive but rarely diagnostic
- Radiographs or MRI are diagnostic
- Treatment is non-operative or operative
- Various operations are performed especially ulna shortening
- Most patients do well even with poor radiographs.

Introduction

Kienböck described avascular necrosis of the lunate in 1910. Over twice as many men than women are affected, with onset usually in the twenties or thirties. Kienbock’s disease is usually unilateral. Although relatively uncommon, the pain, stiffness, and loss of strength may be devastating for otherwise healthy individuals, often in manual employment.

Anatomy

Vascular supply (Figure 6.3.1)

Kienböck’s disease results from vascular compromise to the lunate. Like the scaphoid, most of the surface of the lunate is covered by hyaline cartilage. However, the dorsal and volar poles have small areas with ligamentous and capsular attachments including blood supply. Lee originally described the arterial anatomy in 1963. Gelberman elaborated on this using latex injection; most lunates have vessels entering from both the dorsal and volar sides with intraosseous anastomosis.

Biomechanics

The lunate has been described as the ‘keystone’ of the carpus. It transmits over 50% of the compressive load across the wrist joint. Approximately 80% of the load is transmitted through the radius and 20% through the ulna via the triangular fibrocartilage complex. The different compliance of the two interfaces may cause shear within the lunate.

The shape of the lunate may also affect force transmission; a triangular lunate may be more susceptible to microfracture than a square or rectangular lunate.

Aetiology (Box 6.3.1)

Vascular compromise is the common endpoint in Kienböck’s disease; however, the relative contributions of intrinsic anatomical variants versus extrinsic trauma are contentious.

Box 6.3.1 Causation

- Idiopathic
Intrinsic factors

Ulnar variance (Figure 6.3.2)

Ulnar variance as a risk factor for Kienböck's disease was first described in 1928 by Hultén, who compared the radiographs of 400 normal wrists with those of 23 patients with Kienböck's disease; 23% of normal wrists were ulnar negative, in comparison to 74% of the Kienböck's patients. Sixteen per cent of normal wrists were ulnar positive as opposed to none of the patients with Kienböck's disease.

Some other clinical studies have confirmed this association, others have not. Some studies have questionable validity, poor radiographic standardization, or controls. The consensus remains that Kienböck's disease is more common with an ulnar negative variance.

Biomechanical studies demonstrate the significant effect of changes in ulnar length on lunate strain; ulnar lengthening or radial shortening of 2mm more than halves lunate strain.

Vascular susceptibility

Kienböck speculated that injury may disrupt the lunate's blood supply. The rarity of Kienböck's disease following lunate and perilunate dislocations shows that the lunate can usually survive the loss of a major proportion of its vascular attachments.

Extrinsic factors

Fracture

External injury as an aetiological factor is suggested by increased frequency in manual labourers and in the dominant hand and by its infrequent bilateral occurrence. Clinical studies and cadaver models show susceptibility to fracture in hyperextension.

Vascular and traumatic susceptibility may be cofactors. The arterial supply has few or sometimes no anastomoses. Even a non-displaced stress fracture could disrupt this, causing devascularization. Conversely, a primary vascular injury would weaken the lunate, making it vulnerable to micro-shear fracture.

Clinical evaluation (Box 6.3.2)

Patients usually present with a gradual onset of wrist pain, but may describe a precipitating injury.

The physical findings are non-specific, but consistent. Inspection may reveal dorsal wrist swelling. Pain and tenderness is localized in the mid-dorsal area. Kienböck described exacerbation of pain on percussion of the third metacarpal head longitudinally. Wrist flexion and extension are decreased, as are radial and ulnar deviation to a lesser extent. Forearm rotation is usually normal. Grip strength is typically approximately halved.
### Box 6.3.2 Assessment

- **History:**
  - May be vague
  - There may be an minor injury starting the symptoms

- **Examination:**
  - May be local tenderness
  - Loss of range of movement esp extension

### Diagnostic tests (Box 6.3.3)

Confirmation of the diagnosis requires imaging, including plain radiography, radionuclide bone scan, computed tomography (CT) and/or magnetic resonance imaging (MRI).

### Box 6.3.3 Investigations

- Radiology: usually diagnostic except in early (stage I) disease
- Nuclear medicine: can be used but superseded by MRI
- MRI: diagnostic.

#### Plain radiography

Plain radiographs including posteroanterior and lateral views are essential. The posteroanterior view must be taken with the forearm in neutral rotation, for true assessment of ulnar variance.

Changes on plain radiographs follow a consistent pattern, as described in the staging section. Initially, the lunate may appear normal or may have subtle horizontal lines suggesting compression fracture. Next the lunate appears more dense, consistent with avascularity. Lucency may be seen below the subchondral bone, similar to that seen in avascular necrosis of the femoral head. As the lunate collapses and fragments, the capitate begins to migrate proximally (Figure 6.3.3). The scaphoid falls into palmar flexion, similar to the pattern seen with scapholunate dissociation. In advanced cases, degenerative changes of the radiocarpal and intercarpal joints are seen.

![Click to view larger](image)

**Fig. 6.3.3**
Stage III lunate collapse.

#### Bone scans

Radionuclide imaging is useful in early disease, when history and examination are suggestive but radiographs are normal (Figure 6.3.4). Increased uptake ("hot spots") may be seen in all three phases: flow (angiogram), immediate (blood pool), and delayed (bone), suggesting hyperaemia of the soft tissues and bony reaction or repair.
Magnetic resonance imaging

MRI scanning in Kienböck’s disease is now well established for early detection, assessment of bone viability, and evaluation of the response to treatment, rendering CT and bone scanning much less important (Figure 6.3.5).

Cancellous bone has adipose and haematopoietic tissue, and so high signal intensity on $T_1$-weighted images. Acute and chronic processes, including fracture, ischaemia, necrosis, and repair, alter marrow composition, decreasing signal intensity. MRI can identify lunate injury when plain films are still normal; the $T_1$ image abnormalities in Kienböck’s disease are consistent. MRI cannot reliably distinguish between necrosis and reactive tissue; the zone of avascularity may be exaggerated.

MRI is also used for postoperative evaluation; return to normal signal intensity is observed in patients who undergo radial osteotomies for diseased lunates with normal shape.

Imaging algorithm

A diagnostic algorithm is shown in Figure 6.3.6. If history and examination suggest Kienböck’s disease, plain radiographs are taken. If they show changes consistent with avascular necrosis (i.e. sclerosis, fragmentation, collapse), then no further tests are necessary.
With normal radiographs, a bone scan or MRI is indicated; either can show Kienböck’s disease before plain radiographs. MRI is usually preferred to radionuclide imaging after normal plain films, as it can also show differential diagnoses and anatomical detail. Bone scanning remains useful for patients in whom MRI is contraindicated.

**Staging**

Staging is based on imaging and is divided into five distinct groups (Figure 6.3.7):

- **Stage I**: early disease with either normal radiographs or small linear compression/stress fractures
- **Stage II**: increased radiodensity, normal overall bony architecture
- **Stage IIIA**: collapse and fragmentation, typically with proximal capitate migration
- **Stage IIIB**: as stage IIIA, but with scapholunate dissociation and scaphoid flexion
- **Stage IV**: collapse with degenerative changes.

**Management (Box 6.3.4)**

Treatment options depend on staging, and include immobilization, revascularization, lunate unloading procedures, intercarpal fusions, and salvage procedures. Analysis of results is complicated by the poor correlation of clinical with radiographic findings, as with many wrist disorders.
♦ Non-operative
♦ Immobilization
♦ Steroid injection.

Immobilization

Radiographic deterioration is common. Long-term studies show that no lunate ever returns to normal and that degenerative changes developed in half even when they are immobilized. However, radiographic changes did not correlate with clinical symptoms; despite these findings, most had either no pain or pain only with heavy work.

Revascularization

In a series of patients treated with dorsal metacarpal vascular bundle implantation (the majority of patients also underwent lunate core debridement and iliac crest grafting combined with either external fixation or scaphotrapeziotrapezoid fusion) after a mean of nearly 6 years, 50 of 51 patients had decreased pain and average improvement in grip strength of 13kg.

These techniques seem promising, especially combined with other techniques to protect or unload the lunate, during revascularization.

Unloading procedures

Other procedures designed to reduce stress through the lunate include ulnar lengthening, radial shortening, radial wedge osteotomy, capitate shortening, and intercarpal fusion.

Ulnar lengthening and radial shortening

'Joint-levelling' procedures were developed in response to the perceived relationship between ulnar minus variance and Kienböck’s disease. Despite the controversy regarding the significance of variance, multiple biomechanical studies and computer models have convincingly demonstrated significant decreases in lunate strain and radiolunate contact stress with increases in relative ulnar length. Ulnar lengthening by 3mm reduces lunate strain by more than 70%, with 90% of that in the first 2mm.

Radial shortening has similar clinical success in patients with ulnar minus variance, and has fewer complications than ulnar shortening (Figure 6.3.8). The radius should be shortened to the level of the ulna, with compression plate fixation.

Radial wedge osteotomy

For individuals with positive ulnar variance, and for some with neutral variance, relative ulnar lengthening may risk creating ulnar abutment. Alteration in the radial inclination modifies load transmission through the carpus without significantly changing ulnar variance.

Patients receiving osteotomies to decrease inclination are either pain free or have pain only with strenuous activity.

Intercarpal fusions

A variety of intercarpal fusions have been described that either directly (e.g. capitate shortening with capitate–hamate fusion) or
indirectly (e.g. scaphotrapeziotrapezoid fusion) unload the lunate. They are particularly useful alternatives in ulnar positive variance or possibly when some lunate collapse has already occurred.

Capitate shortening

A 2- to 4-mm thick section of the capitate waist is removed with internal fixation of the remaining portions, generally combined with capitate–hamate fusion. Two-dimensional modelling of the procedure has predicted a 66% decrease in compressive load across the radiolunate articulation, with increases in scaphotrapezial load and triquetrohamate load.

Scaphotrapeziotrapezoid fusion

Scaphotrapeziotrapezoid fusion has been used in Kienböck’s disease to unload the lunate indirectly (Figure 6.3.9); it also treats the rotation of the scaphoid seen in advanced cases. Biomechanical studies demonstrate that scaphotrapeziotrapezoid fusion with the scaphoid in neutral flexion reduces lunate strain by approximately 70%.

Patients treated by scaphotrapeziotrapezoid fusion had either no pain or mild pain with strenuous activity, but reduced range of motion (flexion 18%, extension 23%, radial deviation 69%); 13 of 15 returned to their original occupation. Some patients will require secondary excision of the lunate, and others will require late salvage procedures.

Other intercarpal fusions

Scaphocapitate fusion can both unload the lunate and stabilize rotatory subluxation of the scaphoid. Cadaver and two-dimensional modelling studies predict significant unloading of both the capitulunate and radiolunate articulations. Clinically reports show wrist flexion and radial deviation are reduced by more than 60%, but there is good relief of pain and most patients returned to their original occupation. Although carpal height is maintained, some wrists show early radiocarpal degenerative change.

Isolated capitatohamate fusion has been used as a lunate unloading procedure. Although clinical success has been reported, cadaver studies and two-dimensional modelling do not demonstrate significant decreases in lunocapitate loading, radiolunate loading, or lunate strain.

Prosthetic arthroplasty

Silicone lunate replacement, which was introduced by Swanson (1970), gained popularity for treatment of stages II to IV of Kienböck’s disease. It has also been used in combination with intercarpal fusions to limit the loading of the implant. The original implant, made of standard-grade elastomer, was later replaced by a high-grade elastomer with a deeper concavity to resist dislocation, and a titanium implant has also been designed, but not widely used. Despite early clinical successes, reports have continued linking silicone elastomer implants to particle debris synovitis. The long-term follow-up of patients with implants has shown radiographic and clinical deterioration.

Other treatment alternatives

Other primary treatments reported in the literature include sensory denervation of the wrist, forage of the distal radius, simple lunate excision, excision of the lunate with soft tissue interposition, and bone grafting of the lunate combined with external fixation.

Salvage

Total wrist arthrodesis is the procedure of choice following failed treatment, particularly when secondary osteoarthritis has developed or if return to manual occupation is required. If the articular surfaces are relatively preserved and loss of motion is unacceptable, proximal row carpectomy is an alternative as both a primary or salvage procedure. Most patients will have either mild or no pain. Wrist motion is generally improved slightly while grip strength more than doubles.
Box 6.3.5 Treatment

- Operative
- Revascularization for early (stage I and some stage II) disease
- Unloading the lunoradial joint
- Radial osteotomy
- Intercarpal fusion
- Wrist arthroplasty
- Salvage procedures especially proximal row carpectomy.

As designs improve, third-generation total wrist arthroplasty is becoming an accepted alternative to arthrodesis in non-manual workers.

Conclusions

The diagnosis of Kienböck's disease is based on history, examination, and imaging. Staging is based on plain radiographs, with additional information primarily from MRI.

For stages I, II, and III, the aim of treatment is prevention of further collapse during healing and revascularization. Protection or unloading of the lunate is achieved by various techniques, depending on ulnar variance. In negative or neutral ulnar variance, radial shortening has established effectiveness. Capitate shortening, radial wedge osteotomy, proximal row carpectomy and intercarpal fusions are alternatives for patients with positive variance.

In stage IIIB, a scaphocapitate or scaphotrapeziotrapezoid fusion also corrects rotatory scaphoid subluxation.

For stage IV a wrist arthrodesis is generally indicated.

Summary points

DRUJ Stabilizers:

- Primary: TFCC
- Secondary: interosseous membrane, extensor retinaculum, dorsal carpal ligament complex, and the forearm muscles especially the pronator quadratus.

Investigations:

- Plain or stress radiography
- Arthrography
- CT: for bone alignment especially DRUJ arthritis and subluxation
- MRI: for soft tissue constraints
- Arthroscopy.

TFCC Pathology:

1. Traumatic
   - Central or peripheral
   - Treatment: Central — debridement, Peripheral — repair/decompression.

2. Degenerative
   - Mainly due to ulnocarpal impingement
   - Treatment: decompression by shortening or Feldon wafer.

DRUJ OA:

- Treatment: Steroid injection or Surgery
- Surgical Options
  - Darrach’s
  - Partial resection
  - Sauvé-Kapandji
  - Replacement.

Introduction

Derangements of the distal radioulnar joint (DRUJ) are common causes of acute and chronic ulnar wrist pain and dysfunction. This chapter will focus on triangular fibrocartilage complex (TFCC) disorders, ulnar impaction, instability, and degenerative arthroses. Fractures and dislocations, congenital and developmental disorders, and rheumatic diseases affecting the DRUJ are covered in other chapters.

Anatomy and biomechanics

The anatomy and biomechanics of the DRUJ are complex and interplay with the proximal radioulnar joint, interosseous membrane, and the ulnar carpus during forearm and wrist motion. Pathology at any one of these may affect their composite function.

The DRUJ is a trochoid articulation between the sigmoid notch of the radius and the ulnar head. The sigmoid notch has a 47–80-degree arc of curvature and a radius of approximately 15mm. The ulnar head is semicylindrical in cross-section. It has articular cartilage covering 90–135 degrees of its circumference and a radius of curvature of 10mm (Box 6.4.1 and Figure 6.4.1). Although 60–80 degrees of the ulnar articular surface engages the sigmoid notch in neutral rotation, the contact is less than 10 degrees at the extremes of rotation. Minimal bony constraint allows a wide arc of motion but at the expense of intrinsic instability that is limited primarily by soft-tissue restraints.
♦ Sigmoid notch: arc of 47–80 degrees
♦ Ulna head: arc of articular cartilage 90–135 degrees
♦ Contact: mid part up to 80 degrees but <10 degrees at extremes.

Click to view larger

Fig. 6.4.1
Osseous anatomy and congruity of DRUJ. The articulation between the sigmoid notch of the radius and the ulnar head is viewed both end-on (left) and dorsally (right). The radius of curvature of the sigmoid notch is greater than that of the ulnar head, allowing sliding of the ulna relative to the radius with forearm rotation. The ulnar head has a greater arc covered with articular cartilage than the sigmoid notch. (Reproduced from Chidgey (1995).)

The primary soft tissue stabilizer of the DRUJ is the TFCC (Figure 6.4.2). It separates the DRUJ and the radiocarpal joint, and comprises the triangular fibrocartilage (TFC), the dorsal and palmar radioulnar ligaments, the ulnocarpal meniscus homologue, and the sheath of the tendon of the extensor carpi ulnaris (ECU). The palmar ulnocarpal ligaments are intimately related to the TFCC and contribute to ulnar wrist stability.

Click to view larger

Fig. 6.4.2
Ligaments of the DRUJ and dorsal views of the TFCC. A) All components of the TFCC shown. The sheath of the ECU is an important stabilizer of the DRUJ; the infratendinous portion is sometimes referred to as the ulnar collateral ligament. B) The meniscus homologue attaches to the dorsal margin of the radius and the palmar-ulnar aspect of the triquetrum. As it passes the palmar radioulnar ligaments it forms the roof of the prestyloid recess, a synovial lined recess that may connect to the palmar aspect of the ulnar styloid. C) The meniscus homologue has been removed to show the TFC, also termed the articular disc (AD), and the dorsal and palmar radioulnar ligaments (DRUL, PRUL). D) The articular disc has been removed to expose the ulnolunate (UL) and ulnotriquetral (UT) ligaments, which extend from their respective carpal bones and lunotriquetral ligament to the foveal area and base of the ulnar styloid. (Reproduced from Chidgey (1995).)

The TFCC is triangular in shape and biconcave on its distal surface. It arises from the distal margin of the sigmoid notch and courses medially where its apex inserts into the fovea at the base of the ulnar styloid. It is thickest (approximately 5mm) at its ulnar insertion, and thinnest centrally at its origin from the radius (approximately 2mm). The central portion, or articular disc, is avascular chondroid fibrocartilage with interwoven collagen fibres arising from the hyaline cartilage of the lunate fossa, and is adapted to
compressive loading. The origin is reinforced by thick collagen bundles projecting 1–2 mm from the radius creating a juncture that is a common site of TFC tears. In contrast, the TFC thickens dorsally and volarly to become the dorsal and volar radioulnar ligaments, comprising well-vascularized connective tissue with longitudinally oriented collagen fibres that arise from and insert into bone and are best suited to resisting tensile loads.

Perforations of the TFC are found with increasing prevalence with age over 30 years. Excessive length of the ulna with respect to the radius (positive ulnar variance) is directly proportional to the age-related incidence of TFCC perforation, and inversely proportional to TFC thickness.

Of the TFC components, the palmar and dorsal radioulnar ligaments are the primary stabilizers of the DRUJ, and the joint is most stable when these are in tension at the extremes of rotation. The sheath of the ECU, the floor of which has been called the ulnar collateral ligament, extends from the ECU groove on the dorsal ulna to insert on the dorsal base of the fifth metacarpal. Its role in stabilizing the distal ulna is augmented by the dynamic effects of the ECU tendon.

The volar ulnolunate and ulnotriquetral ligaments arise at the base of the ulnar styloid, where the apex of the TFCs attaches. They course along its volar margin to diverge and insert independently into the lunate and triquetrum and into the lunotriquetal intersosseous ligament. They act primarily in stabilizing the ulna and palmar carpus and resist dorsal displacement of the distal ulna.

The secondary stabilizers of the DRUJ include the bony conformation of the sigmoid notch, the interosseous membrane, the extensor retinaculum, the dorsal carpal ligament complex, and the forearm muscles that cross the pronation/supination axis, especially the pronator quadratus (Box 6.4.2). Watanabe and colleagues found that sectioning the joint capsule affected DRUJ stability in pronation and supination. They also demonstrated that dorsal capsular imbrication contributed to stability in pronation and volar capsular imbrication contributed to stability in supination. This effect was seen in positions of rotation greater than 60 degrees and was most evident in full pronation and supination.

Box 6.4.2 Stabilizers of DRUJ

- **Primary**: TFCC
- **Secondary**: interosseous membrane, extensor retinaculum, dorsal carpal ligament complex, and the forearm muscles especially the pronator quadratus.

The central 80–85% of the TFC is avascular and has no potential for healing. The peripheral 15–20% of the articular disc and the dorsal and palmar ligaments are well vascularized and are capable of healing (Figure 6.4.3).

The radiocarpal joint carries about 80% of the compressive load across the wrist; 20% is transmitted via the TFC and ulna in wrists with neutral ulnar variance. The load distribution between radius and ulna shows only a weak positive relationship to ulnar variance, probably because negative ulnar variants have thicker TFCs. However, surgical changes in ulnar variance alter force transmission dramatically: a 2.5-mm increase raises the ulnocarpal load to 42%; and a 2.5-mm decrease or excision of the disc lowers it to 4.3%. Up to two-thirds of the articular disc can be excised before changes in axial load transmission occur.

**Evaluation**

**History and physical examination**

The clinical assessment of patients with ulnar wrist pain includes the history of injury or onset of symptoms, the nature of the symptoms, and a provocative examination directed at localizing the pathological anatomy.

Provocative manoeuvres such as the ‘ballettement’, ‘shuck’, and ‘shear’ tests attempt to distinguish lunotriquetral abnormalities from the TFC disorders. A positive ‘ulnar fovea sign’ identifies foveal disruption of the distal radioulnar ligaments and lunotriquetral ligament injuries. The DRUJ is assessed by palpation, the ‘grind test’, attempting to elicit the ‘piano key’ sign and comparison with the opposite side, bearing in mind that signs may be dependent on the rotational position of the forearm (Table 6.4.1).

### Imaging studies

**Plain radiographs**

Since the relative length of radius and ulna varies with rotation of the forearm, standardized positioning with the forearm in neutral rotation is critical for meaningful study and comparative measurements of the DRUJ (Figure 6.4.4).
Fig. 6.4.4  
Anteroposterior and lateral radiographs of the wrist. Normal radiographs of the wrist. The anteroposterior radiograph (A) demonstrates neutral ulnar variance and no evidence of degenerative changes of the DRUJ. The lateral radiograph (B) shows the normal overlap of the radius and ulna. The scaphoid proximal pole is central in the lunate, demonstrating a true lateral of the wrist and confirming that subluxation of the DRUJ is not present.

Stress or provocative views causing subluxation or ulnar impaction, such as full pronation while making a tight fist, may be useful in demonstrating instability patterns or impingement.

Arthrography

Arthrography can demonstrate the integrity of the soft tissue structures around the DRUJ (Figure 6.4.5).

Fig. 6.4.5  
Arthrogram with TFC tear of a 45-year-old woman with a history of chronic ulnar wrist pain and clicking. Injection of the DRUJ with contrast dye demonstrates a communication with the radiocarpal joint, confirming a TFC tear.

While intercompartmental dye tracking may suggest an anatomical abnormality, the relation to symptoms is far from clear. Attritional abnormalities increase with age such that up to 50% of asymptomatic wrists will demonstrate ‘lesions’ by age 50. In a study of post-traumatic wrist pain, 74% of patients had ‘abnormal’ communications in the asymptomatic opposite wrist.

Computed tomography

Computed tomography (CT) is useful in diagnosing DRUJ subluxation and dislocation, as well for assessing the congruity of the articular surfaces in fractures and arthritic conditions of the sigmoid notch and ulnar head (Figure 6.4.6). To assess subluxation, CT scans of both wrists in neutral and both full supination and pronation are recommended and stress CT scans may be helpful.
Fig. 6.4.6
CT scan of dislocated DRUJ of a 54-year-old man with an acute distal radial fracture. Plain radiographs suggestive of a DRUJ subluxation. A CT scan performed through plaster confirms a volar dislocation of the ulnar head.

Magnetic resonance imaging

While CT scanning best defines bony anatomy, magnetic resonance imaging (MRI) is the preferred method for non-invasive evaluation of the soft tissues, in particular the TFCC and associated ligaments. Using a wrist coil, T2-weighted images best demonstrate traumatic tears, as synovial fluid has a high-intensity signal that provides contrast to fill defects (Figure 6.4.7). With T1-weighted images, degenerative and traumatic tears are seen but difficult to distinguish. Radiocarpal joint injection of gadopentetate dimeglumine augments diagnostic accuracy for TFCC tears and has taken over from standard arthrography.

Fig. 6.4.7
MRI of TFC tear. MRI of a chronic TFC tear due to ulnar impaction from positive ulnar variance. The discontinuity in the TFC can be seen, as can the effusion in the DRUJ.

Arthroscopy

Arthroscopy is the 'gold standard' assessment of the wrist and TFCC but the DRUJ is difficult to visualize and so arthroscopy of the DRUJ is performed infrequently.

Distal radioulnar joint disorders

DRUJ disorders can be classified as acute, i.e. fractures and dislocations (see Chapter 12.9) or chronic. Chronic DRUJ disorders include TFCC tears, instability, arthritis, extensor carpi radialis subluxation, and contracture.

Triangular fibrocartilage complex

Palmer classified TFCC lesions as traumatic (type I) and degenerative (type II) (Table 6.4.2). Class II lesions are generally associated with ulnocarpal impaction syndrome. Traumatic and degenerative lesions may lead to DRUJ instability, which may be static or, more commonly, dynamic.

### Type I: traumatic injuries

Type I injuries may result from various combinations of distal–proximal compression, shear, torsion, and radioulnar tension. Acute lesions are most frequently secondary to a fall on an outstretched hand in a patient who has ulnar neutral or positive variance.

### Box 6.4.3 Investigations

- Plain radiography: look for variance and shape of DRUJ
- Stress radiography: for instability
- Arthrography: for TFCC tears
- CT: for bone alignment especially DRUJ arthritis and subluxation
- MRI: for soft tissue constraints
- Arthroscopy: difficult and limited role

Patients often present weeks or months after injury. Treatment is directed at relieving pain and restoring stability, with the specific approach being determined primarily by the vascularity of the injured TFCC component and its potential for healing. If positive ulnar variance or significant cartilage damage exists, consideration should be given to ulnar recession to avoid persistent ulnar impaction postoperatively.

Type I injuries are further subclassified.

**Type IA lesions** occur in the central articular disc and are not associated with DRUJ instability. As this avascular area has no ability to heal, arthroscopic debridement is the treatment of choice. Up to two-thirds of the central TFC can be excised without altering force transmission or DRUJ stability providing the peripheral 2mm of the disc, and the dorsal and volar radioulnar ligaments, are preserved.

**Type IB lesions** occur in the well-vascularized periphery of the TFC, at the base of the ulnar styloid. They may be associated with an ulnar styloid fracture and/or mild instability of the DRUJ. Significant displacement of the ulnar styloid fragment in unstable...
injuries requires reduction by closed means or by internal fixation. Type IB injuries may also be associated with acute ECU subluxation that will require reduction and possibly stabilization. Because these tears are located in the well-vascularized periphery of the TFC, they have potential to heal, therefore surgery is not required if the DRUJ is stable. If the DRUJ is unstable, the TFC should be repaired using either an open or arthroscopic technique. Each technique has its proponents.

**Type IC injuries** are least common and involve disruption of the ulnocarpal ligaments. Although readily diagnosed arthroscopically they may be repaired by open or arthroscopic methods.

**Type ID lesions** occur when the TFC detaches radially, from the sigmoid notch of the distal radius. Like IC tears, these injuries are also uncommon. They are frequently painful and destabilizing but are difficult to treat because of the avascularity of the radial margin of the articular disc. Management is controversial, but successful reattachment of the disc margin to the radius has been described both open and closed.

**Type II: degenerative problems**

These disorders comprise a spectrum of clinical and pathological sequelae resulting from recurrent compressive loading through the ulnar carpus, TFCC, and ulna, and have been variably referred to as ulnocarpal ‘loading’, ‘abutment’, ‘impaction’, or ‘impingement’ syndrome.

There are five stages, beginning with TFCC wear and progressing through perforation, lunate and/or ulnar chondromalacia, lunotriquetral ligament disruption, and finally ulnocarpal arthritis.

Clinical features may include: ulnar wrist pain accentuated by rotation (especially pronation), ulnar deviation, and clenched fist loading; tenderness and/or crepitation in the region of the TFCC; and a tendency to ulnar neutral or positive variance. Sclerosis and/or cystic changes in the ulnar head and/or lunate may be seen with plain radiography, joint narrowing, and/or chondromalacia on tomography, and TFC perforations and/or lunotriquetral tears on MRI/arthrography (Figure 6.4.8).

The onset of symptoms may vary from insidious to abrupt depending on any predisposing condition or injury, the pattern and repetitive use of hand, wrist, and forearm, and the loading applied. Positive ulnar variance may be a congenital variant of normal or may be acquired, e.g. post-traumatic radial shortening, premature physeal closure including Madelung deformity, and, most commonly, age-related relative radial shortening due to thinning of the radial head articular cartilage.

Non-operative treatment includes activity modification, anti-inflammatory medications, splints, and steroid injections.

A positive ulna variance can be corrected by shortening the ulna (Figure 6.4.9) (which is simpler) or lengthening the radius which is typically performed when there are other concomitant abnormalities such as dorsal tilt of the radius following fracture malunion.
Ulnar shortening osteotomy for ulnar impaction syndrome in a 35-year-old woman with a history of chronic ulnar wrist pain and a documented TFC tear. A) Anteroposterior radiograph demonstrates 2-mm ulnar positive variance. B) Radiographs following an ulnar shortening osteotomy demonstrate neutral ulnar variance. Her pain was relieved.

If length discrepancy osteotomies will leave the DRUJ incongruous or if degenerative changes are already present then new or persistent symptoms are likely postoperatively and additional procedures as for DRUJ arthritis need to be considered (see later).

Alternatively, the ‘wafer’ procedure may be performed with minimal effect on radioulnar relations at the DRUJ. It involves resection of 2–3mm of the distal ulnar pole, leaving the styloid intact (Figure 6.4.10), via an open approach or arthroscopically through the perforated TFC.

The need to treat accompanying TFCC lesions is controversial. Some authors recommend arthroscopic or open debridement of central perforations and repair of any destabilizing peripheral lesions of the TFCC. Others believe that decompression of the ulnocarpal space by ulnar recession will suffice in most cases.

### Traumatic

- Common
- Central or peripheral
- Treatment:
  - Central—debridement
  - Peripheral—repair/decompression.
Degenerative

- Common, may even be ‘normal’
- Mainly due to unocarpal impingement
- Treatment: decompression by shortening or Feldon wafer.

Distal radioulnar joint instability (Box 6.4.5)

By convention, instabilities, subluxations, and dislocations of the DRUJ have been described in terms of the direction of the ulnar head displacement relative to the radiocarpal unit. Strictly speaking though, it is the radiocarpal structures that move about the stationary ulna.

Box 6.4.5 DRUJ instability

- Common, often asymptomatic
- Treatment:
  - TFCC repair
  - Complex reconstruction with tendon graft.

Although sometimes occurring in isolation, acute DRUJ instability or dislocation is seen in up to 60% of forearm fractures. It is especially common in complex distal radius fractures, where the TFCC and/or the sigmoid notch may be disrupted. Failure to recognize and manage these injuries adequately can result in chronic DRUJ dysfunction and instability.

Chronic DRUJ instability may result from disruption of any of the three major determinants of stability: the ulnar head/sigmoid notch articular congruence and alignment; the relative length, rotational, and angular relationship of the radius and ulna; and the integrity of the primary soft tissue stabilizers of the DRUJ (i.e. the TFCC). The adequacy of each must be ensured to restore stable DRUJ function. The presence and degree of instability and malunion is best evaluated clinically, and confirmed and quantified with plain radiography and a CT scan of both the involved and contralateral forearms and wrists.

Instability that results from malunion of forearm fractures may be improved by corrective osteotomy. Reattachment of the TFCC to the fovea has been described for minor degrees of instability, and if associated with an ulnar styloid fracture the bone fragment may be reduced and internally fixed if large or excised if small (Figure 6.4.11).

![Fig. 6.4.11](https://example.com/fig6411.png)

Open reduction and internal fixation of ulnar styloid nonunion. A) Anteroposterior radiograph of a 25-year-old laborer with a painful wrist following a distal radial fracture. Arthroscopic examination demonstrated moderate degenerative changes in the radiocarpal and mid-carpal joints with intercarpal ligament injuries. B) He was successfully treated by a wrist arthrodesis and internal fixation of the symptomatic ulnar styloid nonunion.

In the absence of a radial or ulnar malunion, soft tissue reconstruction alone can be undertaken. Many techniques for reconstruction of the distal radioulnar ligaments have been described. Each uses a tendon graft, which is weaved through drill holes in the distal radius and ulna and tied onto itself. The most anatomic, and the one most commonly used, is the technique described by Adams and Berger (Figure 6.4.12). It has been reported to restore clinical stability in 12 of 14 patients, and recovery of strength and range of motion averaged 86% of the unaffected wrist.
Chronic DRUJ instability may also be treated with hemiresection interposition arthroplasty. In a series of 23 patients, 17 had good to excellent results, and 21 had increased range of motion. Radioulnar fusion (a one-bone forearm) should be considered in patients doing heavy labour or who have failed soft tissue reconstructions (Figure 6.4.13).

Distal radioulnar joint arthritis (Box 6.4.6)

DRUJ arthritis may be primary or secondary to fracture malunion. The commonest cause is inflammatory arthropathy, e.g. rheumatoid arthritis (RA).

Non-operative management includes activity modification, anti-inflammatories, splinting, and steroid injections. Four types of DRUJ ‘arthroplasty’, with multiple variations, are in common use: excision of the distal end of the ulna (Darrach procedure); hemiresection interposition arthroplasty; DRUJ arthrodesis with creation of a proximal ulnar pseudarthrosis (Sauvé–Kapandji procedure); and ulna hemiarthroplasty.

**Box 6.4.6 DRUJ arthritis**

- Common, especially in RA
- Treatment:
  - Steroid injection
  - Surgery:
    - Darrach’s
    - Partial resection
    - Sauvé-Kapandji
    - Replacement

Darrach procedure
The Darrach procedure is a subperiosteal excision of the ulnar head with or without the ulnar styloid. It may be considered in any condition that interferes with DRUJ function, causing painful or limited motion as a result of articular surface destruction (Figure 6.4.14). Because the "DRUJ is rendered unstable it is best performed with a minimal resection in low demand patients, typically patients with inflammatory arthropathy or elderly patients following a Colles’ fracture.

Fig. 6.4.14
Darrach procedure in a 54-year-old woman with long-standing rheumatoid arthritis and disabling wrist pain. (A) Pain and function improved following wrist arthrodesis and Darrach resection of the distal ulna (B)

Hemiresection interposition arthroplasty

Several variants of this procedure have been described. They attempt to minimize instability of the distal ulna by maintaining bony contact between the ulnar shaft and the TFCC attachments. In the hemiresection interposition arthroplasty of Bowers, only the articular portion of the ulnar head is removed, retaining the shaft/styloid relationship and interposing tendon, muscle, or joint capsule between the distal ulna and radius to limit contact. This procedure requires an intact or reconstructable TFCC to confer any advantage over a Darrach procedure.

Stylocarpal impingement may occur as the ulna migrates toward the radius. Concomitant ulnar shortening osteotomy should be performed in ulnar positive wrists, or if impingement can be anticipated preoperatively.

In the ‘matched’ distal ulna resection, the ulnar head is partially resected in an oblique fashion parallel to the inclination of the sigmoid notch. The ulnar styloid is removed and ulnar shortening distally is possible. Most are pain free and the remainder are significantly improved (Figure 6.4.15).

Fig. 6.4.15
Matched hemiresection interposition arthroplasty in a 48-year-old woman with chronic ulnar wrist pain and crepitus from DRUJ arthritis. B) Pain improved following matched resection of the distal ulna and interposition of a portion of the extensor retinaculum.

Sauvé–Kapandji procedure

The arthritic DRUJ is fused and a mobile pseudarthrosis is created by excision of segment of distal ulnar shaft (Fig 6.4.16). While effective in relieving pain at the DRUJ, adequate bone must be resected at the proposed pseudarthrosis to allow full forearm rotation but prevent ossification between the segments of ulna.
Fig. 6.4.16
Sauvé–Kapandji procedure in a 29-year-old man with a long-standing forearm malunion and dislocation of the DRUJ. A). Pain improved following radial osteotomy and a Sauvé–Kapandji arthrodesis of the DRUJ (B).

The indications for this procedure remain unclear. Excellent results for relief of pain, range of motion, and patient satisfaction have been reported. Instability of the proximal ulna segment and radioulnar convergence are the commonest problems. Although infrequently symptomatic, when they are they can be difficult to treat although ulna hemiarthroplasty articulating with the underside of the fused ulna head is a recent salvage option.

Arthroplasty

Replacement arthroplasty of the ulnar head is an emerging technology with promising early results. The primary indication for ulnar head arthroplasty is pain and stiffness secondary to rheumatoid, degenerative, or post-traumatic arthritis; failed excisional arthroplasty (Darrach or hemiresection interposition arthroplasty); bone tumour (Figure 6.4.17); and less commonly, an unreconstructable fracture of the ulnar head or neck due to comminution or poor bone stock. Ulnar stump instability or radioulnar impingement syndrome after excisional arthroplasty can also be successfully managed with this technique. There are various metal or pyrocarbon options. Silastic replacements have been abandoned because of implant failure. While the solid prostheses have shown favourable early results, long-term outcomes have not yet been reported.

Fig. 6.4.17
Distal ulnar hemiarthroplasty (E-centrix) used to reconstruct a benign bony tumour. A) Preoperative radiographs. B) Postoperative radiographs with an E-centrix prosthesis incorporating an available spacer block to compensate for bone deficiency.

Other DRUJ-related disorders

Extensor carpi ulnaris subluxation

The course and action of the ECU tendon change with forearm rotation. In full pronation the ECU is linear and acts as an ulnar deviator while in supination it is an extensor of the wrist. In full supination, especially with ulnar deviation, the course of the ECU tendon is angular with the tunnel at its apex. Forcible contraction of the ECU in this position creates a strong ulnar translocating force that may disrupt the ECU sheath. This position and mechanism are often recalled by patients, in conjunction with a ‘snapping’ or ‘popping’ sensation. Examination in the acute setting will reveal local features of inflammation and painful ulnar subluxation of the ECU provoked by supination and ulnar deviation. Treatment acutely is with 6 weeks of forearm immobilization in pronation with the wrist slightly extended and radially deviated to reduce the tendon. Surgical repair may also be used acutely and is appropriate for chronic painful ECU snapping that has been untreated or failed non-operative immobilization. Operative treatment may consist of repair of the sheath lesion, reeling of local tissues, reconstruction of the tunnel using retinacular flaps or other tissues, and/or deepening of the ulnar groove.
DRUJ contractures

Restriction of forearm motion may result from a multitude of pathological processes occurring in isolation or combination at the wrist, elbow, or forearm. Among these are bony abnormalities (congenital or acquired shaft or articular incongruence of the radius and ulna, synostoses), neuromuscular disorders (paralytic, spastic, or post-traumatic contractures), interosseous membrane insufficiency (instability, contracture), and proximal or distal radioulnar joint restrictions (articular deficiency, mechanical interference, soft tissue instability, or capsular contracture).

DRUJ capsular contracture is uncommon and generally post-traumatic. It may be associated with bony abnormalities. It may also result from prolonged forearm immobilization. Pathologically, the normally lax joint capsule becomes shortened and thickened with fibrosis, especially on the palmar side. Contracture of the palmar capsule restricts supination; contracture of the dorsal capsule limits pronation. Pronation contractures with restricted supination are most common. However, global limitation due to involvement of both the dorsal and volar capsule may occur.

Non-operative treatment with physiotherapy, dynamic splinting, and serial casting is often effective; if it fails, surgical release may be useful provided that there is no suggestion of joint incongruency. A volar capsulectomy is performed, proceeding dorsally as needed to restore motion. Care must be taken to preserve the radioulnar ligaments, TFCC, and articular surfaces. Intra-articular adhesions are lysed and the forearm is gently manipulated in rotation and translation under anaesthetic.

Summary

Derangements of the DRUJ are a significant cause of ulnar wrist pain that have traditionally been poorly understood. Our improved understanding of the normal anatomy and biomechanics of this region has lead to a more successful approach to the diagnosis and treatment of DRUJ disorders.

Further reading

Rheumatoid arthritis of the hand and wrist

Summary points

♦ RA is common
♦ Medical treatment is the mainstay and newer anti-TNF drugs are reducing morbidity and thus referral for surgery
♦ Assessment is primarily clinical
♦ Investigations – Primarily radiographs
♦ Treatment
  • Non-operative
  • Steroid injections are often very useful
  • Operative
  • Site and condition specific
♦ In general
  • DRUJ – excision ulna head
  • Wrist – partial fusion, arthrodesis, arthroplasty
  • MP joints – synvestomy, arthroplasty
  • PIP joints – soft tissue rebalancing, arthrodesis
  • DIP joints – arthrodesis
  • Thumb MP and IP joints – arthrodesis

Introduction

The hands and wrists are frequently affected in rheumatoid disease. Function can be impaired by painful acute inflammation of joints or by their later destruction. Involvement of tendons can lead to rupture, bulky synovitis may cause secondary nerve compression syndromes, and painful subcutaneous nodules may interfere with use of the hands.

Disease-modifying drug therapy has reduced referrals to surgeons for treatment of persistent acute inflammation of joints and tendon sheaths. Early synovectomy of joints is effective in relieving pain but does not appear to protect them from destruction over the long term. However, the benefit of tenosynovectomy of flexor and extensor tendons is frequently long lasting.

Patients generally present to the surgeon in the late stage of rheumatoid disease. Requests for surgical advice may be for one or more of the following problems:

♦ Painful joints
♦ Loss of movement interfering with function
♦ Loss of strength interfering with function
♦ Cosmetic deformity.

Assessment (Box 6.5.1)

Assessment of the rheumatoid hand and wrist should involve not only ‘look, feel, move, and radiograph’ but also an assessment of function. A systematic approach is essential to avoid being distracted by obvious cosmetic deformities. Functional deficits may be due to joint disease, but the equally important effects of tendon rupture, nerve compression, and cervical radiculopathy should not be forgotten.

Box 6.5.1 Assessment

History

The prime symptoms are:

♦ Pain
♦ Stiffness
Weakness
Cosmesis.

Examination

The most important is pain, but remember:

- Instability
- Local versus combined stiffness
- Active and passive loss of movement
- Neuropathy
- Also remember to assess other local joints, e.g. shoulder/elbow.

Patients should be asked how far they can reach with the hand—to the mouth, to the top of the head, to the natal cleft. These abilities are strongly influenced by disease at the elbow and shoulder. They should also be asked what they can do with the hand in these positions. Can they feed, dress, and attend to personal hygiene independently? Does disease of the lower limbs compel the patient to bear weight with the hands through a stick or crutch? Questions about common activities of daily living will identify specific functional problems and help to determine the surgical priorities.

Inspection of the hand should note the deformities, which frequently reflect zigzag compensatory phenomena such as flexion contracture of the proximal interphalangeal joint accompanied by fixed hyperextension of the distal joint (boutonnière deformity). Deformities may be in more than one plane (Figure 6.5.1). Ulnar deviation at the metacarpophalangeal joints is frequently associated with palmar subluxation and pronation (especially in the index finger). Palpation will detect residual synovitis and signs of active disease in joints and tendon sheaths. Sensory testing is useful in detecting peripheral nerve entrapment; motor testing is more difficult as weakness and wasting may be due to disease in adjacent joints.

Movement is the most detailed part of the examination and must include the following:

- Detailed assessment of active movement of each joint
- Comparison with the passive range. A difference between active and passive range of movement indicates loss of tendon function (adhesion or rupture), or paralysis (nerve entrapment)
- Are deformities correctable passively?
- Assessment of overall movement, such as fingertip to palm distance (Boyce’s index) and ability to touch the thumb to index and middle fingers for tripod pinch grip. The fingers may be able to grasp narrow objects such as the examiner’s single finger. If movement is limited, grip may be restricted to larger objects. The patient may use the tip of the thumb for key pinch, or may be obliged to bypass an unstable terminal segment and use instead the head of the proximal phalanx.

Radiographs may show far greater bone and joint destruction than the functional assessment and examination had suggested. Radiographic abnormalities are not themselves an indication for surgery but are useful in determining the surgical options that are available (e.g. joint destruction precludes synovectomy).

Assessment by an occupational therapist experienced in rheumatoid disease can be most helpful, by observing the patient in a simulated home and kitchen environment, by selecting aids which may improve function, and by clarifying the need (or lack of...
Medical assessment includes degree of control of disease activity and monitoring of drug treatment, especially for ‘new’ drugs such as anti-tumour necrosis factor (TNF)-alpha agents for which temporary withholding of the drug is advised by manufacturers over the course of major surgical procedures.

Priorities for treatment (Box 6.5.2)

The priorities for treatment of the rheumatoid hand and wrist are pain relief and restoration of function. Cosmetic improvement would be regarded as a bonus but is seldom an indication for surgery on its own. The patient’s expectations of outcome should be assessed carefully, bearing in mind that surgery often relieves pain but is much less effective at improving strength and movement. Unrealistic expectations should be corrected by counselling before surgery is undertaken. Not every patient with deformed hands needs surgery. Young patients whose lifestyle is affected by mild disease should be advised to modify their activities. Older patients who have minimal pain and satisfactory function despite deformity will not be improved by surgery.

Box 6.5.2 Treatment priorities

- Pain
- Prevention of future problems, e.g. tendon ruptures
- Improved function
- Cosmesis
- Surgery should mostly be performed only once the systemic disease is under control.

Relief of pain is the most common indication for surgery at the wrist. A painful wrist will prevent good use of the hand, even if the fingers and thumb are in good condition. A painful thumb will affect many everyday actions, especially if it is also unstable. Souter emphasized that surgery of the rheumatoid hand and wrist should begin with simple and reliable procedures, so that the patient’s confidence is gained, before moving on to less predictable operations. Provision of a pain-free wrist and stabilization of the thumb are top of Souter’s list.

Assessment of the wrist should attempt to localize pain to the radiocarpal joint, to the distal radioulnar joint, or to both joints. The site of local tenderness and the provocation of pain by flexion/extension and forearm rotation are useful.

In the thumb, stability is more important than movement. When hand function is compromised, the thumb should be regarded as a stable ‘post’ against which the fingers can act. When finger movement is also limited, key pinch to the side of the index finger may be the only achievable type of pinch. It is acceptable to fuse the metacarpophalangeal joint and the interphalangeal joints of the thumb if its basal joint is mobile. An iliac crest graft may be needed to maintain length in cases of severe bone loss. Surgery of the painful subluxed basal joint will fail and basal subluxation will recur unless secondary web contractures and fixed deformities of more distal joints are corrected at the same time.

In the fingers, the priority is to maintain movement at the base of the digit. In severe cases, movement at the metacarpophalangeal joints and stability of the interphalangeal joints in a functional position may be all that can be achieved. In less severe cases, surgical correction at the metacarpophalangeal joints (e.g. by silastic interposition arthroplasty) may give good finger function, especially where the metacarpophalangeal joints are diseased but the interphalangeal joints are spared. Stiffness of the proximal interphalangeal joints in hyperextension (swan-neck deformity) can severely limit grip even if the metacarpophalangeal joints are mobile; surgical correction is often helpful. However, stiffness of the proximal interphalangeal joints in flexion is compatible with good power grip and seldom needs surgery.

Tendon rupture is a potentially preventable cause of functional loss in rheumatoid disease and merits careful assessment. Early clearance of persistent tenosynovitis and elimination of bony spicules will reduce the risk of rupture of additional tendons. The ruptured tendon should be regarded as diseased and not suitable for direct repair. Reconstruction is by transfer of a synergistic intact tendon, by side-to-side suture to an adjacent intact tendon, or, occasionally, by tendon graft. Fusion is sometimes simpler and more appropriate than tendon transfer (e.g. interphalangeal joint of thumb after flexor pollicis longus tendon rupture). The cause of rupture (e.g. ulnar head) should be treated to eliminate the risk to other tendons, even if tendon reconstruction is impracticable.

Loss of function caused by sensory deficiency secondary to nerve compression can often be improved by nerve decompression. For median nerve compression at the wrist, synovectomy of the flexor tendons should be added if there is obvious bulky synovitis.

Wrist and distal radioulnar joint

A stable pain-free wrist is essential for good function of the hand. Although the wrist is seldom the first joint affected by rheumatoid disease, it is ultimately affected in over 90% of patients with severe arthritis. Surgery is frequently required to deal with pain, weakness, and instability of the rheumatoid wrist and distal radioulnar joint.

Synovectomy

In the acute stage of pain and swelling, pain is frequently due to synovitis of the overlying flexor and extensor tendons rather than
to disease in the wrist joint itself. In these cases, swelling and local tenderness will follow the synovial tendon compartments, which extend proximal and distal to the wrist joint. Tenosynovectomy (see later) may be useful. However, open synovectomy of the wrist joint is technically impracticable because of the many small joints and the difficulty in reaching their palmar recesses through a dorsal approach. Chemical synovectomy may be considered, or arthroscopic synovectomy may be performed.

In cases of continued pain with minimal destruction, wrist denervation has been used successfully and detailed descriptions of the techniques are available. Preoperative assessment by local anaesthetic blocks of all nerves supplying the wrist is mandatory. The author has found denervation useful in juvenile rheumatoid arthritis, where painful stiffness is a greater problem than joint destruction.

Two patterns of deformity are commonly seen in the stage of late destruction of the wrist and distal radioulnar joint. The carpus may supinate on the forearm, with translation of the extensor carpi ulnaris tendon over the axis of flexion/extension so that it ceases to act as an extensor of the wrist. The ulnar head becomes prominent dorsally. In other cases, destruction of the distal radius affects the palmar surface more than the dorsal surface, leading to palmar subluxation of the carpus.

Distal radioulnar joint (Box 6.5.3)

Distal radioulnar pain may arise from synovitis alone, from destruction of the joint surfaces, or from loss of radial length with impingement of the ulnar head on the carpus. Persistent synovitis with healthy joint surfaces is an occasional indication for distal radioulnar synovectomy. More often, joint damage will be obvious and surgical correction will require excision of the ulnar head (Darrach procedure). Just enough bone should be removed to clear any impingement against the sigmoid notch of the radius. The level of excision is just proximal to the articular surface. The ulnar stump should remain within the distal radioulnar joint capsule, which should be repaired as securely as possible. Painful instability of the ulnar stump, which is very difficult to treat, may occur if too much bone is excised. Subluxation of the extensor carpi ulnaris tendon should be corrected, so as to rebalance the wrist and stabilize the ulnar stump. This is performed using part of the proximal half of the extensor retinaculum as a ‘slings’ (see ‘Extensor tenosynovectomy’ section).

Box 6.5.3 Treatment of the distal radioulnar joint

- Non-operative: steroid injections often help
- Operative:
  - Little role for synovectomy alone
  - Darrach’s procedure is very successful
  - Extensor tendons need to be checked

The results of ulnar head excision are much more satisfactory and predictable in rheumatoid arthritis than in post-traumatic disorders. Progressive ulnar translation of the carpus may occur after ulnar head excision. Although it is probably due more to softening of radiocarpal ligaments by disease (Figure 6.5.2) than to loss of support of the ulna, ulnar carpal translation is a contraindication to ulnar head excision. The presence of spontaneous radiolunate fusion, or a shelf of bone projecting toward the ulna from the lunate fossa of the radius, protect against ulnar carpal translation. Radiolunate fusion may be performed at the time of ulnar head excision in patients who are thought to be at risk of carpal translation because of limited radiolunate contact or excessive radial inclination.

Fig. 6.5.2
Erosion of the lunate fossa of the radius with loss of support of the lunate and early ulnar translation of the carpus.

An alternative to ulnar head excision is the Sauvé–Kapandji procedure, in which the ulnar head is fused to the sigmoid notch of the
radius and a segment of distal ulnar shaft is excised to allow rotation through the resulting pseudoarthrosis. Although a stable radioulnar surface is provided, the procedure may not prevent ulnar carpal translation. Instability of the proximal ulnar stump may cause troublesome impingement against the shaft of the radius.

**Wrist arthroplasty**

Arthrodesis and arthroplasty are the surgical options for the severely damaged radiocarpal joint. Excision arthroplasty has been unsatisfactory in rheumatoid disease. Swanson silastic interposition arthroplasty has a high failure rate by fracture and bone resorption over the longer-term failures are seen particularly in patients who load the wrist heavily or who gain a large range of motion. Silastic arthroplasty remains a satisfactory procedure for patients with low demands and well-balanced wrists, aiming to achieve no more than 30 degrees each of flexion and extension, but is now rarely performed.

Cemented metal on polyethylene total wrist arthroplasties have been beset with problems of bone resorption, fracture, loosening, and infection. Cementless implants and improved methods of rebalancing wrist tendons may help to improve the results. Salvage of failed arthroplasties remains difficult because of the loss of bone stock. All wrist arthroplasties bridge the midcarpal joint but many do not 'line up' with the normal anatomical 20–24 degrees of radial inclination and 10-degree volar inclination of the radiocarpal joint so must have a propensity to fail because of shear stresses. Many designs have had to be withdrawn from the market because of unacceptable early and medium-term failure rates.

**Wrist arthrodesis (Box 6.5.4)**

Total arthrodesis provides excellent stability and relief of pain in the rheumatoid wrist in cases where arthroplasty is inappropriate or contraindicated (Figure 6.5.3) Arthrodesis is also indicated for salvage of failed arthroplasties. In the patient with severe bilateral wrist disease, a total arthrodesis will provide stability and freedom from pain on one side while a motion-preserving procedure (arthroplasty or limited wrist fusion) will retain some flexibility on the other side. However, many patients function very well with bilateral wrist fusions and are pleased with the stability and relief of pain. When considering the indication for bilateral fusion, the movement of the elbow, shoulder, and forearm rotation should be taken into account; a functional assessment by an occupational therapist may be invaluable. At least one wrist should be fused in neutral, rather than slight extension, so as to permit perineal hygiene.

**Flexor and extensor tendons**

Synovitis involving the flexor and extensor tendons is common in rheumatoid disease. It is more obvious on the extensor surface, particularly on the back of the hand where the tenosynovium extends beyond the distal limit of the extensor retinaculum and may produce a sizable swelling. The swelling extends proximally but is less evident beneath the unyielding extensor retinaculum.
• Splints
• Steroid injection

Operative:
• Almost no role for synovectomy
• Partial fusion is increasingly used
• Total fusion is reliable but overperformed
• Arthroplasty is controversial.

Flexor tenosynovitis produces less obvious swellings, but restriction of active movement and crepitus as bulky tendons move beneath pulleys are common. The swelling is seldom visible or palpable beneath the flexor retinaculum, but appears in the palm, distal forearm, and digits. Restriction of active flexion, or persistent pain and stiffness in the presence of healthy joints, should always raise the suspicion of flexor tenosynovitis, even if swelling is minimal. Median nerve compression secondary to flexor tenosynovitis may cause pain without the sensory symptoms which characterize its presentation in the non-rheumatoid patient.

The consequences of tenosynovitis are pain, restricted active motion, and tendon rupture. Two mechanisms cause tendon rupture: destruction of tendon fibres by invading synovial tissue, and attrition on rough bony prominences. Typically, the tendons are abraded sequentially by the ulnar head. A bony spicule protruding from the scaphotrapezial joint into the carpal canal may damage the flexor pollicis longus tendon, followed by the profundus tendon of the index finger, the superficialis tendon of the index finger, and the profundus tendon of the middle finger.

Rupture of extensor tendons causes drooping at the metacarpophalangeal joints and loss of active extension. Provided that the metacarpophalangeal joint is healthy, passive extension is normal. Two important differential diagnoses may mimic extensor tendon rupture. Dorsal wrist pain on active resisted finger extension may signify impending rupture. However, ruptures which are due to attrition on bone frequently occur without warning or pain. Ruptures of the extensor digiti minimi and flexor digitorum superficialis tendons may pass unnoticed by patient or doctor, but their detection is vital because they indicate that other ruptures may be imminent.

Extensor tenosynovectomy (Box 6.5.5)

The indications for extensor tenosynovectomy are tenosynovitis which persists after appropriate medical management and incipient or actual tendon rupture. In common with other wrist operations in rheumatoid disease, a straight longitudinal dorsal wrist incision is preferred because it minimizes the risks of skin necrosis and dorsal sensory nerve damage. It can be reopened for subsequent wrist operations as necessary. The essential steps are removal of diseased tenosynovium, excision of bony spurs (e.g. ulnar head), and replacement of part or all of the extensor retinaculum beneath the tendons to protect them from later disease in the wrist joint. The third, fourth, and fifth compartments are frequently involved and should be opened routinely. Tenosynovectomy of the second and sixth compartments may also be necessary. The first compartment is seldom involved.

Box 6.5.5 Extensor tendons

• Commonly rupture especially over the ulna head
• Sequential ruptures are common
• Reconstruction is very valuable and more reliable early
• The cause—typically distal ulna—needs to be excised
• The tendons are repaired with transfers or grafts

The frequency of rupture of the extensor tendons in a review of 202 cases was as follows: extensor pollicis longus, 20%; extensor digitorum (little), 17%; extensor digitorum (ring), 15%; extensor digitorum (middle), 7%; extensor digitorum (index), 2%; flexor pollicis longus, 12%; flexor digitorum profundus (index), 7%.

The ruptured tendons are not amenable to direct repair as their stumps are diseased and have retracted. Reconstruction is generally by transfer of an intact and expendable tendon into the ruptured tendon (Figure 6.5.4), but a tendon graft may be used if the original muscle is in good condition and no expendable tendon is available for transfer.
Operative illustration of reconstruction of multiple extensor tendon ruptures. The only intact finger tendons are extensor indicis proprius and extensor digitorum communis to index finger. The former was transferred to extensor digitorum communis to ring and little fingers; the latter shared with extensor digitorum communis middle finger. The distal ulna has been excised. Note the stabilization of extensor carpi ulnaris using part of the extensor retinaculum as a sling (see text).

Commonly used transfers are shown in Table 6.5.1. The wrist extensor tendons can be used for transfer if the wrist is fused, but their excursion is limited and they may be too short to reach the distal tendon stumps.

Flexor tenosynovectomy (Box 6.5.6)

The indications for flexor tenosynovectomy are persistent painful tenosynovitis, incipient or actual tendon rupture, median nerve compression in the carpal canal, and triggering. As in the extensor system, timely tenosynovectomy is vital in preventing tendon rupture and preserving function of the hand.

At the wrist, the tendons are exposed by dividing the flexor retinaculum and extending the incision proximally and distally as necessary. The diseased tenosynovium is removed from the musculotendinous junction to the lumbrical insertion, taking care to minimize retraction of the median nerve. The floor of the carpal tunnel is inspected for bone spicules, which most commonly arise from the scaphotrapezial joint. Spicules are excised and the capsule repaired by direct suture or local capsular flap.

Segments of the digital flexor sheath can be exposed through transverse or zigzag incisions. Tenosynovitis is seen most often beneath the A1 pulley and just distal to the A2 pulley (Figure 6.5.5), but can affect the entire sheath. Diseased synovium and intratendinous nodules are excised. Release of the A1 pulley in rheumatoid disease is controversial, as it may allow ulnar migration of the flexor tendons and aggravate ulnar drift deformity of the metacarpophalangeal joints. Some surgeons prefer to decompress the digital sheath by excision of the ulnar slip of the superficialis tendon, a procedure that achieves decompression at the A2 as well as at the A1 pulley and which removes any possibility of entrapment of the flexor digitorum profundus tendon between the two slips of the superficialis tendon.
The management of flexor tendon rupture is also controversial. Rupture of flexor pollicis longus requires prompt exploration of the carpal canal and removal of the cause of rupture (osteophyte from the scaphotrapezial joint or invasive tenosynovitis), to prevent rupture of other tendons. Active flexion of the interphalangeal joint can be restored by transfer of a superficialis tendon, but the range of motion thus gained is usually small. Fusion of the interphalangeal joint in slight flexion is often preferred in the weak hand of the rheumatoid patient, as it gives a stable thumb with good power transmitted from the short muscles.

Loss of both tendons within the digital sheath is disabling but reconstruction is difficult. Transfer of the flexor digitorum superficialis tendon from another finger can be used if a healthy distal flexor digitorum profundus stump is present; otherwise tendon grafting may be necessary despite its unpredictable outcome.

Options for reconstruction of ruptured flexor tendons are shown in Table 6.5.2. The results of tendon reconstruction are dependent on the number and level of the ruptures. Full active flexion is seldom regained.

**Box 6.5.6 Flexor tendons**

- Less often affected
- A CTR often suffices to settle symptoms
- Sequential rupture is much less common
- Reconstruction is with transfers or grafts

**Metacarpophalangeal joint**

Many factors have been implicated in the production of ulnar deviation at the metacarpophalangeal joints. Synovitis at the metacarpophalangeal joint causes distension of the joint capsule and stretching of the collateral ligaments. The lax joints are then vulnerable to malalignment under the influence of muscle and other forces. The main factors appear to be the strong forces applied by the flexor tendons, which produce palmar subluxation, and by the thumb, which exerts pressure on the sides of the fingers during grip and pinch. If movement of the fingers is painful, the thumb may become the main source of functional grip and its use for key pinch against the sides of the fingers, rather than 'tripod' pinch to the tips, may deform the lax metacarpophalangeal joints. Subluxation of the extensor tendons and tightness of the ulnar intrinsic muscles are commonly seen in ulnar deviated fingers, but whether they are a contributory cause or a consequence of ulnar drift is uncertain (Box 6.5.7). Ulnar drift at the metacarpophalangeal joints is also associated with radial deviation deformity of the wrist, but again it is unclear if the wrist deformity is a cause or a consequence of ulnar drift. It is clear, however, that surgical correction of ulnar drift will fail if fixed radial wrist deviation is not also corrected.

**Box 6.5.7 Metacarpophalangeal (MP) joints**

- Ulna drift is caused by:
  - Deforming forces of life, especially pinch and holding
  - Pull of tendons which worsen as the deformity progresses
• Laxity of restraining structures especially ligaments
• MP joint surgery

♦ Non-operative treatment:
• Splintage is used but unproven
• Steroid injections often help

♦ Operative treatment:
• Synovectomy and soft tissue balancing has a role but recurrent deformity can occur early
• Silastic MP joint replacement is well established and reliable
• Silastic joints often break up but patients only infrequently need revision surgery.

The early stages of metacarpophalangeal joint synovitis are amenable to medical management. Synovectomy is effective in relieving pain and swelling that have persisted after appropriate medical treatment, but probably does not alter the course of the disease. Synovectomy may be performed in isolation or in combination with soft tissue reconstruction.

Synovectomy and soft-tissue reconstruction are indicated when synovitis is associated with passively correctable ulnar deviation and well-preserved joints without palmar subluxation. Subluxation of extensor tendons to the ulnar side of the metacarpophalangeal joint often occurs at this stage. The reconstruction may require release of tight intrinsic muscles, centralization of extensor tendons, reefing of lax radial collateral ligaments, and transfer of ulnar intrinsic tendons to the radial side of the adjacent digit (crossed intrinsic transfer). The intrinsic tendon may be attached to the radial aspect of the proximal phalanx, to the fibrous flexor sheath, or to the radial lateral band. Ulnar deviation of the index finger may be improved by reefing the tendon of the first dorsal interosseous muscle.

The extensor tendon is centralized by reefing of the radial sagittal bands and, if necessary, release of tight ulnar sagittal bands. Alternatively, a distally based strip of extensor tendon can be passed palmar to the deep transverse metacarpal ligament and sutured back to the remaining tendon. This type of reconstruction may cause some limitation of extension but it is effective in securing the alignment of the tendon (Figure 6.5.6). Persisting ulnar deviation may be improved by reefing of the radial collateral ligaments, but at the risk of some loss of metacarpophalangeal joint movement.

Fig. 6.5.6
Ulnar deviation of little finger suitable for extensor loop procedure. The patient is failing to control abduction with a thick rubber band around ring and little fingers.

The essence of postoperative management is to allow early motion but protect against ulnar deviation forces until the soft tissues have healed. If the reconstruction is secure, protection in a static splint between exercise sessions for 6 weeks is sufficient. Alternatively, a dynamic extension outrigger splint supports the metacarpophalangeal joints in extension and radial deviation but allows flexion.

Metacarpophalangeal arthroplasty is required for fixed ulnar deviation, palmar subluxation, and metacarpophalangeal destruction. Excision arthroplasty does not provide stability and may be followed by progressive loss of bone stock. Hinged and other total replacement arthroplasties have a high rate of early failure. The gold standard is the Swanson silastic flexible implant arthroplasty. A fibrous capsule forms around the implant, which pistons freely in the medullary cavities and acts as a spacer which maintains length and supports the soft-tissue reconstruction.

Not all patients with metacarpophalangeal joint destruction require metacarpophalangeal joint arthroplasty. The best indications are relief of pain and correction of deformity which is interfering with function. Moderate ulnar drift is compatible with satisfactory function, particularly if metacarpophalangeal joint pain is modest and interphalangeal movement is good.
Silastic metacarpophalangeal arthroplasty has given consistent and predictable relief of pain and improvement of ulnar deviation. The active flexion range at long-term review is 35–55 degrees. Mild recurrence of ulnar deviation may occur over several years, depending partly on the rate of progression of the disease. Particulate silicone synovitis is rare around metacarpophalangeal joint implants. Fracture of the implant occurs but does not necessarily cause symptoms or necessitate removal of the implant.

Metacarpophalangeal arthroplasty is performed through a single transverse or multiple longitudinal incisions. The metacarpal head is removed at a level just distal to the origin of the collateral ligaments. Release of the ulnar collateral ligament may be needed if ulnar deviation is severe. Release of the palmar plate may also be necessary. It is vital that sufficient space is created to accept the implant without buckling on flexion and extension. The medullary canals are reamed to accept the largest implant which will fit comfortably.

The implant provides a flexible and stable base for the soft-tissue reconstruction, which is vital to the success of the operation. The reconstruction may include intrinsic release, crossed intrinsic transfer, and extensor realignment. The radial collateral ligament may require reefing or, if it is deficient, reconstruction using the radial half of the palmar plate.

Postoperative management aims to encourage the formation of a soft tissue envelope which allows flexion/extension but is stable from side to side. Dynamic splintage, as described earlier for synovectomy and soft-tissue reconstruction, is widely used. However, crossed intrinsic transfer may remove the need for dynamic splintage.

**Proximal interphalangeal joint (Box 6.5.8)**

The proximal interphalangeal joint is a hinge joint which allows motion from 0–120 degrees. The stout collateral ligaments and palmar plate confer good lateral stability and resistance to hyperextension. Synovitis of the proximal interphalangeal joint produces a spindle-shaped swelling of the finger and rapidity limits movement. Synovectomy is indicated for persistent painful synovitis in the face of adequate medical therapy. Access is limited and may require incisions between the central slip and the lateral band on each side. The incisions are closed securely to prevent palmar migration of the lateral bands.

Deformity of the proximal interphalangeal joint is common in rheumatoid arthritis and is usually in the sagittal plane. It reflects disturbance of the delicately balanced muscle and tendon systems which act across the proximal interphalangeal joint.

**Swan-neck deformity**

Swan-neck deformity is hyperextension at the proximal interphalangeal joint and flexion of the distal interphalangeal joint. It results from imbalance in the tendon systems which cross the proximal interphalangeal joint and is generally due to weakening of a tendon insertion or static joint restraint by diseased synovium. Because the three joints are interdependent though their tendon and ligament systems, swan-neck deformity can be caused by synovitis at any one of the three finger joints. Swan-neck deformity can occur only if hyperextension is possible at the proximal interphalangeal joint.

**Box 6.5.8 Proximal interphalangeal (PIP) joints**

- Instability is a particular problem.
- Early treatment is much more effective and can prevent later problems
- Swan neck deformity: can be caused by problems at the MP, PIP, or DIP joints
- Boutonniere deformity: caused by central slip failure
- Treatment:
  - Swan-neck deformity—should be treated early with soft tissue balancing
  - Boutonniere—rarely needs treatment
  - Joint destruction
  - Arthrodesis is simple and reliable but less good for the ring and little fingers
  - Arthroplasty works reasonably well in low-demand patients.

Proximal interphalangeal joint synovitis weakens the palmar plate and superficialis insertion, allowing hyperextension of the proximal interphalangeal joint. Later, the lateral bands migrate dorsally as the transverse retinacular ligaments elongate and a secondary extension lag appears at the distal interphalangeal joint.

 Destruction of the terminal tendon of the dorsal aponeurosis by synovitis at the distal interphalangeal joint may also initiate swan-neck deformity. Without the attachment of the terminal tendon, the dorsal aponeurosis migrates proximally and pulls excessively on the central slip, resulting in hyperextension of the proximal interphalangeal joint.

 Flexion deformity at the metacarpophalangeal joints is often associated with swan-neck deformity. Many factors may be involved, including intrinsic muscle contracture.

 Swan-neck deformity has been graded into four types, depending on the mobility of the proximal interphalangeal joint and the condition of the joint surfaces.
- Type I: the proximal interphalangeal joint is mobile in all positions of the metacarpophalangeal joint. The zigzag posture is due to imbalance.

- Type II: proximal interphalangeal joint flexion is full while the metacarpophalangeal joint is flexed but limited when the metacarpophalangeal joint is extended. Intrinsic tightness is present.

- Type III: the proximal interphalangeal joint is stiff in all positions of the metacarpophalangeal joint but the joint surfaces are healthy.

- Type IV: the proximal interphalangeal joint is stiff and the joint surfaces are damaged.

The disability of swan-neck deformity is due mainly to lack of flexion of the proximal interphalangeal joint. If the proximal interphalangeal joint is mobile, it may ‘lock up’ in hyperextension and flex with a snap as flexion effort is increased and the lateral bands slide from dorsal to palmar over the sides of the joint.

Type I swan-neck deformity may require no treatment. Locking of the proximal interphalangeal joint in extension (Figure 6.5.7) can be prevented by blocking hyperextension with a figure-of-eight splint. If a thermoplastic splint is effective, a more durable splint may be constructed from metal and worn like a ring. Hyperextension may also be corrected by tenodesis across the palmar aspect of the proximal interphalangeal joint, using one slip of the superficialis tendon which is detached proximally and sutured to the A2 pulley. Alternatively, the lumbrical tendon can be rebalanced as a flexor of the proximal interphalangeal joint. Fusion of the distal interphalangeal joint may also be useful, particularly when the swan-neck deformity is due to elongation of the terminal tendon.

Type II deformity is due to tightness of the intrinsic muscles. Proximal interphalangeal joint flexion is limited when the metacarpophalangeal joint is extended but normal when the metacarpophalangeal joint is flexed (the intrinsic tightness test). The restriction is often increased by deviation of the metacarpophalangeal joint to the radial side, showing that the tightness is greater on the ulnar side. A distal intrinsic release is performed, excising a triangle of the dorsal aponeurosis which includes the ulnar lateral band and adjacent oblique fibres. A tenodesis or tendon rebalancing may be required, as for type I.

If the swan neck deformity was initiated at distal interphalangeal joint level as a ‘mallet finger’ fusion of the terminal joint in a position just short of full extension may need to be added.

Type III deformity prevents grasp because the proximal interphalangeal joints are fixed in extension. Passive flexion is prevented by soft tissue contracture which may involve the dorsal aponeurosis, the dorsal capsule of the proximal interphalangeal joint, and the skin. The lateral bands are fixed dorsally and cannot slide toward the palm to allow flexion. Manipulation of the proximal interphalangeal joint may restore flexion in less severe cases. An oblique skin release over the middle phalanx may be needed if the skin blanches on flexion. The joint can be stabilized temporarily with a pin across the joint. This procedure may be useful in psoriatic arthropathy, where the finger joints characteristically become stiff at an early stage without marked joint destruction. Mobilization of the lateral bands from the central slip may be needed in more severe cases. These procedures may be performed at the same time as metacarpophalangeal joint arthroplasty.

Type IV deformity is best managed by arthrodesis (see later). In selected patients, Swanson or pyrocarbon arthroplasty of the proximal interphalangeal joints can be considered, provided that tendon imbalance is corrected. Arthroplasty should be restricted to the proximal interphalangeal joints of the ring and little fingers, which require flexion for power grip. The index and middle fingers are also used for tripod pinch to the tip of the thumb; stability of pinch is more important than additional flexion in these digits. Aids such as large-handled cutlery can mitigate the effects of loss of flexion.

Arthrodesis of the proximal interphalangeal joint should be performed using a technique that gives stable fixation, allows early movement of other joints, and does not require plaster immobilization. Tension band wire fixation provides stable fixation without unduly prominent metalwork (Figure 6.5.8) and avoids protruding pins with their inconvenience, risk of infection, and need for removal before fusion is secure. Care must be taken to preserve the cancellous bone of the head of the proximal phalanx.
excessive resection exposes the hard cortical bone of the neck and may delay union. The angle of fusion depends on the digit and the range of motion of other joints in the hand. The angles usually selected are: index 35 degrees; middle 45 degrees; ring 55 degrees; and little 65 degrees.

Fig. 6.5.8
Proximal interphalangeal joint fusion using tension band wire technique.

Arthrodesis of the distal joint is performed in a few degrees of flexion, though greater flexion may be required to accommodate to deformity of other joints or for specific functional needs. Tension band fixation is stable and avoids protruding pins, but an oblique K-wire and interosseous wiring technique is easier in these small joints. Fixation with a Herbert screw is also effective (Figure 6.5.9).

Fig. 6.5.9
Interphalangeal joint fusion using a Herbert screw.

Boutonnière deformity

Boutonnière deformity comprises flexion of the proximal interphalangeal joint and hyperextension of the distal joint. It is compatible with surprisingly good function in the rheumatoid hand, especially if some flexion is possible at the distal joint (Figure 6.5.10). Boutonnière deformity in the fingers always results from disease at the proximal interphalangeal joint, leading to destruction of the central slip. The lateral bands migrate in a palmar direction, where they become fixed by contracture of the transverse retinacular ligament. In this position, they no longer act to extend the proximal interphalangeal joint and their pull on the distal joint is excessive. Unfortunately, the results of soft tissue reconstruction of rheumatoid boutonnière deformity are unsatisfactory. If surgery is needed, it should be fusion of the proximal interphalangeal joint in a functional position. Tenotomy of the extensor tendon over the middle phalanx may improve the range of flexion of the terminal joint in less severe cases.
Lateral deformities and instability of the proximal interphalangeal joint are usually due to joint destruction; arthrodesis in a functional position is the only way to improve grip. In cases of mutilating arthritis with multiple joint destruction, loss of length, and instability, the principle is to provide stable fingers in the best functional position with movement concentrated at the base of the finger. It may be necessary to fuse both proximal and distal interphalangeal joints.

**Thumb (Box 6.5.9)**

The joints of the thumb are frequently affected by rheumatoid disease. Any of the three joints can be affected. The thumb is used in nearly all daily activities and the complaint is almost always of painful interference with function rather than of pain alone. The loss of pinch strength is frequently associated with instability of one or more joints. Repeated loading of the distended and inflamed joints leads to failure of the ligaments and to deformity. As in the fingers, the interdependence of the joint mechanisms results in a zigzag posture in which the failure of one joint leads to opposite deformity of adjacent joints.

Deformities of the thumb fall into three patterns.

1. **Boutonnière thumb** Flexion at the metacarpophalangeal joint with hyperextension at the interphalangeal joint. The basal joint is not affected. The primary deformity is usually at the metacarpophalangeal joint, where synovitis weakens the dorsal hood and the resulting flexion posture leads to secondary hyperextension at the interphalangeal joint.

2. **Swan-neck thumb** Damage of the basal joint causes dorsal subluxation with flexion and adduction of the first metacarpal, hyperextension of the metacarpophalangeal joint, and flexion of the interphalangeal joint.

**Box 6.5.9 Thumb**

- **Thumb**
  - The thumb is very important but relatively simple to treat.
    - **Carpometacarpal joint:**
      - It is often destroyed/subluxed but usually does not need treatment.
      - Trapezectomy ± ligament reconstruction is reliable.
    - **MP and IP joints:**
      - Soft tissue procedures are unreliable.
      - Fusion is reliable and well tolerated.

3. **Lateral instability** Lateral deformity is due to failure of the radial collateral ligament and/or destruction of the metacarpophalangeal or interphalangeal joints. Metacarpal adduction can occur secondarily.

A more complicated classification into six types has been proposed by Nalebuff and others, but the scheme listed here describes the great majority of thumb deformities.

In considering treatment, the thumb must be regarded as providing a stable post against which the fingers can work to provide pinch grip. Mobility is needed at the basal joint so that the thumb can be positioned appropriately. At the metacarpophalangeal and interphalangeal joints, stability is more important than movement. Therefore instability at these joints should be managed by arthrodesis in 0–20 degrees of flexion. In the author’s opinion, silastic interposition arthroplasty has no place in the treatment of the
arthrodesis in 0–20 degrees of flexion. In the author's opinion, silastic interposition arthroplasty has no place in the treatment of the rheumatoid thumb.

Arthrodesis of the interphalangeal joint of the thumb is performed by a tension band wiring technique through an S-shaped dorsal incision with care to protect the nail-bed. At the metacarpophalangeal joint, the bones are large enough to use a ‘chevron’ method in which a V-shaped notch is made in the head of the metacarpal and the base of the proximal phalanx is trimmed to fit it. The large surfaces of cancellous bone will fuse rapidly and can be held with K-wires at 90 degrees to each side of the V in a crossed-wire configuration. Alternatively, a tension band wire technique can be used, as in the proximal interphalangeal joint of the finger (Figure 6.5.11). In the case of marked bone loss in mutilating arthritis, it may be necessary to fuse both metacarpophalangeal and interphalangeal joints to maintain length or indeed to gain length by interposing corticocancellous grafts from the iliac crest. This apparently drastic surgery can improve function remarkably and help to maintain the patient’s independence for dressing, cooking, and eating.

Fig. 6.5.11
Thumb metacarpophalangeal joint fusion using tension band wire technique. The interphalangeal joint has been fused with a Herbert screw passed from proximal to distal before fixation of the metacarpophalangeal joint.

In the swan-neck thumb, the primary abnormality is usually at the basal joint. The aim of providing mobility at the base of the thumb precludes fusion. Trapezial excision arthroplasty with stabilization of the metacarpal base using a distally-based strip of the flexor carpi radialis tendon is effective and straightforward. Release of the contracted muscles of the thumb web and correction of metacarpophalangeal joint hyperextension by arthrodesis may also be necessary.

Rheumatoid nodules
Nodules on the hand are more than a cosmetic problem. They occur commonly on the dorsum of the proximal interphalangeal joint, where they are easily knocked, and in the pulps of the digits, where they cause pain and interfere with grip. Many patients have relatively little joint destruction and their function can be improved by removal of painful nodules. Excision under local or regional anaesthesia may be very helpful, but patients should be aware that the tendency to form nodules can continue for many years and many operations may be needed.

Further reading
Summary points

- Prevalence of hand osteoarthritis increases with age
- Most hand osteoarthritis causes few symptoms
- Non-operative management is sufficient for the majority of cases
- Surgical treatment is sometimes required
- Total joint replacements have significant failure rates.

Prevalence and aetiology

Osteoarthritis of the hand is uncommon under the age of 50, but is very common, although usually painless, in older people. Some hand joints are more susceptible than others: over 50% of women aged 55–65 years have distal interphalangeal, about 40% have proximal interphalangeal, one-third trapeziometacarpal, and a fifth metacarpophalangeal joint osteoarthritis (Box 6.6.1).

Box 6.6.1 Incidence of osteoarthritis of the hand

- Common in those over 50
- In women aged 55–65 years:
  - 62% distal interphalangeal joint (DIPJ)
  - 40% proximal interphalangeal joint (PIPJ)
  - 33% thumb base
  - 20% metacarpophalangeal joint (MPJ)
- But often pain free.

The aetiology of hand osteoarthritis is poorly understood. ‘Repetitive manual work’ has been implicated as an aetiological factor with little, if any, supportive evidence. Most hand osteoarthritis is idiopathic (cause unknown) and this may either be localized to the hand or generalized. Idiopathic osteoarthritis is more common in women and has a hereditary predisposition.

Secondary hand osteoarthritis may occur as a complication of intra-articular fractures and infections. However, only a minority of properly treated intra-articular fractures develop symptomatic osteoarthritis and most joint infections are now treated promptly before the articular cartilage is destroyed.

Isolated osteoarthritis of the index and middle finger metacarpophalangeal joints is seen in haemochromatosis and may be the first clinical manifestation of the condition.

Clinical presentation

Hand osteoarthritis commonly causes joint stiffness, hand weakness, and deformity. It rarely causes disabling pain and only a few of those affected require treatment. For example, only 30% of women with radiological trapeziometacarpal joint osteoarthritis experience any pain. Thus when assessing patients with hand pain and radiological osteoarthritis, it is vital to confirm that the osteoarthritis is causing the pain and is not merely coincidental.

Finger interphalangeal joint osteoarthritis

History, examination, and radiographs (Box 6.6.2)

Osteoarthritis of these joints is usually painless. However, it commonly causes finger stiffness which may cause loss of dexterity and weakness. Osteophytes and soft tissue hypertrophy produce the characteristic Heberden’s (distal) and Bouchard’s (proximal) nodes (Figure 6.6.1).
Fig. 6.6.1
A) Osteoarthritic swelling of the distal interphalangeal (Heberden’s nodes) and proximal interphalangeal (Bouchard’s nodes) joints. B) Radiographs show advanced osteoarthritis. The index finger proximal interphalangeal joint has spontaneously fused.

Painful osteoarthritic interphalangeal joints are usually mildly tender and painful when stressed (rocked from side to side). Interphalangeal joint extension is usually preserved, but the range of flexion gradually reduces and may become painful at its extreme. Crepitus may be elicited and mucous cysts (ganglia arising from a joint) sometimes appear on the dorsum of the osteoarthritic distal interphalangeal joint. These may cause nail deformity.

Radiographs should include the metacarpophalangeal and both interphalangeal joints of the involved finger, not just the affected joint, in order to see the condition of the neighbouring joints. The standard views are posteroanterior and lateral for the interphalangeal joints, with an additional oblique view for the metacarpophalangeal joint.

Box 6.6.2 Finger interphalangeal joint osteoarthritis: assessment

- **History:** usually clear. May be a history of injury
- **Examination:**
  - Deformity
  - Tenderness
  - Stiffness
- **Investigation:**
  - Plain radiography—confirms diagnosis
  - X-ray features are not well correlated with symptoms.

Management (Box 6.6.3)

Painless osteoarthritis causing stiffness and hand weakness may improve with physiotherapy and is not an indication for surgical treatment. Interphalangeal joint osteoarthritic pain is commonly transient and may respond to conservative measures such as reassurance, rest, activity modification, analgesia, physiotherapy, and steroid injections. Surgery is reserved for patients with persistent joint pain which restricts activities and does not respond to conservative measures. The surgical options are arthroplasty and arthrodesis, and both have their drawbacks (Box 6.6.4).

Box 6.6.4 Finger interphalangeal joint osteoarthritis: surgery

- **Arthroplasty:** unreliable either silastic or newer resurfacing implants
- **Arthrodesis:**
  - Reliable but awkward
  - Better in the DIPJs and index PIPJ
  - But less good for MPJs and ulnar PIPJs.

Interphalangeal joint arthroplasty
Arthroplasty of the distal interphalangeal joint has been reported but is seldom performed as distal interphalangeal joint arthrodesis causes little disability.

Proximal interphalangeal joint arthrodesis causes considerable disability and elderly patients with osteoarthritis of this joint are usually satisfied with a silicone interposition arthroplasty (Figure 6.6.2). Pain relief is predictable in the majority of cases but as a general rule the range of movement remains the same as preoperatively. Silicone interposition arthroplasty should be used with caution in younger patients who place greater demands on their hands as these implants have a limited lifespan and may fracture or wear and cause silicone synovitis. Furthermore, they have little collateral stability and thus pinch strength is weak. Silicone synovitis may cause severe osteolysis which makes salvage surgery difficult. Silicone proximal interphalangeal joint arthroplasty may be performed through dorsal, palmar, or lateral approaches with equivalent results.

Box 6.6.3 Finger interphalangeal joint osteoarthritis: non-operative treatment

- Activity modification
- Non-steroidal anti-inflammatories
- Splint
- Steroid injection.

Dissatisfaction with the results of silicone interposition arthroplasty has lead to the development of two-piece proximal interphalangeal joint replacements. Initial designs were simple hinges allowing single-plane motion and these rapidly loosened. Subsequent semiconstrained surface replacement designs preserve the collateral ligaments, seek to balance the flexor and extensor forces, and require minimal bone resection. The first surface replacement design was developed by Linscheid and Dobyns in 1979 and was modified in 1987. The results of 66 of these at a mean follow-up of 4.5 years revealed 32 good, 19 fair, and 25 poor results. Significant complications, including instability, angular deviation, swan-neck deformity, subluxation, and flexion contracture, were seen in 19 cases, but there was no loosening.

Further development of surface replacement arthroplasty has concentrated on the bone–implant interface and on the material composition of the implant. There is currently much interest in pyrolytic carbon implants (Figure 6.6.3), which are known to have excellent wear properties. Short-term results are encouraging, with predictable pain relief and generally good patient satisfaction, though with high complication and reoperation rates. Metal and polyethylene implants have also been developed. Currently no clear advantage over silicone interpositional arthroplasty has been demonstrated.
Interphalangeal joint arthrodesis

This is the standard treatment for painful distal interphalangeal joint osteoarthritis. Although the best cosmetic result is achieved by fusing this joint in extension, fusion in slight flexion may produce better function.

Proximal interphalangeal joint arthrodesis is the best option for young manual workers who require strong resilient fingers, especially for the index finger. The position of fusion is debated: around 30–40 degrees for the index finger increasing to 45–60 degrees for the little finger. Arthrodesis of the index proximal interphalangeal joint is better tolerated as pinch is facilitated and power grip minimally compromised. Some patients with arthrodesis of a single proximal interphalangeal joint subsequently request amputation.

Arthrodesis techniques

Both interphalangeal joints are usually arthrodesed through a dorsal approach. The articular surfaces are either resected with appropriately angled saw cuts (difficult to judge accurately) or rongeured to create concentric cancellous surfaces. The latter technique allows some adjustment of the fusion angle and preserves more length. The arthrodesis can then be stabilized with K-wires, a tension band wire, a lag screw, or a headless bone screw (Figure 6.6.4). The critical point is that the bone ends are held in close approximation for the 8–10 weeks needed to achieve bone union.

Arthrodesis results

The reported non-union rates for distal interphalangeal joint arthrodesis range from 0–20%. Not all distal interphalangeal joint non-unions are painful and require revision surgery. The proximal interphalangeal joint is larger and more accessible than the distal joint and thus is easier to fuse and has a higher union rate.

Mucous cyst treatment

See Chapter 6.13.
Metacarpophalangeal joints of the fingers

Primary metacarpophalangeal joint osteoarthritis is usually asymptomatic but painful secondary osteoarthritis can occur following severe intra-articular fractures or infections (e.g. following a human bite sustained in a fight).

Occasionally, an otherwise painless osteoarthritic joint can lock in flexion as a result of the radial collateral ligament catching on an osteophyte on the metacarpal head (Figure 6.6.5) (best seen on the posteroanterior oblique radiograph). This locking usually affects the index or middle fingers. Joint distension with local anaesthetic and manipulation is the first-line treatment though the prominent osteophytes often need excision.

Management

Painful metacarpophalangeal joint osteoarthritis can be treated by arthrodesis or arthroplasty. Options for arthroplasty include excision, silicone interposition, or surface replacement.

Arthrodesis

Arthrodesis of the metacarpophalangeal joint is a disabling procedure though it is sometimes indicated in young manual workers, especially for the index finger. Fusion in 25 degrees of flexion is recommended though better function may be achieved by fusing the ring and little fingers in 35–45 degrees of flexion. The bone ends can either be prepared as flat saw cuts or as a matching peg and socket and the arthrodesis can be stabilized with K-wires, a tension band wire, lag screws, or a dorsal mini-fragment plate. If the arthrodesis is stabilized with a plate, external splintage may not be required postoperatively. However, all the other fixation techniques require splint immobilization until bony union (6–8 weeks).

Excision arthroplasty

Excision arthroplasty is an option for young manual workers in whom silicone arthroplasty is contraindicated. In palmar plate arthroplasty, the metacarpal head is excised and the metacarpal attachment of the palmar plate is reattached to the dorsal surface of the metacarpal neck. Although this surgery inevitably results in a weak finger, typically a 50-degree arc of movement is preserved and pain relief in the short term is satisfactory. In the long-term, bone resorption and metacarpal shortening may occur, causing progressive instability and palmar subluxation. Because of a lack of collateral instability, excision arthroplasty is probably not indicated for the index finger metacarpophalangeal joint.

Silicone implant arthroplasty

Silicone implant arthroplasty is well established in rheumatoid surgery and is an option for the osteoarthritic metacarpophalangeal joint, particularly in the elderly, lower-demand patient.

Surface replacement arthroplasty

The potential for complications with silicone implant arthroplasty, such as implant fracture and silicone synovitis, has led to the development of fixed fulcrum articulating designs. Failure of early hinged and ball and socket designs prompted progression to unconstrained and semiconstrained surface replacement arthroplasties which preserve soft tissue support and require minimal bone resection. Materials and designs continue to evolve. Short-term results of the latest design of pyrolytic carbon implant (Figure 6.6.6) are encouraging, with excellent pain relief, range of motion, and maintenance of pinch and grip strength, but its long-term outcome is unknown.
Osteoarthritis of the thumb

The treatment aim for thumb osteoarthritis is to create a painless stable thumb which is sufficiently strong to allow the patient to resume his or her normal daily and work activities. Arthrodesis is a successful treatment for single joint (trapeziometacarpal, metacarpophalangeal, or interphalangeal) thumb osteoarthritis. Indeed, reasonable thumb function is preserved following combined thumb metacarpophalangeal and interphalangeal joint arthrodeses, provided that the trapeziometacarpal joint is mobile and painless. If two or more thumb joints are osteoarthritic, it may be difficult to decide whether both are painful or all the pain arises from one joint. In this instance careful examination of each joint separately, while the others are carefully supported, is essential and intra-articular local anaesthetic injections are useful.

Incidence and prevalence (Box 6.6.5)

Trapeziometacarpal joint osteoarthritis is usually idiopathic and is particularly common in postmenopausal women (25%), although it is usually asymptomatic. It only rarely causes sufficient symptoms to warrant surgery. Symptomatic thumb metacarpophalangeal joint osteoarthritis is usually idiopathic but can complicate chronic ulnar collateral ligament laxity and severe intra-articular fractures. Interphalangeal joint osteoarthritis is common but usually only causes minor symptoms.

Box 6.6.5 Thumb base osteoarthritis

- Common, found in 25% of postmenopausal women
- Typically minimally symptomatic
- Probably due to beak ligament failure.

Anatomy

The thumb metacarpophalangeal and interphalangeal joints are similar to their finger counterparts but have different ranges of movement. The interphalangeal joint mean range of movement is −30 to 60 degrees; the metacarpophalangeal joint range of movement is variable and the normal range is determined by examining the contralateral normal thumb.

The basal thumb articulation consists of the trapeziometacarpal, the scaphotrapezial, scaphotrapezoid, trapeziotrapezoid, and trapezial–second metacarpal joints (Fig 6.6.7). The scaphotrapezial and scaphotrapezoid joints constitute part of the midcarpal joint though the former also allows some thumb abduction and adduction. Most basal thumb movement occurs at the trapeziometacarpal joint which has a saddle-shaped articulation allowing palmar abduction, radial abduction, adduction, and opposition. This joint is inherently unstable and its stability depends on the palmar (‘beak’) ligament. Trapeziometacarpal joint laxity is a common finding in young females and is usually asymptomatic. It may predispose to osteoarthritis in later life.
Classification of basal thumb osteoarthritis

Basal thumb osteoarthritis may be classified according to which joints are degenerate and the radiological appearance of the trapeziometacarpal joint. The trapeziometacarpal joint alone is osteoarthritic in most cases but the scaphotrapezial and scaphotrapezoid joints are also osteoarthritic in 10% of cases. Trapeziometacarpal osteoarthritis is graded 1 to 4 according to its radiological appearances. In stage 1 the joint is painful when stressed and standard radiographs are normal though stress views show joint subluxation. In stage 2 there is minor osteoarthritic change and in stage 3, moderate change. In stage 4 there is subchondral sclerosis and joint space narrowing, with osteophytes and cysts. Although a higher proportion of patients with stage 4 osteoarthritis complain of symptoms, extreme radiological osteoarthritis may be asymptomatic and minor radiological osteoarthritis may be very painful: hence the distinction between stages 2–4 is of little clinical value.

History and examination (Box 6.6.6)

Patients complain of pain around the involved joint that is typically use-related. The clinical findings are similar to those described for the finger joints.

The majority of patients with painful trapeziometacarpal osteoarthritis are middle-aged women who initially complain of gradually worsening basal thumb pain which occurs with or after use. This pain usually develops spontaneously though it is sometimes precipitated by a fall or other injury. Night pain is uncommon but patients may be woken at night by symptoms of carpal tunnel syndrome, which coexists in 32% of cases. Functional disability (e.g. undoing screw top jars, writing, and turning door keys) should be assessed.

In the early osteoarthritic stages, the trapeziometacarpal joint is tender and painful when stressed or moved under axial compression ('grind' test). In advanced disease, osteophytes are palpable and the thumb has the characteristic adduction deformity (Figure 6.6.8). This adduction deformity is usually accompanied by compensatory metacarpophalangeal joint hyperextension to maintain hand span.

Radiographs

The basal thumb articulations, as well as the thumb metacarpophalangeal and interphalangeal joints are clearly seen on...
anteroposterior and lateral views in the plane of the thumb (Gedda views). Trapeziometacarpal joint laxity and subluxation (stage 1) is assessed using stress views (Figure 6.6.9). However, painless joint laxity is exceedingly common in young females.

Fig. 6.6.9
Thumb stress views showing marked subluxation of both trapeziometacarpal joints. These stress views are taken with the patient pushing her thumb tips together as strongly as possible in order to provoke subluxation of the trapeziometacarpal joints.

Management

Osteoarthritis causing minimal symptoms is treated by standard conservative techniques as described earlier. Surgery should be deferred until conservative methods have failed and thumb pain significantly restricts normal daily activities.

Metacarpophalangeal and interphalangeal joint osteoarthritis

Arthrodesis in about 15 degrees of flexion is the treatment of choice for painful thumb interphalangeal joint osteoarthritis. Isolated thumb metacarpophalangeal osteoarthritis is also best treated by arthrodesis in about 10–20 degrees of flexion. Both joints can be arthrodesed using any of the techniques described for the fingers. If thumb metacarpophalangeal and trapeziometacarpal osteoarthritis occur concurrently and the latter joint has an adduction deformity, a metacarpophalangeal arthrodesis or volar plate stabilization should only be performed if a trapeziometacarpal arthroplasty (excision or other) is also performed.

Box 6.6.6 Thumb base osteoarthritis: history and examination

♦ Assessment: history and examination are often clear cut
♦ There may be subluxation
♦ Radiography is diagnostic
♦ Note subluxation and possible scaphotrapeziotrapezoid osteoarthritis.

Basal thumb osteoarthritis

Painless trapeziometacarpal joint adduction deformity is not usually an indication for surgery.

Conservative management

Thumb splints can provide useful pain relief but are poorly tolerated. Intra-articular steroid injections may produce significant pain relief for several months though rarely give lasting benefit. If trapeziometacarpal osteoarthritis is causing significant functional restriction and pain, then surgery should be contemplated.

Surgical management

The surgical treatment options can be divided into five general categories:

♦ Trapeziometacarpal joint capsular reinforcement
♦ Thumb metacarpal osteotomy
♦ Trapeziometacarpal joint arthrodesis
♦ Trapeziometacarpal arthroplasty with preservation of the trapezium and scaphotrapezial joint
♦ Excision of the trapezium with or without soft tissue or silicone interposition or ligament reconstruction.
The appropriate surgical procedure depends on the patient’s age and activities, the severity (stage) of the osteoarthritis, and the condition of the scaphotrapezial joint (Box 6.6.7).

**Box 6.6.7 Thumb base osteoarthritis: surgical treatment**

- Soft tissue, i.e. ligament reconstruction for early disease
- Joint surgery for most
- Trapezeotomy is simple and reliable
- Trapezeotomy and soft tissue reconstruction is popular but not more reliable
- Arthrodesis best for manual labourers
- It can be technically difficult
- Joint replacement is as yet not established.

Trapeziometacarpal joint capsule reinforcement.

For stage 1 disease (painful laxity with no radiological changes of osteoarthritis). The palmar ligament and joint capsule are reinforced, usually with a length of the flexor carpi radialis tendon (Figure 6.6.10) and the thumb is then immobilized in a plaster cast for 4–6 weeks. High success rates have been reported, although complete pain relief is not always obtained and trapeziometacarpal joint abduction and extension are often restricted.

Metacarpal osteotomy.

A radial closing wedge osteotomy is performed at the base of the thumb metacarpal. Good patient satisfaction with the procedure has been reported with Stages 1, 2, and 3 osteoarthritis, but this procedure is unpredictable and has not gained widespread popularity.

Trapeziometacarpal joint arthrodesis.

This is historically indicated for young manual workers who need to retain strong thumb pinch. It is contraindicated if both the trapeziometacarpal and scaphotrapezial joints are osteoarthritic as the latter joint may become more painful. The joint is best fused in the ’clenched fist position’ (20–30 degrees of radial abduction and 20 degrees of palmar abduction) which preserves reasonable thumb span and allows opposition to the ring fingertip. The arthrodesis can be stabilized with K-wires, a tension band wire, or a small plate (Figure 6.6.11) and the thumb is immobilized until union occurs (6–8 weeks). Ten per cent non-union rates are typical though these are not always painful. A small amount of basal thumb movement remains due to the scaphotrapezial joint. Some patients have difficulty performing fine dextrous tasks, especially if the metacarpophalangeal joint has a restricted range of flexion. Arthrodesis does not restore normal thumb pinch strength and a 30% reduction is typical, such that it may not provide any better function than a trapezeotomy and ligament reconstruction in young manual workers.
Basal thumb arthroplasty.

The majority of patients with painful basal thumb osteoarthritis are middle-aged or elderly women who do not place large force demands on their thumbs. In these patients it is best to preserve basal thumb mobility and some form of arthroplasty should be performed. Patients without scaphotrapezial joint osteoarthritis can be treated with a trapeziometacarpal arthroplasty which either preserves or excises the trapezium. If the scaphotrapezial joint is osteoarthritic then an arthroplasty which excises the trapezium should be performed.

Trapeziometacarpal total arthroplasty.

Most trapeziometacarpal total arthroplasties are of a constrained or semiconstrained ball and socket design, with all metal or metal-on-polyethylene articulations. There are cemented and cementless designs (Figure 6.6.12). In the short term, these implants have a high success rate in terms of pain relief and restoration of function. Promising medium-term (up to 5 years) results have been published for some prostheses but others have been shown to have high loosening and dislocation rates.

Surface replacement prosthesis designs have been developed that require minimal bone excision. The lack of constraint inherent to these designs should reduce the risk of loosening, but their short-term results are disappointing.

Independent long-term follow-up studies are required as presently it is not known whether total arthroplasty produces better results than simpler and cheaper procedures such as trapeziectomy. The salvage procedure for failed total arthroplasty is trapeziectomy.

Trapezium excision arthroplasty.

Trapeziectomy without additional soft tissue procedures was the standard treatment for trapeziometacarpal joint osteoarthritis for many years but fell out of favour because it was reputed to have a protracted rehabilitation time (6 months), cause thumb weakness, and be complicated by subluxation, dislocation, or painful degeneration of the scaphotrapezial pseudoarthrosis. Numerous modifications to “simple” trapeziectomy have been devised to prevent these problems, including insertion of a silicone
trapezial implant, interposition of a rolled-up ball of tendon into the trapezium void (tendon interposition), and construction of a suspensory ligament between the bases of the thumb and index metacarpal bones (Figure 6.6.13). All these procedures aim to prevent the base of the first metacarpal articulating with the distal pole of the scaphoid and the suspensory ligament is also intended to prevent pseudarthrosis subluxation and dislocation.

![Image]

**Fig. 6.6.13**

Trapeziectomy with insertion of a silicone trapezium implant.

This is no longer widely performed, predominantly because of the risk of silicone synovitis which occurs when silicone wear particles cause a painful foreign-tissue body reaction. This can cause severe bone loss though long-term studies suggest that this complication, as well as implant dislocation or subluxation, are uncommon.

Trapeziectomy with tendon interposition.

Trapeziectomy with tendon interposition is still widely used. Palmaris longus, flexor carpi radialis, and extensor carpi radialis longus have all been used with satisfactory results.

Trapeziectomy with ligament reconstruction.

Many techniques of ligament reconstruction have been described. Most commonly the flexor carpi radialis, the abductor pollicis longus, or a combination of both tendons is used to suspend the thumb metacarpal base. Excess tendon may be interposed in the trapezial void, and a K-wire may be used to stabilize the construct during early healing.

**Rehabilitation**

Considerable swelling and pain can occur following trapeziectomy and strict postoperative elevation is essential.

After simple trapeziectomy, splintage in a plaster slab for 2 weeks followed by early motion, resting in a removable splint, is well tolerated. Formal physiotherapy is not usually required.

During trapeziectomy with ligament reconstruction, a K-wire may be passed across the scaphometacarpal pseudarthrosis to prevent proximal migration of the thumb metacarpal before the suspensory ligament becomes sound. The thumb is therefore immobilized in abduction in a plaster backslab until the K-wire is removed (4 weeks), after which some rest it in an abduction splint for a further 2 weeks. The thumb is generally immobilized for no more than 2 or 3 weeks following a total arthroplasty.

**Results**

There are good published results for all the surgical treatments of basal thumb osteoarthritis. Most patients regain good thumb function within 3 months. Typically 80–90% of patients achieve a painless thumb or only experience mild aching after use. All surgical procedures are reported to produce thumbs which have 70–80% of normal key and tip pinch strengths.

There is no good evidence that any procedure produces a better result than simple trapeziectomy in which the trapezium is excised, the trapezial void is left empty, and no ligament reconstruction is performed. Comparative studies have shown no advantage of adding suspension to simple trapeziectomy. Recurrence of pain and adduction deformity are uncommon following both simple trapeziectomy or trapeziectomy with ligament reconstruction.

**Management of metacarpophalangeal hyperextension deformities**

A compensatory metacarpophalangeal joint hyperextension deformity may occur in conjunction with the trapeziometacarpal joint adduction deformity found in severe osteoarthritis. Many would recommend that this is treated surgically to prevent recurrence of the basal thumb adduction deformity (which may cause implant/pseudarthrosis subluxation/dislocation) and improve thumb dexterity and strength. Hyperextension deformities of more than 30 degrees may be managed by metacarpophalangeal joint palmar plate advancement, sesamoid tenodesis, or fusion (Figure 6.6.14).
Complications

Complex regional pain syndrome, which may cause prolonged finger stiffness and hand disability may occur following procedures involving excision of the trapezium and should be treated urgently with intensive physiotherapy. Troublesome scar tenderness and paraesthesia may occur if superficial branches of the radial nerve or the palmar cutaneous branch of the median nerve are divided or stretched during surgery. Trapeziectomy is occasionally complicated by subluxation of the scaphometacarpal pseudarthrosis which may cause an adduction deformity and basal thumb pain, but the incidence of this problem is unknown.

Further reading

Summary points

- Dupuytren’s disease is characterised by contracture of a finger resulting from thickening and shortening of the palmar fascia
- A genetic component to the aetiology is apparent, smoking, alcohol and diabetes can increase the risk
- The pathogenesis of Dupuytren’s disease remains elusive
- Non-surgical treatment options include splintage, steroid injection and collagenase injection
- Surgery cannot cure the disease but can straighten bent digits and minimize recurrence
- Operative methods can be considered with regards to incision, management of the diseased fascia and closure techniques
- Operative complications include injury of digital nerves and arteries

History

The first observation that contracture of a finger resulted from thickening and shortening of the palmar fascia was recorded in the notebook of Henry Cline Sr of St. Thomas’ Hospital, London in 1777. Guillaume Dupuytren was born in the same year and published a detailed description of the condition that bears his name in 1831. Both Cline and Dupuytren performed palmar fasciotomy. It is remarkable that all of the operations in routine use today, except dermofasciectomy, were described before 1850.

Prevalence

Geographic variation

Dupuytren’s disease shows a striking geographic variation in population prevalence, with high prevalence in Norway (30% of men over 60 years) and England (approximately 15% of men over 60 years), and much lower prevalence in the Mediterranean basin. It is very uncommon in Africa and rare in much of Asia.

Age and sex

The prevalence of Dupuytren’s disease is strongly related to age. The onset is earlier in men and the disease is more common in men at every age (Figure 6.7.1).

Aetiology (Box 6.7.1)

Genetic predisposition

A genetic influence in Dupuytren’s disease is supported by the geographic variation in prevalence and by clustering of cases in families. Many pedigrees show a pattern consistent with an autosomal dominant model of inheritance with variable penetrance but other cases appear to be sporadic. Investigation of the genetic influence is complicated by the high prevalence, late age of onset, incomplete penetrance, and the possibility that some cases have non-genetic causes. The search for a causative gene has not yet
Smoking and alcohol

Smoking and alcohol independently increase the risk of Dupuytren’s contracture.

Epilepsy

An association with epilepsy has been suggested by several studies, but a large case-control study has not confirmed it.

### Box 6.7.1 Causes

- Strong for genetics, diabetes, smoking
- Weaker for trauma and alcohol.

Diabetes

Dupuytren’s disease has an increased prevalence in both type I and type II diabetes. The disease is more evenly distributed across the palm and the predilection for the ring and little fingers that is seen in idiopathic cases is less marked.

Trauma

In rare cases, there seems to be a clear link between a single episode of trauma and the subsequent appearance of Dupuytren's disease at the same site. However, causal relationships with repeated trauma or types of manual work have not been established, and there is no association with exposure to vibration.

### Pathogenesis

The pathogenesis of Dupuytren’s disease remains elusive. Theories have centred on traumatic, neoplastic, and inflammatory processes. Histologically, the disease has many of the features of wound healing, including proliferation of fibroblasts, presence of myofibroblasts, and synthesis of collagen. The normal palmar and digital fascia is replaced by cords of collagen that are thicker and, in cases of contracture, shorter than the original bands. The collagen has a higher ratio of type III to type I collagen than normal fascia.

Myofibroblasts are a characteristic feature of Dupuytren’s disease. They share the morphological characteristics of both fibroblasts and smooth muscles cells but are probably derived from fibroblasts. Myofibroblasts contain arrays of cytoplasmic actin filaments (stress fibres) that attach to specialized adhesion sites at the cell membrane, through which force could be transmitted to the extracellular matrix. The mechanical environment may influence the differentiation of myofibroblasts. The role of transforming growth factor (TGF)β1 and other growth factors in this proliferative disorder remains unclear at present.

### Clinical features

Anatomy of palmar fascia

The concept that Dupuytren’s disease affects normal palmar and digital fascial structures and does not arise in a haphazard manner is fundamental to its safe and effective treatment and confirms the importance of thorough knowledge of the normal fascial anatomy.

The palmar and digital fascias form a three-dimensional array of ligaments that have transverse, longitudinal, and vertical components. The longitudinal fibres anchor the skin and resist shearing forces during gripping. They are connected to the skin and skeleton by vertical fibres and to each other by transverse fibres. The palmar fascial structures are called bands or ligaments in the normal state and cords when affected by Dupuytren's disease.

Each ray has a pretendinous band of fascia that runs longitudinally from the proximal palm to the base of the digit (Figure 6.7.2) and terminates in three ways: into the skin between distal palmar and proximal digital crease; into the spiral band; and deeply towards the metacarpal neck (the band of Legueu and Juvara) (Figure 6.7.3). The lateral digital sheet of fascia is continuous with transversely orientated layers termed Grayson’s and Cleland’s ligaments (respectively palmar and dorsal to the neurovascular bundle) (Figure 6.7.4).
The pretendinous cord may continue directly into the finger to run into the lateral digital sheet and/or Grayson’s ligament. Alternatively, it may connect only with the spiral cord and thence into Grayson’s ligament, to insert into the base of the middle phalanx or the overlying flexor tendon sheath. The spiral band passes deep to the neurovascular bundle; as it becomes contracted, the spiral cord pulls the bundle in a superficial direction so that it comes to lie immediately under the skin of the distal palm (Figure 6.7.5). The bundle is easily divided if the incision is carried directly down to the cord (Figure 6.7.6). A useful clue is that the skin is...
not adherent to the cord (since the cord lies deep to the bundle and its surrounding fat); a quantity of fat can be palpated between skin and spiral cord, whereas a pretendinous cord is more centrally placed in the ray and more likely to be adherent to the overlying skin.

Fig. 6.7.5

Fig. 6.7.6
Spiral cord displacing the radial digital nerve of the ring finger.

Dupuytren’s contracture is much more common in the ring and little fingers than in other digits (Figure 6.7.7).

Fig. 6.7.7
**Ectopic Dupuytren's disease**

Knuckle pads are nodules of fibromatosis in the subcutaneous tissues over the dorsal surface of the proximal interphalangeal joints (PIPJs), described by Garrod in 1893 (Figure 6.7.8). Plantar fibromatosis (Lederhose disease) presents as nodules in the plantar fascia that may cause discomfort or interfere with footwear (Figure 6.7.9). Penile fibromatosis (Peyronie’s disease) is associated with Dupuytren’s disease. Ectopic fibromatosis may be associated with severe or aggressive Dupuytren’s disease.

**Management**

### Non-operative treatment

**Splintage**

There is no good evidence that splintage prevents or retards the progression of contracture.

**Steroid injection**

Steroid injection of palmar nodules may reduce bulk and local tenderness. It has no reliable effect on contracture.

**Collagenase injection**

A randomized controlled trial of enzymatic fasciotomy by injection of collagenase has shown good correction of deformity but complications, recurrence rate and the cost–benefit relationship has not been defined.

### Indications for operative treatment

The primary aim of operative treatment is to straighten bent digits and the secondary aim is to minimize the risk of recurrence.
Surgery cannot cure the disease, which probably extends in a subclinical fashion throughout the hand. The choice of procedure remains as controversial as in Dupuytren’s day and good evidence to support one method of treatment over another is lacking.

### Box 6.7.2

| ♦ Pathogenesis: overactivity of myofibroblasts |
| ♦ Sites:                                      |
| • Commonly ring and little fingers           |
| • Ectopic sites suggest a stronger diathesis.|

**Metacarpophalangeal joint**

Metacarpophalangeal joint (MPJ) contracture is correctable almost regardless of its severity and secondary joint contracture is rare. The indication for surgery is a contracture that is interfering with function of the hand. Hueston’s table-top test is a good guide; if the hand cannot be placed flat on the table and the patient reports limitation of hand function, operation may be considered.

**Proximal interphalangeal joint**

Excision of contracted fascia often fails to restore full extension of the PIPJ because of secondary shortening of other structures that cross the palmar aspect of the joint, especially the check-rein ligaments of the palmar plate and the accessory collateral ligaments. Shortness of skin, involvement of the flexor tendon sheath, and shortening of the flexor muscles also limit extension in some cases.

The secondary contracture is variable and unpredictable, but generally the greater the severity and duration of contracture, the greater the risk of secondary joint contracture.

It might seem, therefore, that early operative treatment is appropriate. But the average residual PIPJ contracture after fasciectomy of the little finger is approximately 25 degrees and the patient is unlikely to feel that the operation was beneficial if the preoperative contracture was less than 30 degrees.

Serial measurements of the contracture with a goniometer at intervals of a few months can be most helpful. Progressive contracture is a good indication for surgery, as both patient and surgeon can see that deterioration is otherwise inevitable and a residual contracture after surgery will be more acceptable.

**Distal interphalangeal joint**

Involvement of the distal interphalangeal joint (DIPJ) is uncommon but often associated with a contracture of the PIPJ of the little finger by a band that spans both joints.

**Information to patients**

The risks of surgery should be explained and recorded. Risks specific to fasciectomy include delay in wound healing, incomplete PIPJ correction, temporary or permanent digital nerve impairment, limitation of flexion, recurrence and complex regional pain syndrome (CRPS) type 1.

**Anaesthesia**

Brachial plexus block by the axillary route gives excellent anaesthesia and postoperative analgesia. It is rare for patients to require any more than simple oral analgesia thereafter. Pain that requires strong analgesics usually signifies a complication such as tight bandage, haematoma, or infection, and requires inspection of the wound. General anaesthesia is sometimes needed for tourniquet discomfort or restlessness during a lengthy procedure. Intravenous regional anaesthesia gives a less satisfactory operative field and does not provide postoperative analgesia.

### Box 6.7.3 Consent

| ♦ Crucial as the indications are relative |
| ♦ Risks: especially incomplete correction, recurrence, nerve injury, CRPS. |

**Operative methods**

Understanding of the operative treatment of Dupuytren’s disease is simplified by considering separately the incision, the management of the diseased fascia, and the mode of closure.

**Incision**
A good incision should provide well-vascularized skin flaps, extensile exposure, and access for identification and preservation of the digital nerves and arteries. In the digit, a midline longitudinal incision gives excellent exposure and generally leaves the most heavily involved skin at the edge of the wound. Conversion to one or more Z-plasties breaks up the linear scar and provides some lengthening. Transfer of Z-plasty flaps is difficult in the stiff flat palmar skin; the author prefers a longitudinal incision in the digit that is extended in zigzag fashion in the palm, closing the digital component with a single large Z-plasty in the proximal segment (Figure 6.7.10).

![Figure 6.7.10](image)

Fig. 6.7.10

The Bruner zigzag incision also provides good exposure. However, raising large flaps over a midline longitudinal cord of Dupuytren's disease may damage the subdermal plexus at the base of the flap, leaving its tip ischaemic. The modified Bruner incision, with shorter flaps, is less prone to this problem (Figure 6.7.10).

Multiple ray disease in the palm is more easily exposed through a transverse distal palmar crease incision that can be extended as necessary into each digit and proximally in the palm. The palmar skin in each web is supplied by perforating vessels and will survive provided that these vessels are preserved.

**Management of diseased fascia**

The contracted fascia may be divided or removed; removal may be segmental, regional, or total.

**Fasciotomy**

Percutaneous fasciotomy can be employed for well-defined bowstringing cords that cause contracture at the MPJ but recurrence is common. Under local anaesthesia, a knife is slid between skin and cord and used to separate skin from cord. The knife is then turned through 90 degrees and used to cut the cord from superficial to deep as the cord is held taut by pulling the finger firmly into extension. The wound is dressed and an extension splint is worn at night for a few weeks. Fasciotomy is relatively safe if performed at or proximal to the distal palmar crease, as the digital nerves lie beneath the superficial transverse ligament at that level. In the distal palm and finger, fasciotomy carries a risk of nerve injury because of the variability of the position of the neurovascular bundle.

**Needle fasciotomy.**

French rheumatologists developed needle fasciotomy as an alternative to fasciectomy. As with percutaneous fasciotomy, the technique is more effective at the MPJ than at the PIPJ, and recurrences are more common than after fasciectomy. In 100 cases followed for 3.2 years the recurrence rate was 58%. Damage to digital nerves and flexor tendons appears to be less frequent than one might imagine.

**Segmental fasciectomy**

Though several short C-shaped incisions, 1-cm segments of contracted fascia are excised. There is no attempt to remove all affected fascia from a digit. Postoperative extension splintage is continued for several months. The concept is that breaking up the longitudinal transmission of force in the fascia encourages the remaining fascia to remodel. Recurrence rates are reported to be similar to those of regional fasciectomy.

**Regional fasciectomy**

Regional fasciectomy is the most widely performed procedure for Dupuytren's contracture and has a low rate of recurrent MPJ contracture. The digital neurovascular bundles are identified proximally and traced distally (or vice versa), removing diseased fascia that is causing contracture from one or more rays. Safety dictates that the nerves are identified at points where their location is
predictable—at the distal palmar crease, over the middle phalanx, and (usually) at the base of the finger. Some surgeons emphasize thorough clearance of diseased fascia from the fingers while others limit the excision to the cord causing contracture. It is not known if the former approach reduces the risk of recurrence. But the difficulty of any subsequent procedure is increased by extensive dissection. The more tissue is left undisturbed around the neurovascular bundle, the easier its dissection will be at the next operation.

Box 6.7.4 Treatment

- **Non-operative:** little role
- **Surgery:**
  - Indication—table top test
  - Fasciotomy—best for older patient, MPJ disease
  - Fasciectomy—the mainstay
  - Dermofasciectomy and full thickness skin graft—for recurrence or a bad primary disease with a marked diathesis
  - PIPJ release—controversial, largely not indicated.

**Closure**

The options for handling the wound after dealing with the fascia are:

**Direct closure**

Zigzag incisions are closed directly. A longitudinal midline incision is closed with one or more Z-plasties, which are cut after fasciectomy is completed as the orientation will depend on the location of thin skin. The author leaves the proximal limb of the palmar wound open, to minimize the risk of haematoma.

**Open palm technique**

In primary Dupuytren’s disease, no skin is missing. The transverse distal palmar can be left open and allowed to heal spontaneously. Skin that has undergone shortening over the contracted fascia will return to its original length as the open wound heals. The open palm technique is not appropriate when there is a true shortage of skin; in this case, a graft is required.

The open palm method is associated with a low incidence of complications. Haematoma cannot occur and the risk of skin flap necrosis due to tension is avoided. The chief disadvantages are the need to wear a dressing for up to 4 weeks and a slight risk of infection of the open wound. The open method is less applicable in the fingers, where the wound interferes with rehabilitation.

**Dermofasciectomy and skin grafting**

Hueston’s concept that recurrence of Dupuytren’s disease is reduced substantially if the overlying skin is excised and replaced with a full-thickness skin graft is supported by many studies. An absolute indication for grafting is lack of viable skin flaps at the completion of fasciectomy. Relative indications include skin shortage, recurrent disease, aggressive primary disease, and primary disease in a young patient. The proximal digital segment is the area most often needing replacement (Figure 6.7.11). As grafting requires an intact flexor tendon sheath, a longitudinal or zigzag incision is used for exposure and the skin is excised only if the tendon sheath has remained intact after completion of the fasciectomy. The graft should extend to the midaxial line on each side, to avoid the risk of contracture of the scar along its edges. The graft may be obtained from the medial surface of the arm, from the antecubital fossa or from the groin crease. Graft take is very reliable if attention is given to precise operative technique and haemostasis.
Dermofasciectomy and full-thickness skin graft for recurrent disease at the base of the ring finger. The little finger had been amputated previously for recurrence after several fasciectomies.

Proximal interphalangeal joint release

Release of the secondary capsular contracture of the PIPJ is controversial and data on its effect are limited. Although release of the check-rein ligaments and accessory collateral ligaments can improve a contracture persisting after fasciectomy, the decision to proceed to joint release should balance the likely gain against the significant risk of losing flexion, which is more disabling than loss of extension. Tenotomy of the terminal tendon of the dorsal aponeurosis over the middle phalanx can improve flexion of the distal joint when Dupuytren’s disease results in a boutonnière deformity.

Dupuytren’s disease of the thumb web

The thumb web is affected in at least 25% of cases undergoing surgery on the ulnar side of the hand but in most older patients the contracture is minimal and does not require operative treatment. However, thumb web contracture may be severe and disabling, especially in individuals showing risk factors for aggressive disease (young age at onset, family history, and ectopic disease). A cord affecting the thenar fascia along the radial border of the thumb may cause contracture at the interphalangeal joint. Contracture of the thumb web may be due to fibres passing from the radial end of superficial transverse ligament of the palm to the thenar fascia, or to involvement of the fascia running in the crest of the web between the thenar fascia and the base of the index finger (Figure 6.7.12). Moderate contractures can be treated by regional fasciectomy but in severe cases restoration of the width of the thumb web requires dermofasciectomy and skin grafting.

Postoperative management

Dressings

Non-adherent dressings of paraffin gauze, dry gauze, and wool are held with a non-elastic bandage. Many surgeons feel that a palmar plaster slab from forearm to fingertips helps to control wrist position for the duration of the regional anaesthetic block, relieve pain, and prevent reactionary bleeding, which can occur if the hand is moved excessively in the first day or two. The fingers sit in midflexion; no attempt is made to hold them in extension, so as to avoid tension on skin flaps. Some surgeons inspect the wound the next day. The author leaves the dressings in place for 2–4 days unless a skin graft has been used, in which case the hand is immobilized for 7 days.

Hand therapy

Supervision by a hand therapist and diligent exercise by the patient are crucial to achieving consistent results after fasciectomy. The first priority is restoration of flexion by active exercise, with the objective of flexion of the fingertip to the palm within 2 weeks of surgery. A palmar thermoplastic extension splint is worn at night until the scar is mature. Silicone inserts attached to the inner surface of the splint may assist scar remodelling.

Recurrent disease

Incidence

A new contracture after operative management can be due to extension (appearance of disease in previously unoperated areas), recurrence (new disease in the previous operation field), scar contracture, or some combination of these. Recurrence is common and exceeds 50% at 10 years, though not all recurrences require further surgery. The usual presentation of recurrence is a
contracture of the PIPJ, most frequently in the little finger.

Assessment

Assessment of recurrent disease should include evaluation of the digital nerves (by two-point discrimination), digital arteries (by digital Allen’s test), severity of contracture, and quality of skin (Box 6.7.5). Digits that lack a patent digital artery are surviving on collateral vessels and are at risk of ischaemia during extensive procedures; they are poor candidates for surgery. Digital nerves may be densely adherent to scarring from previous operations and their preservation may be difficult.

**Box 6.7.5 Recurrence**

- Common
- Common finger more than pain
- Especially little finger, strong diathesis
- Treatment:
  - Usually dermofasciectomy
  - Increased complications.

Management

Surgery for recurrent Dupuytren’s disease is more difficult and more risky than primary operations. The indication for operation is a recurrent contracture that is interfering with function of the hand, but the decision is influenced by the condition of the finger. The state of the digital nerves, digital arteries, and skin will give an estimate of the risks of surgery and these can be balanced against the severity of contracture and degree of functional impairment. An additional factor is the pattern of recurrent disease. A welldefined cord lying beneath good skin is favourable. Diffuse thickening with adherence to skin is not.

Recurrence of the palmar branch is amenable to fasciectomy and is seldom problematic. The difficulties lie in the finger, where the mixture of scar tissue and recurrent disease may greatly hamper the safe dissection of nerves and arteries. It is also important to preserve the tendon sheath, as most cases of recurrence will require skin grafting. If the tendon sheath is deficient, closure with the original skin flaps or by a local flap will be needed.

Dermofasciectomy and full-thickness skin grafting is the procedure used most frequently for recurrent disease (see Figure 6.7.1). The rarity of recurrence beneath a skin graft, demonstrated by Hueston, probably reflects the importance of residual disease in skin flaps as a source of recurrence; when this skin is excised, recurrence is rare. Recurrence can occur, however, at the graft margins.

Skin grafting also corrects the skin shortage that is often evident at the base of the finger in recurrent disease and it allows removal of skin flaps of uncertain viability.

**Salvage procedures (Box 6.7.6)**

Flap cover

Local skin flaps have limited application in Dupuytren’s disease and are used mainly in surgery for recurrent disease when the flexor tendons are exposed.

Proximal interphalangeal joint arthrodesis

Arthrodesis of the PIPJ in 30–40 degrees of flexion can overcome severe recurrent contractures that are not amenable to fasciectomy. Some skeletal shortening is necessary to overcome the flexion deformity. Arthrodesis is most applicable in the little finger, especially when some hyperextension at the MPJ compensates for the fixed PIPJ.

**Box 6.7.6 Salvage procedures**

- Flap cover
- PIPJ arthrodesis
- PIPJ arthroplasty
- Amputation.

Proximal interphalangeal joint arthroplasty

Silicone rubber implant arthroplasty of the PIPJ has been used in combination with fasciectomy and dermofasciectomy. A good arc of motion cannot be expected and the possibility of recurrent deformity remains.

Amputation
Liberal use of skin grafts in recurrent disease has reduced the need for amputation. Patients who request amputation of the little finger should be warned of the adverse effect on power grip, reminded that a flexion contracture of 60 degrees at the PIPJ is compatible with good function if the MPJ will extend fully and advised about the risk of a painful neuroma. But amputation may be appropriate for a digit that is interfering with function because of persistent contracture after multiple operations. Its dorsal skin may be useful in resurfacing the adjacent digit or palm.

## Complications

### Operative complications

#### Digital nerve injury

Dissection of the digital neurovascular bundle is the essence of fasciectomy—once the bundle has been protected, excision of the diseased fascia is straightforward. Manipulation of the nerve may impair its function temporarily. Division of a digital nerve should be a very rare event during a primary fasciectomy if appropriate care and magnification are employed. The nerves are at much greater risk at second or subsequent operations because they may be heavily embedded in scar or recurrent disease. A divided digital nerve should probably be repaired, though most patients are at an age where useful recovery is unlikely.

#### Digital artery injury

The plentiful cross-connections between the two digital arteries will ensure survival of the finger if one artery is damaged. However, every effort should be made to preserve both arteries because of the likelihood that further operations will be needed. Loss of one artery will restrict the surgeon's room for manoeuvre at any subsequent procedure and will increase the risk of digital ischaemia. Injury of a single digital artery is not an indication for repair. Repair may be required if the other artery is also damaged. Spasm of the arteries may be caused by extensive dissection or by forcible stretching of the finger into extension. Positioning in flexion, patience, and application of warm saline will usually restore perfusion.

### Postoperative complications

#### Skin necrosis

Small areas of skin loss (<5mm) create a risk of sepsis but will heal spontaneously. Larger areas may need excision and skin grafting. Spontaneous healing of larger areas is slow and likely to result in scar contracture, especially at the base of the finger.

#### Haematoma

Haematoma is a potentially disastrous complication that may lead to permanent loss of flexion, skin necrosis, or infection. The risk can be minimized by careful attention to haemostasis and by appropriate drainage, either by leaving a portion of the palmar wound open or by inserting a drain.

#### Infection

Maceration of skin in the folds and pits of a severely contracted digit increases the risks of infection. Prophylactic antibiotic therapy should probably be given if any pit or crease is macerated, but antibiotics are not needed routinely. A preliminary palmar fasciotomy under local anaesthesia may allow the skin to be brought into good condition for fasciectomy a short time later. Infection may develop in wounds that have been left open, in which case the response to appropriate antibiotic therapy is usually good.

#### Flare

The combination of diffuse swelling, stiffness and shiny redness of the hand has been termed 'flare'. Its cause is unknown but it may represent a minor variant of CRPS type 1. Treatment comprises elevation, control of pain and swelling, active exercise, and extension splintage at night. Early recognition and treatment are essential in preventing permanent loss of finger flexion.

### Complex regional pain syndrome type 1

This serious complication is rare but can have devastating consequences for function of the hand. The cardinal features are excessive pain, swelling, stiffness and vasomotor instability. Early recognition and treatment are essential (see Chapter 1.11).

## Conclusion

Dupuytren’s disease affects at least 10% of older men of Northern European origin. Its cause and predilection for the ulnar side of the hand are unexplained. Operative treatment aims to straighten bent digits, not to cure the disease. Deeper understanding of the nature of the disease will be required to devise means of modifying its behaviour and, in particular, reducing the likelihood of recurrence after surgery.

Summary points

- The term tenosynovitis should be restricted to inflammatory disorders; De Quervain’s syndrome and trigger finger do not show inflammatory changes histologically and are more appropriately termed tenovaginosis.
- The cause of most tenovaginoses is unclear; they are occasionally secondary to trauma and rarely linked to overuse.
- Rupture of individual tendons may not require surgical reconstruction but it is important to establish the underlying cause of rupture to prevent sequential rupture of adjacent tendons.

Congenital anomalies

Congenital anomalies of the tendons and tendon sheaths of the hand and wrist are common but rarely cause symptoms of pain or functional impairment. Asymptomatic anomalies are important as they may cause confusion in the interpretation of the physical examination.

Palmaris longus

Palmaris longus is absent in about 15% of hands and anomalous in 9%. It is implicated in the pathogenesis of carpal tunnel syndrome as it is absent in only 3% of patients with this condition. Its clinical significance is its use as a tendon transfer or free tendon graft.

Flexor pollicis longus

The Linburg–Comstock anomaly consists of a tendinous slip or tenosynovial adhesion connecting the flexor pollicis longus tendon to the flexor digitorum profundus tendon of the index finger. It is found in 25% of cadavers and can cause pain by restricting independent movement of the index and thumb. The pathognomonic sign is obligatory flexion of the index finger when the thumb is flexed actively. There is pain in the wrist if flexion of the index is blocked as the thumb is flexed. The anomaly is usually only problematic in musicians. Surgical division of the connection is usually curative.

Flexor digitorum superficialis

The flexor digitorum superficialis tendons of the index, middle, and ring fingers generally have individual muscle bellies and can act independently. Only 60% of little fingers have an independent flexor digitorum superficialis tendon. About 20% have no discernable function of the tendon though it may be present. This can lead to uncertainty when interpreting physical signs after lacerations of the little finger. In the remaining 20% the little finger superficialis tendon is linked to that of the ring finger. This can be demonstrated by the standard and modified flexor digitorum superficialis tests: the little finger cannot be flexed actively at the proximal interphalangeal joint whilst the other digits are held extended. When the ring finger is released, the ring and little finger proximal interphalangeal joints can be flexed together, but independently of the other digits.

Abductor pollicis longus

Abductor pollicis longus is subject to considerable variation in the number of tendon slips and their insertion. Slips may attach to the abductor or extensor pollicis brevis tendons, the trapezius, joint capsule, or thumb metacarpal.

Extensor pollicis brevis

The extensor pollicis brevis tendon is also rather variable. Its anomalies include absence, connection with abductor pollicis longus, and insertion into the distal phalanx or extensor hood in place of (or in addition to) the proximal phalanx. In 30–60% of wrists, the extensor pollicis brevis tendon runs in a subcompartment of the first extensor compartment. Symptoms of de Quervain’s syndrome may persist if a subcompartment is overlooked at the time of release.

Extensor digitorum communis

Anatomical variations in the contribution of the extensor digitorum communis tendon to the little finger account for the variable deficit that results from rupture or laceration of the extensor digit minimi. Rupture of extensor digitorum minimi, which may herald rupture of extensor digitorum communis in rheumatoid arthritis, may pass unnoticed unless independent extension of the little finger is tested.

Terminology of tendon disorders

The terminology of tendon disorders is unsatisfactory. The terms tendinitis and tenosynovitis mean inflammation of the tendon and tenosynovium respectively. These conditions have recognizable and reproducible physical signs (swelling, tenderness, and crepitus along the line of the tendon), as well as characteristic pathological changes on histology (e.g. rheumatoid arthritis). In the absence
of these features, and especially in the context of pain in the workplace, it is inappropriate to assign these diagnoses. The term tendinosis, which makes no aetiological or pathological assumptions, is preferable, but its use is not widespread. In many cases, a recognized tendon disorder can be diagnosed (e.g. de Quervain’s syndrome). If the clinical picture does not conform to a recognized disorder, but is clearly attributable to the action of a tendon, then a neutral term such as flexor carpi ulnaris tendon pain is appropriate. Terms such as forearm pain or non-specific arm pain can be used when the symptoms and signs are poorly localized.

### Tenosynovitis

**Pathology**

Tenosynovitis is inflammation of the tenosynovium. Tenosynovitis is ultimately a pathological diagnosis, but a clinical diagnosis may be made in the presence of the characteristic features of tenderness, swelling, and crepitus along the line of the tendon sheath, along with restricted tendon excursion. Not all the signs are necessarily present simultaneously, but it would be difficult to justify the diagnosis of tenosynovitis in the absence of localized tenderness.

Tenosynovitis may be acute or chronic. Pyogenic tenosynovitis (see Chapter 6.14) is the commonest cause of acute tenosynovitis but rarely acute gout, calcium pyrophosphate deposition, and repetitive trauma may be responsible. Rheumatoid disease (see Chapter 6.5), mycobacterial infection, fungal infection, foreign body, sarcoidosis, gout, and amyloid may cause subacute or chronic tenosynovitis. Chronic flexor tenosynovitis can lead to median nerve compression.

**Mycobacterial infection**

Infection with atypical mycobacteria such as *Mycobacterium kansasii* and *Mycobacterium marinum* is now more common than tuberculous tenosynovitis (see Chapter 6.14). Mycobacterial infection should be considered whenever chronic tenosynovitis is not clearly associated with inflammatory arthritis and appropriate specimens sent for histology and mycobacterial culture.

The management is tenosynovectomy, which is both diagnostic and therapeutic, followed by appropriate antismycobacterial chemotherapy.

**Retained foreign body**

Foreign material within the tendon sheath may incite an inflammatory response in the absence of infection. The thorns of the blackthorn tree (*Prunus spinosa*) and *Pyrocantha* species are particularly liable to cause a subacute aseptic inflammation of joint or tendon sheath. The flexor tendon sheath of the finger is the most common site. Small foreign bodies may be identified by ultrasound examination. Tenosynovitis generally resolves once the foreign material is removed.

### Painful disorders of tendons and tendon sheath (Box 6.8.1)

**Pathology**

There are several conditions, including de Quervain’s syndrome and trigger finger, which have previously been attributed to inflammation of the tendon, sheath, or synovial lining, and which have been called ‘tenosynovitis’. The clinical features of tenosynovitis may indeed be seen when the tendon sheath is affected by an inflammatory disorder such as rheumatoid arthritis. However, histological studies of the common idiopathic forms of these disorders seldom show inflammation of the tendon, tendon sheath, or tenosynovium.

The pathological changes of de Quervain’s syndrome and trigger finger, which are the only conditions to have been studied in detail, are similar. The changes comprise an increase in extracellular matrix, thickening of the collagen fibrils, and areas of fibrocartilage metaplasia in the tendon sheath. Fibrillation or delamination of the tendon surface may be seen. Evidence of inflammation is notably absent. In the absence of clinical or pathological evidence of inflammation, it is illogical to refer to ‘tendinitis’ or ‘tenosynovitis’.

**Aetiology**

The cause of these common disorders is unclear. The symptoms may be initiated by a single injury such as a direct blow or sudden strain. While damage by overuse is an intuitively plausible theory, the evidence that these disorders are initiated by excessive activity is scant, except in the case of intersection syndrome (peritendinitis crepitans) affecting the second extensor compartment. However, the symptoms that these conditions produce are often aggravated by activity.

**Management**

Rest, avoidance of aggravating activities, splintage, and analgesic medication constitute the first line of management. Injection of the tendon sheath with corticosteroid, which can be dramatically effective, is the second line of treatment. Complications of steroid injection are uncommon. Injection is very rare but potentially disastrous. Tendon rupture is also very rare and is probably due to underlying pathology in the tendon or its surroundings (e.g. rheumatoid arthritis) rather than to the injection itself. Atrophy of dermis or subcutaneous fat results from inadvertent injection into the subcutaneous tissues, which should be avoided. Surgical decompression of the affected tendon may be needed in cases that fail to respond to non-operative treatment.
**Box 6.8.1 Tenovaginosis and other tendon condition**

### Causes
- Mostly wear and tear of life. Congenital causes are rare. Work related causes are infrequent and contentious
- The pathology is often not primarily in the tendon:
  - De Quervain’s and trigger finger—the sheath
  - Tendon ruptures—underlying pathology of bone or synovitis.

### Presentation
- Pain
- Triggering
- Failure.

**De Quervain’s syndrome**

The first dorsal compartment of the wrist, containing the tendons of abductor pollicis longus and extensor pollicis brevis, is the site of this painful disorder (Figure 6.8.1). The cause is unknown. It occurs spontaneously, more often in females than males, and may arise during or just after pregnancy. The chief symptom is pain during use of the thumb. Loss of ulnar deviation of the wrist and triggering of the abductor pollicis longus tendon are seen occasionally in severe cases. The physical signs are pain on resisted active extension of the thumb, swelling and tenderness over the compartment, and a positive Finkelstein’s test. The test described by Finkelstein is reproduction of pain by ‘grasping the patient’s thumb and quickly abducting the hand ulnarward’. Another test, originally described by Eichhoff but often attributed erroneously to Finkelstein, deviates the wrist ulnarward while the thumb is held in the palm beneath the flexed fingers. The differential diagnosis includes the intersection syndrome and arthritis of the trapeziometacarpal, scaphotrapezial, or radioscaphoid joints.

![Fig. 6.8.1](image)

The six extensor compartments at the wrist, shown (A) diagrammatically and (B) on axial MRI. (Courtesy of Dr E. McNally, Department of Radiology, Nuffield Orthopaedic Centre, Oxford.)

Management comprises rest, analgesics, thumb splintage, and steroid injection. Injections are effective in the long term in at least 80% of cases but injection into the extensor pollicis brevis tenosynovium resulted in 100% success in one series. Care should be taken to avoid subcutaneous extravasation of long-acting steroid, which can produce an unsightly patch of atrophic skin and subcutaneous tissue.

Operative release is indicated if pain persists or recurs after injection. It requires a longitudinal division of the roof of the first dorsal compartment and of any subcompartments (30-60% of first dorsal compartments have a septum that separates the abductor pollicis longus tendon from the extensor pollicis brevis). A transverse skin incision gives good exposure and a better scar than a longitudinal incision. It is crucial to protect the superficial radial nerve; a neuroma can be very troublesome. Release of the retinaculum toward the dorsal edge of the compartment leaves a palmar ridge of retinacular tissue that may help to prevent the uncommon complication of palmar subluxation of the abductor pollicis longus tendon on wrist flexion.

**Intersection syndrome (peritendinitis crepitans)**

This condition is probably the only tendon disorder for which a consistent association with overuse has been demonstrated.
Repetitive gripping activities, such as weightlifting and rowing, are often implicated. It is characterized by pain, tenderness, swelling, and, in severe cases, crepitus where the abductor pollicis longus and extensor pollicis brevis muscle bellies run obliquely across the second dorsal compartment. This point lies about 5 cm proximal to the radial styloid and is well above the site affected in de Quervain's syndrome. The pathology was previously thought to be due to friction between the first and second compartments causing tendinitis. However, Grundberg and Reagan (1985) found tenosynovitis in the second extensor compartment in each of 13 cases; in every case the symptoms were relieved by decompressing only the second compartment.

Conservative treatment of rest, splintage, and steroid injection is usually effective. Operative release of the second extensor compartment is rarely required.

**Flexor carpi radialis**

The flexor carpi radialis tendon passes over the wrist joint in a fibro-osseous tunnel lined with synovium, running past the ulnar side of the tubercle of the scaphoid and along a groove in the medial face of the trapezium before inserting onto the base of the second metacarpal.

Pain related to the flexor carpi radialis tendon may arise spontaneously, typically in females of late middle age (in whom it may be associated with scaphotrapezial osteoarthritis), but may occasionally be associated with activities requiring strenuous flexion of the wrist.

The patient complains of pain localized to the tendon at the wrist. There is tenderness and swelling of the tendon sheath. Pain is aggravated by resisted flexion of the wrist. The differential diagnosis includes de Quervain's syndrome, palmar wrist ganglion, and scaphotrapezial osteoarthritis. Treatment is by rest, splintage, analgesics, and steroid injection of the sheath. Operative release of the sheath is occasionally required.

**Other tendons**

Pain syndromes may be associated with several other tendons, including extensor pollicis longus, extensor indicis proprius, flexor carpi ulnaris, and extensor carpi ulnaris. The diagnosis is made from the findings of pain, swelling, local tenderness, and pain on active resisted tendon action. The management follows the lines described previously.

**Trigger digits**

**Trigger digits in adults**

Trigger digit in adults is caused by a nodular thickening of the flexor tendon that is accompanied by stenosis of the first annular (A1) pulley of the tendon sheath at the level of the metacarpophalangeal joint. It occurs most often in middle-aged females. The ring finger, middle finger, and thumb are the most frequently affected digits.

Trigger digit presents with clicking or locking of the finger during flexion and extension. The digit may lock in flexion, typically with the finger flexed into the palm (Figure 6.8.2). Locking is often most troublesome on waking, requiring forcible extension using the opposite hand. Although locking appears to affect the interphalangeal joints of the fingers or the interphalangeal joint of the thumb, pain and tenderness are felt over the tendon sheath at the level of the metacarpophalangeal joint. The thumb occasionally locks in extension. Persistent locking of the finger may lead to a fixed flexion contracture at the proximal interphalangeal joint, especially in diabetic patients. Triggering at the A3 pulley is a rare variant described in bowlers that affects the flexor digitorum profundus and therefore the distal interphalangeal joint only.

Most cases arise spontaneously in otherwise normal individuals. There is no relationship to occupation but repetitive gripping activities may cause acute transient triggering. Triggering may be due to intratendinous nodules or tenosynovitis in rheumatoid disease, or to a tendon flap caused by a partial tendon division. Trigger digit is common in diabetes and in association with amyloidosis and mucopolysaccharidoses. Several digits may be affected in these groups of patients.

Triggering may resolve spontaneously. Mild triggering may need no treatment apart from reassurance. Splintage of the interphalangeal joints in extension at night improves locking on waking and may suffice in mild cases. Taping of the proximal
interphalangeal joint by day may prevent flexion to the point of locking. Steroid injection of the tendon sheath cures about 70% of cases but is less effective in diabetic patients.

In the non-rheumatoid patient, surgical release of the A1 pulley is indicated for persistent or severe triggering with almost 100% success for open release. Percutaneous release with a needle shortens recovery while being equally effective and safe. In longstanding cases with persistent proximal interphalangeal joint contracture and tendon thickening, division of the proximal part of the A2 pulley or resection of the ulnar slip of flexor digitorum superficialis may be required.

Release of the A1 pulley is contraindicated in rheumatoid as it may exacerbate a tendency to ulnar drift. Synovectomy and resection of the ulnar slip of flexor digitorum superficialis is preferred.

Trigger thumb in children

Trigger thumb is the most common hand condition requiring operative treatment in children. A young child, usually between the ages of 6 months and 3 years, presents with a painless fixed flexion contracture of the interphalangeal joint of the thumb. On rare occasions, there is a history of triggering. Thickening of the flexor tendon and its sheath is palpable at the level of the metacarpophalangeal joint. It is often termed ‘congenital’ although this seems inappropriate, as no cases were found during examination of 4719 newborn infants and children rarely present before the age of 6 months. The cause is unknown. The differential diagnosis is congenital clasped thumb, which is caused by absence or hypoplasia of the thumb extensors. Trigger thumb may resolve spontaneously; almost half of 53 patients recovered after observation for a mean of 7 months. Spontaneous improvement after age 3 is uncommon. If the thumb is reducible, splinting is more effective than observation alone in improving triggering. For persistent triggering, operative treatment involves division of the proximal pulley with care to avoid the digital nerves, which are close to the midline and lie immediately beneath the skin.

Trigger finger in children

Trigger finger is rare in children, accounting for about 14% of trigger digits. Unlike the thumb, locked trigger finger is uncommon. The middle finger is most commonly affected, followed by the ring and little fingers. Spontaneous recovery is common and splinting for trigger finger in children has had mixed success. Unlike adult trigger finger, release of the A1 pulley alone results in 44% recurrence. In some cases, there is nodular thickening of the tendon and A1 pulley release alone suffices, while in others, there appears to be an abnormal relationship between the deep and superficial flexor tendons. In these patients, partial division of the A2 pulley or resection of one of the slips of flexor digitorum superficialis is effective.

Trigger wrist

Rarely, thickening of the tendon or synovium or may impede gliding at the wrist. This may cause triggering of the wrist (true trigger wrist) or fingers as well as median nerve compression. The cause is usually flexor tendon tenosynovitis for which tenosynovectomy and carpal tunnel release is usually curative. It is occasionally due to a discrete mass or extensor tendon pathology.

Tendon rupture (Box 6.8.2)

Tendon rupture is an important condition in the hand, not only because it impairs function but also because in some cases it can be prevented by timely intervention. The pathology of tendon rupture involves mechanical factors that increase tendon stress and pathological processes that weaken the tendon. Mechanical factors include abrasion on sharp surfaces (fractures, implants), change in direction, tendon anomalies (abnormal interconnections), and acute or chronic overloading. The tendon may be weakened by inflammation (rheumatoid disease, systemic lupus erythematosus, crystal deposition, osteoarthritis), ischaemia, or metabolic causes (chronic renal failure, systemic or local steroids).

Rupture of the extensor pollicis longus or flexor carpi radialis tendons is almost always an isolated lesion with a very low likelihood of other ruptures. Rupture of the finger extensors and of the tendons passing through the carpal tunnel is often sequential, so that detection of the first rupture and prompt intervention are crucial in preventing further loss of function.

Osteoarthritis

The classical lesion of attrition rupture of extensor tendons was described by Vaughan-Jackson in two cases of osteoarthritis of the distal radioulnar joint (Figure 6.8.3A). The roughened ulnar head erodes through the dorsal capsule and then lies in contact with tendons in the fifth and fourth compartments. Rupture is generally painless and sequential, beginning with the extensor digiti minimi tendon. Since extension of the little finger can, in many cases, be activated by a tendon slip from the extensor digitorum communis of the ring finger, rupture of extensor digitorum minimi may pass unnoticed until the ring and little finger drop together. Loss of independent extension of the little finger (Figure 6.8.3B) signifies rupture of extensor digitorum minimi and the need for appropriate surgery of the distal radioulnar joint.
Click to view larger

**Fig. 6.8.3**

A) Osteoarthritis of the distal radioulnar joint. B) Loss of independent extension of the little finger, owing to rupture of extensor digiti minimi.

Osteoarthritis of the radiocarpal, scaphotrapezial, and distal radioulnar joints can lead to tendon ruptures within the carpal tunnel. Osteoarthritis of the scaphotrapezial joint may cause rupture of the flexor carpi radialis tendon (Figure 6.8.4), the proximal stump of which may form a painful fusiform swelling in the distal forearm.

**Box 6.8.2 Treatment of tendon rupture**

- Rest and waiting (many resolve spontaneously)
- Splintage for some conditions
- Steroid injections
- Release of tendons sheaths open or percutaneously
- Open reconstruction of tendon failure and removal of the cause, e.g. Darrach’s procedure.

**Distal radial fracture**

The most common tendon rupture is of extensor pollicis longus, occurring a few weeks after fracture of the distal radius. The incidence is approximately 1% of all distal radial fractures. The rupture occurs typically in undisplaced fractures. The pathogenesis is uncertain but ischaemia probably plays a role. The tendon may be vulnerable to narrowing or irregularity of its sheath as it passes around the dorsal tubercle of the radius. At this point, it is subject to bending forces, has a poorly vascularized segment and lacks mesotenon. Nutrition at this point is from diffusion from the synovial fluid which may be hindered by haematoma contained in the intact sheath. The intact retinaculum also holds the tendon down against the sharp fracture edge.
Pain and crepitus over the third compartment with thumb movement is an indication for release of the retinaculum. Generally, however, the rupture occurs without warning.

There may be an extension lag at the interphalangeal joint (Figure 6.8.5), but a more reliable sign is loss of retroposition wherein the patient cannot lift the thumb off the table when the hand is placed flat—a movement that only extensor pollicis longus can achieve. Reconstruction by tendon transfer (using extensor indicis proprius or a slip of abductor pollicis longus) is straightforward and effective.

![Click to view larger](image)

**Fig. 6.8.5**  
Rupture of the extensor pollicis longus tendon after fracture of the distal radius. The palpable distal tendon stump is marked.

With the increasing use of plate fixation of the distal radius, iatrogenic tendon rupture is encountered. The distal edge of a dorsal plate can abrade the long finger extensors; excessive length of screws securing a volar plate may do the same. Dorsally angulated malunion of the distal radius may also cause rupture of flexor tendons in the distal forearm. Volar locking plates can cause flexor or extensor tendon ruptures.

**Other causes of tendon rupture**

Less common causes of tendon rupture include long-standing Kienböck’s disease, scaphoid non-union, and scapholunate dissociation. The flexor digitorum profundus tendon of the little finger is particularly prone to rupture; this can be due to non-union of the hook of the hamate, calcium pyrophosphate deposition in the triangular fibrocartilage, pisiform–triquetral instability, and osteoarthritis.

When no definite cause can be found, the rupture is termed spontaneous. In flexor tendons these are rarer than avulsion from the distal phalanx. Typically they occur in zone III of the flexor digitorum profundus to the little finger. Although the aetiology is unclear, the likely predisposing factors include tendon anomalies, repetitive microtrauma, vascular alterations, and genetic influences.

**Summary points**

- Late reconstructive procedures may improve function if there is persisting paralysis after nerve injury
- Transfer of a functioning musculotendinous unit to the tendon of the paralysed muscle is the most common type of procedure
- Passive mobility must be maintained in affected joints before tendon transfer can be performed
- The transferred muscle should be expendable, have normal power, and have properties appropriate to the function it is required to restore
- Tendon transfers can provide reliable improvement in function after isolated radial nerve palsy
- A number of procedures have been described for reconstruction of thumb opposition but impaired sensation after median nerve injury may limit gain in function
- Tendon transfers are possible to improve clawing of fingers and lateral pinch of the thumb after ulnar nerve palsy or other cases of intrinsic paralysis.

**Introduction**

Loss of function in a peripheral nerve is commonly caused by trauma but can also be caused by tumours, neuropathy, or infections such as polio or leprosy. Injury to a mixed peripheral nerve results in paralysis of the muscles that it innervates and loss of sensation in its cutaneous territory. Recovery may occur spontaneously in the case of neurapraxia or axonotmesis and may be possible after surgical repair of the nere in cases of neurotmesis. Nerve regeneration is slow even under optimum conditions. Denervated muscles deteriorate rapidly and effective reinnervation is possible only if regenerating axons reach them within 1–2 years. Early repair of divided nerves is especially important where the injury is some distance from the muscles to be reinnervated, such as in the brachial plexus.

The results of a successful early nerve repair are often superior to those of late reconstructive procedures: nerve repair can increase muscle power in a paralysed limb; tendon transfer can only redistribute what remains. Partial nerve recovery may still be supplemented by other measures. However, tendon transfer potentially provides an earlier improvement in function than nerve repair and this option may better suit the patient’s overall rehabilitation.

Reconstructive procedures must be considered when nerve repair has been unsuccessful, or was not performed. They may also be necessary where nerve or muscle function has been irretrievably damaged by other pathologies such as compression, tumour, and ischaemia.

The most commonly used reconstructive operation is transfer of a healthy tendon or muscle to replace the function of a paralysed muscle, but other options are occasionally indicated, including tenodesis, arthrodesis, and free muscle transfer. Reconstruction is usually delayed until the final result of nerve recovery is evident, but may be indicated much earlier if it is known that recovery is unlikely or, occasionally, to prevent secondary joint contractures. Reconstructive procedures to improve sensation are occasionally indicated.

**Principles of tendon transfer**

1) A full range of passive movement should ideally be available in all joints on which the transfer will act. Regular physiotherapy should be given from the outset in cases of nerve injury, as it is much easier to maintain movement than to restore it. In complex injuries, early skeletal fixation with repair of tendon injuries and provision of stable skin cover gives the best chance of providing appropriate conditions for subsequent tendon transfer
2) The transferred muscle should be expendable. Its use must not remove an important function. In cases of blunt trauma to a limb, it is common for more than one nerve territory to be affected. Therefore the full extent of nerve and muscle injury should be carefully evaluated to check which muscles are functioning
3) Normal power of the transferred muscle is desirable, as at least one grade on the Medical Research Council scale is generally lost by transfer. It is not always possible to satisfy this requirement, particularly after injuries to the brachial plexus; each case should be considered individually. It is rarely appropriate to transfer a muscle that has previously recovered after repair of its nerve
4) The amplitude and power of the transferred muscle should be appropriate to the function that is being restored (see later)
5) Synergistic muscles should be used for transfer where possible. For example, a wrist flexor which is synergistic in finger extension may be transferred to restore this movement. Experience has shown that synergistic muscles are more easily retrained to perform their new function
6) Some transferred muscles, such as brachioradialis, retain their original function, and their effectiveness therefore depends on the activity of the antagonist to that original function. If brachioradialis is transferred to flexor pollicis longus, for example, triceps must be strong enough to resist its normal elbow flexor action and allow its power to be transmitted distally to the thumb
7) The transferred tendon should have a straight line of action. Acute angulation should be avoided
8) The transfer is attached to the tendon of the paralysed muscle if this is available, thus achieving the most effective biomechanics at the insertion. In cases where some nerve recovery may occur later, the attachment is performed end-to-side.

Properties of muscles and tendons

There are three important mechanical properties of muscles:

1) The mass or volume of muscle fibres, which is proportional to work capacity
2) The average length of the constituent muscle fibres, which is proportional to excursion (the distance through which a muscle can contract). The excursion of a muscle is about one-third of the resting length of its fibres
3) The physiological cross-sectional area of a muscle, which is proportional to the maximum force of contraction.

The relationship between these properties depends on the architecture or arrangement of fibres within a muscle. The properties of forearm and hand muscles have been studied in cadavers and some of the results are shown in Table 6.9.1. The actual mass or volume of a given muscle varies considerably between individuals but the relative mass compared with other muscles in the same arm is quite consistent. Therefore mass is presented as the ‘mass fraction’, which is the percentage of the total weight of all the muscle in the forearm and hand. Physiological cross-sectional area was calculated by dividing volume of a muscle by the fibre length and is also presented as a percentage of the total called ‘tension fraction’.

Muscles generate tension and create excursion, but tendons transmit the muscle work to the part of the skeleton that is to be moved. The amplitude of gliding of a tendon depends mostly on the excursion of its muscle but is also a function of the direction of the muscle fibres, amplitude being greater if the angle the fibres make with the tendon (pennation angle) is acute. The amplitude of tendon excursion is also influenced by other factors such as the freedom of gliding allowed by the paratenon, changes in direction around a pulley, and the crossing of articulations. The amplitude of gliding of the tendons of the extrinsic muscles of the hand also varies in the same tendon depending on the level at which it is measured. For example, the amplitude of gliding of the flexor digitorum profundus tendons is 5mm at the distal interphalangeal joint, 17mm at the proximal interphalangeal joint, 38mm at the carpal tunnel, and 85mm in the distal forearm. The maximal excursion for each tendon is shown in Table 6.9.2.

**Surgical techniques used in tendon transfer**

Transferred tendons are passed through subcutaneous tunnels where possible, so as to allow gliding. Since the tendon is likely to adhere to the surrounding tissue to some degree, that tissue should be pliable; passage over unyielding surfaces such as bone and fascia should be avoided if possible. The transfer is usually attached to the tendon of the paralysed muscle by a tendon weave (Figure 6.9.1), which is considerably stronger than end-to-end suture. If there is sufficient overlap of the two tendons being joined, at least three passes through tendon should be made. Each pass is locked with non-absorbable sutures. Such a weave is very strong but is also bulky, so there should be sufficient space to allow gliding. Where no tendon is available to receive the transfer, an attachment must be made directly to bone, using suture anchors or sutures passed through bone holes.

**Tenodesis**

Tenodesis is the automatic movement of a joint produced by motion of another, usually more proximal, joint. A tenodesis can be created surgically often by fixing a tendon to bone so that motion of a proximal joint causes a force on the tendon. For example, the EPL tendon can be anchored to the distal radius so that the thumb extends with wrist flexion.

**Reconstruction for shoulder paralysis**
The Glenohumeral joint

Paralysis of the important rotator cuff muscles and deltoid, which both stabilize the glenohumeral joint and produce abduction and external rotation, usually results from lesions to the C5 and C6 roots or the upper trunk of the brachial plexus. Although muscle transfer can sometimes help in cases of partial paralysis, shoulder arthrodesis is the only effective procedure for a completely flail shoulder.

Arthrodesis corrects subluxation of the glenohumeral joint and allows transfer of scapulothoracic motion to the arm, but at the expense of irreversible fusion of the glenohumeral joint. The active range of motion depends upon the function of the muscles controlling the shoulder girdle particularly serratus anterior. The usual position of fusion is around 30 degrees of glenohumeral abduction, 30 degrees of forward flexion, and 30 degrees of internal rotation. The technique involves exposure of the shoulder through an extensive posterior and lateral approach and decortication of the glenoid and humeral head. Internal fixation is provided by cancellous screws passed through the humeral head into the glenoid and a reconstruction plate placed from the spine of the scapula and acromium to the neck of the humerus (Figure 6.9.2). A spica cast is usually necessary for at least 6 weeks after operation. The mean range of active flexion and abduction was reported to be 75 degrees and 65 degrees respectively in a series of 11 patients (Figure 6.9.3).

Restoration of elbow flexion

Active elbow flexion is required for almost every activity of the upper limb. Because elbow extension is aided by gravity, triceps function is less vital. Elbow flexion may be lost as a result of supraclavicular injuries to the upper roots of the brachial plexus or infraclavicular injuries involving the musculocutaneous nerve. In cases where nerve reconstruction is unsuccessful, muscle transfer to restore elbow flexion may be worthwhile, particularly in patients who have satisfactory hand function. The possibilities for muscle transfer are greater in isolated musculocutaneous nerve damage than in supraclavicular brachial plexus injuries, where the donor...
muscles may also be completely or partially denervated. The following muscle transfers have been described:

- Pectoralis major
- Latissimus dorsi
- Triceps
- Steindler transfer (transfer of the common flexor origin of the forearm to a more proximal position on the humerus)
- Functioning free muscle transfer (gracilis most commonly used).

### Radial nerve palsy

The radial nerve is most commonly injured below its branches to the triceps, often in association with fractures of the humerus. Occasionally higher lesions occur which may be associated with more widespread damage to the brachial plexus. While triceps function can largely be replaced by gravity, it should be considered that, in the absence of supinator, the biceps can only supinate the forearm, if the triceps is stabilizing the elbow. Possible transfers to replace triceps include latissimus dorsi and deltoide lengthened with a tendon graft. It is not uncommon for the deficit to be confined to finger and thumb extension either as a result of injury to the posterior interosseous nerve or partial recovery of a more proximal lesion.

A patient with an irreparable radial nerve palsy needs tendon transfers to replace:

- Wrist extension
- Finger (metacarpophalangeal joint (MPJ) extension
- A combination of thumb extension and abduction.

Providing that the median and ulnar nerves are normal there are a number of possible combinations of tendon transfers for replacing these functions. Transfer of PT to ECRB for wrist extension appears to be universally accepted. Its use relies on the function being present in pronator quadratus. If PT is not available then the author has successfully used FDS to the middle finger. Wrist arthrodesis is rarely required and is generally undesirable since wrist movement enhances finger movement by the tenodesis effect.

Although the Jones (1916) transfer included the use of FCR and FCU for finger and thumb extension, it is now generally agreed that it is desirable to leave one wrist flexor intact. In making a choice between these donor tendons for transfer to EDC it is important to consider the balance of muscles that provide radial and ulnar deviation of the wrist. Those who prefer to use FCR argue that retention of a strong ulnar deviator of the wrist (FCU) is important for function of the hand. EPL function is restored with transfer of Palmaris longus.

Overall, the author has been slightly more impressed with the FCR set of transfers (Figure 6.9.4). The FCR has the advantage of having greater excursion than FCU. For posterior interosseous nerve palsy FCR should be used in order to balance radial and ulnar deviation. If PL is absent then EPL is usually included in the transfer for finger extension.

### Median nerve palsy

The median nerve is most often damaged either by trauma or by compression at the wrist or distal forearm. Hence the thenar muscles are denervated and opposition of the thumb is impaired. The degree of functional loss in isolated median nerve palsy is variable. Opposition is a combination of two movements: abduction or lifting of the thumb away from the palm of the hand; and rotation of the thumb into pronation so that the pulp surfaces of the thumb and index face each other. Before undertaking...
reconstruction it is important to overcome any contracture of the first web space. In the presence of severe sensory deficit in the median nerve distribution, patients are less likely to benefit from tendon transfer. A number of opposition transfers (opponensplasties) have been devised, and the circumstances of each case should be considered before making a choice.

Donor tendons include FDS to the ring finger, palmaris longus, extensor indicis, and abductor digiti minimi.

**Flexor digitorum superficialis opponensplasty**

In this procedure the FDS tendon is divided at the base of the ring finger and delivered into an incision just proximal to the wrist crease. The tendon is passed through a subcutaneous tunnel round the ulnar side of the pisiform and then across the palm to the MPJ of the thumb. An attachment is then made to the tendon of APB or directly to the base of the proximal phalanx; there is some debate about the exact method of distal attachment.

**Palmaris longus opponensplasty (Camitz transfer)**

This is quite a simple procedure in which the PL tendon is mobilized in continuity with a strip of palmar fascia (Figure 6.9.5). The tendon is then passed through a subcutaneous tunnel from the forearm to the MPJ of the thumb, where it is sutured to the tendon of APB. This transfer has its greatest application in severe carpal tunnel syndrome where it can be carried out simultaneously with carpal tunnel release. However, the line of pull of PL tends to produce thumb abduction with little rotation and is therefore not a true opposition transfer.

**Extensor indicis proprius opponensplasty**

This transfer is particularly useful when there has been tendon damage at the wrist in addition to a median nerve injury or in high lesions of the median nerve. The extensor indicis tendon is removed at the index finger MPJ with a small portion of the extensor hood. It is delivered into an incision on the dorsum of the forearm and then passed, in a subcutaneous tunnel, round the ulnar aspect of the wrist and across the palm to the thumb MPJ, where it is attached to the tendon of APB (Figure 6.9.6). A similar opponensplasty can be performed using EDM.
then lie in a straight position.

(Froment’s sign), this may be intermetacarpal space and then to the proximal phalanx of the thumb. If there is excessive flexion of the IPJ of the thumb abductors can be overpowered if a strong transfer such as ECRL is used. The tendon is passed through the second or third indicis proprius, brachioradialis, and ECRL or ECRB. The choice depends to some extent on the power of abduction; weak tendons that can be transferred for thumb adduction include extensor carpi radialis brevis. Often the radial half of this tendon can be used, or the ulnar half if the EPL is to be transferred. If necessary the profundus tendons of the ring and little fingers can be attached to that of the middle finger in the forearm, so improving the strength of finger flexion. In addition to lesions of the ulnar nerve, damage to the lower roots of the brachial plexus can cause a similar deficiency of the intrinsic muscles of the hand.

Paralysis of adductor pollicis and the first dorsal interosseous considerably weakens thumb–index pinch. Typically there is excessive flexion of the IPJ during pinch (Froment’s sign). Tendons that can be transferred for thumb adduction include extensor indicis proprius, brachioradialis, and ECRB or ECRB. The choice depends to some extent on the power of abduction; weak abductors can be overpowered if a strong transfer such as ECRL is used. The tendon is passed through the second or third intermetacarpal space and then to the proximal phalanx of the thumb. If there is excessive flexion of the IPJ of the thumb (Froment’s sign), this may be corrected by an FPL split transfer in which half the FPL tendon is transferred to EPL. The IPJ will then lie in a straight position.

**Hypothenar muscle opponensplasty (Huber transfer)**

The abductor digiti minimi, which is an ulnar-innervated intrinsic muscle, can be transferred to restore opposition. The muscle is detached from its insertion and mobilized on its neurovascular pedicle which enters at the proximal end. It is then pulled through a subcutaneous tunnel and sutured to the APB. The Huber transfer is a good choice in children but involves quite an extensive dissection in adults. It has the advantage of using an intrinsic muscle which shortens throughout its length and therefore does not require tendon gliding.

**High median nerve paralysis**

In proximal injuries, such as those occurring in association with elbow injury, of the median nerve there is paralysis of FCR, FPL, FDS, and the radial half of FDP. In practical terms, transfers are usually performed to replace FPL and the FDP to the index and middle fingers. Tendons available for transfer include the brachioradialis and ECRL. The brachioradialis transfer to the FPL provides independent flexion of the thumb interphalangeal joint (IPJ). Flexion of the index and middle fingers can be obtained by side-to-side suturing of the FDP tendons so that the functioning ulnar half acts on all the digits. However, index finger flexion tends to be rather weak. Greater strength and independent flexion of the index finger can be restored by transfer of ECRL to FDP. The excursion of brachioradialis and ECRL is less than that of FDP and FPL. Therefore mobility of the wrist joint is important in enhancing the function of these transfers using the tenodesis effect.

**Ulnar nerve palsy and other intrinsic deficiencies**

The main motor deficit in ulnar nerve palsy is paralysis of the ulnar-innervated intrinsic muscles of the hand causing loss of flexion of the MPJs of the fingers, finger abduction and adduction, and thumb adduction. There is consequent clawing of the fingers and weakness of key pinch of the thumb. Paralysis of the ulnar half of the FDP and the FCU does not usually cause a functional problem. If necessary, the profundus tendons of the ring and little fingers can be attached to that of the middle finger in the forearm, so improving the strength of finger flexion. In addition to lesions of the ulnar nerve, damage to the lower roots of the brachial plexus can cause a similar deficiency of the intrinsic muscles of the hand.

**Metacarpophalangeal joint flexion**

The lumbricals and interossei, which insert into the extensor expansions of the fingers, normally act to flex the MPJs and extend the IPJs. If these muscles are paralysed and extrinsic muscle function is intact, the fingers will claw with hyperextension of the MPJs and flexion of the IPJs. In ulnar nerve palsy only the ring and little fingers are affected, but other causes of intrinsic paralysis (e.g. lesions of the lower roots of the brachial plexus) may affect all the fingers. If the MPJs are passively flexed then the EDC can extend the IPJs (Bouvier’s manoeuvre). Normal finger flexion is initiated at the MPJ, so intrinsic paralysis also results in a loss of integration of MPJ and IPJ flexion. A number of procedures have been described to control the claw deformity.

**Superficialis techniques**

These techniques make use of the FDS tendons to replace intrinsic function. The FDS tendon to the middle or ring finger is divided and split into two or four slips. These slips may be passed through the lumbrical canals and inserted into the radial lateral band of the extensor mechanism of each finger. Alternatively, Zancolli (1979) recommended the ‘lasso’ procedure in which the tendon slip is looped through the annular pulley system at the base of the proximal phalanx and sutured to itself, so acting to flex the MPJs.

**Transfer of extensor carpi radialis longus**

Transfer of the FDS has the disadvantage that it does not add to overall grip strength. An alternative is transfer of ECRL. The tendon is lengthened using free tendon grafts to reach the lateral bands of the extensor mechanism of the fingers. In order to pass through the lumbralcanals on the volar aspect of the deep transverse metacarpal ligament, the tendons are routed either through the intermetacarpal spaces or through the carpal canal.

**Thumb adduction**

Paralysis of adductor pollicis and the first dorsal interosseous considerably weakens thumb–index pinch. Typically there is excessive flexion of the IPJ during pinch (Froment’s sign). Tendons that can be transferred for thumb adduction include extensor indicis proprius, brachioradialis, and ECRB or ECRB. The choice depends to some extent on the power of abduction; weak abductors can be overpowered if a strong transfer such as ECRL is used. The tendon is passed through the second or third intermetacarpal space and then to the proximal phalanx of the thumb. If there is excessive flexion of the IPJ of the thumb (Froment’s sign), this may be corrected by an FPL split transfer in which half the FPL tendon is transferred to EPL. The IPJ will then lie in a straight position.

Peripheral nerve entrapment

DOI: 10.1093/med/9780199550647.003.006010

Summary points

- Peripheral nerve compression syndromes are common when involving the median nerve at the wrist and the ulnar nerve at the elbow
- All patients are primarily diagnosed using a careful history and clinical examination
- Neurophysiological studies are very helpful especially in confusing presentations but do have a low false positive and false negative rate
- Conservative management should be tried in nearly all patients for 6-12 weeks
- Surgical treatment is generally very successful in relieving the symptoms of peripheral nerve compression
- Delayed treatment can result in permanent nerve damage which cannot be corrected by surgery.

General considerations

The term 'peripheral nerve entrapment' implies nerve compression based on impingement by adjacent soft tissue or bony structures, usually occurring in well-defined locations in the upper extremity. However, other factors frequently play a role in the onset of symptoms. Inflammation of the surrounding or adjacent structures can apply direct pressure to the nerve itself or increase pressure within a confined space. Systemic conditions, such as pregnancy, diabetes, and disorders of thyroid function, after symptom manifestation and pressure applied to the nerve. Appropriate epineural blood supply also appears to be critical in the production of symptoms. Direct trauma to the nerve, although a relatively uncommon cause, can produce symptoms based on swelling, haematoma formation, or direct axonal injury. Similarly, abnormal tethering of the nerve can restrict its normal gliding motion leading to a traction phenomenon which impairs physiological function.

Peripheral nerve entrapment has several stages (Box 6.10.1):

- The first is intermittent impairment of the intraneural microcirculation. The raised pressure in the surrounding tissues intermittently exceeds the perfusion pressure in the epineurial vessels, which indirectly affects the resting membrane potential and propagated action potentials. Characteristically there are nocturnal and positional symptoms, for example, of early carpal tunnel syndrome, but otherwise normal function in the daytime; decompression provides immediate relief
- In the second stage, axonal transport is impaired and the myelin sheath may be lost from some fibres, leading to continuous symptoms and mild constant neural deficits such as muscle weakness and blunting of sensibility. Symptoms typically resolve within a few weeks of decompression
- In the third stage, axonal loss occurs through Wallerian degeneration. Recovery after decompression is slow (sometimes over a year) and may be incomplete.

Box 6.10.1 Stages of peripheral nerve entrapment

1. Intermittent impairment of the intraneural microcirculation
2. Impaired axonal transport and loss of some myelin sheath
3. Axonal loss occurs through Wallerian degeneration

The outcome is best with stage 1.

Historically, peripheral nerve entrapment has been seen in the middle-aged and elderly population, more commonly in females than males, with a predictable and gradual progression of numbness and tingling. Patients with long-standing compression often presented with dense impairment of sensibility, with or without atrophic muscles, and with a poor prognosis for recovery after decompression. During the last 10–15 years, there have been increasing presentations from younger industrial or clerical workers undertaking repetitive hand tasks or using vibratory tools. The reasons remain unclear, although greater awareness of these conditions in the general population has contributed. The increase of workers’ compensation claims for peripheral nerve entrapment has complicated the diagnosis and treatment of these conditions.

Clinical considerations (Box 6.10.2)

Nerve compression usually occurs gradually. Paraesthesia occurring at night or in response to specific activities is typical. Acute nerve compression is rare; patients note immediate symptoms of dense numbness and tingling in the appropriate distribution, often after a defined traumatic event. Bleeding and haematoma formation secondary to the injury are the most common cause and patients with these findings are often best treated by immediate surgical decompression.
Box 6.10.2 Assessment and examination

- **Assessment:**
  - History—this is the mainstay
  - It should indicate the diagnosis and severity

- **Examination:**
  - Should confirm the diagnosis
  - Provocative tests include Tinel’s sign
  - Fixed neurological changes indicate severity
  - Neurophysiology is often not required
  - Neurophysiology has false positive and false negative results.

Since the clinical manifestations of impaired nerve function (sensory symptoms and muscle weakness or wasting) are projected to the distal terminations of the peripheral nerves, the site of the nerve lesion may, in theory, be deduced from the distribution of the symptoms. This is not always reliable. Assessment of the patient requires a careful interpretation of patient history and physical examination, as well as a thorough knowledge of the neural anatomy of the upper extremity. In most patients, clinical signs point to involvement of a single nerve. Once the affected nerve is identified, the site of compression can be localized by a combination of specific symptoms, physical signs, and electrodiagnostic testing. One should always be alert to unusual causes of peripheral nerve compression such as tumour surrounding the brachial plexus, radiation plexopathy, and the possibility of a double-crush phenomenon involving two sites of compression in the same nerve at different levels.

Sensibility testing can also provide valuable information although is rarely used in routine clinical practice. The Semmes–Weinstein monofilament test and vibration tests that examine the threshold for neural stimulation (a reflection of the function of single nerve fibres supplying one or more receptors) are more effective early since conventional sensory tests often show no abnormality in early and intermediate stages of neural entrapment. These are, in practice, only used in research. In contrast, static and moving two-point discrimination which test innervation density reflect the interpretation of signals from many overlapping receptor fields and require a considerable drop-out of fibres before performance is impaired. These tests are most frequently used to plot recovery after nerve repair.

Electrodiagnostic testing remains the most objective method available for investigating peripheral nerve compression (Table 6.10.1). The general assumption that electrodiagnostic testing is highly reproducible and completely accurate is incorrect. These tests are operator dependent, rely on the establishment of ‘normal’ values for each laboratory, and are affected by environmental conditions such as patient temperature, room temperature, and electromagnetic interference.

A summary of the physical signs and usefulness of electrodiagnostic testing in peripheral nerve compression

#### Carpal tunnel syndrome (Box 6.10.3)

Carpal tunnel syndrome is compression of the median nerve beneath the transverse carpal ligament in the wrist. It is the most common peripheral nerve entrapment syndrome, affecting about one in 1000 of the population per year, but its frequency of presentation may be increasing in parallel with greater community awareness.

The classical clinical picture is of nocturnal paraesthesiae that wake the patient and are relieved by shaking the hands or hanging them in a dependent position. In severe cases, patients wake several times each night. In milder cases, patients will often note numbness and tingling upon waking in the morning, with fine motor activities of the hand, or when gripping the hand for extended periods of time (e.g. holding a steering wheel while driving a car). Numbness and tingling should be related to the median nerve distribution involving the thumb, index, and middle fingers, and the radial half of the ring fingers. Possible proximal causes of numbness and tingling, such as thoracic outlet syndrome, cervical radiculopathy, or pronator syndrome, should always be considered.

#### Box 6.10.3 Carpal tunnel syndrome

- Median nerve compression at the wrist
- Very common
- Female incidence greater than male
- Typically bilateral
- Symptoms may be throughout the hand
- Provocative tests include Tinel’s sign, pressure test, and Phalen’s test
- Early disease may resolve non-operatively
- Splint, steroid injection
- Most patients require a carpal tunnel release
- The outcome is very reliable.
Physical examination includes tests of median nerve function (sensibility and thenar muscle power) and provocative tests. The two classic manoeuvres are Phalen’s test and Tinel’s test. In Phalen’s test (generally performed on both hands simultaneously), the wrist is held fully flexed for up to 60s, noting the onset of paraesthesiae in the median nerve distribution. For Tinel’s test, the examiner’s finger or a rubber mallet is used to tap over the median nerve within and just proximal to the transverse carpal ligament, provoking positive if the patient has distal radiation of ‘electric shocks’ or tingling in the median nerve distribution. Phalen’s test is sensitive but sometimes renders false-positive results. Tinel’s test is more specific but is less sensitive, so that a positive result is informative but a negative one is still consistent with carpal tunnel syndrome. Median nerve compression (the compression or pressure test) can also be used. The median nerve is compressed/pressed upon by the examiner’s finger just proximal to the carpal canal. Like Phalen’s test, if positive there is usually a response in 20s but it may be necessary to press for 60s.

Electrodiagnostic testing is the single best test in diagnosing carpal tunnel syndrome, and is especially invaluable when the clinical impression is inconsistent with the typical history and physical signs of the syndrome. Although this test provides the most objective examination of the median nerve, it should be used in conjunction with the clinical signs and symptoms.

Conservative management includes the use of a neutral-position wrist splint to be worn at night and during repetitive activities of the hands, and occasionally the use of oral anti-inflammatory medications. Steroid injections can offer two benefits in patients with a relatively short duration of symptoms: a cure (in less than half of patients) and diagnostic confirmation if there is a response even transiently.

Most patients eventually require surgical release of the transverse carpal ligament. Operative treatment is indicated in patients who have fixed neurological symptoms, i.e. thenar atrophy or constant sensory impairment (implying severe compression), although relief of symptoms may be incomplete. The carpal ligament can be divided open or with the newer techniques of endoscopic or mini-open ligament release. Open techniques are safer, with less chance of injury to the median nerve, common digital nerves, and flexor tendons, and a lower recurrence rate; however, increased palmar tendon is a drawback (Figure 6.10.1). Though pillar pain is certainly not eliminated, endoscopic release provides the benefit of less palmar tenderness.

Pronator syndrome (Box 6.10.4)

Entrapment of the median nerve in the proximal forearm is rare. Although called the pronator syndrome, compression may occur at various sites. Occasionally, patients will present with compression of the median nerve under a ligament of Struthers arising from a supracondylar process of the humerus. Alternative sites of compression as it passes through the proximal forearm and elbow region include the lacertus fibrosus, the origin of the pronator teres, and the arch of the flexor digitorum superficialis muscle distally. Patients classically complain of numbness in the radial three and a half digits and occasional thenar weakness. Unlike carpal tunnel syndrome, nocturnal paraesthesiae and tingling are generally absent with paraesthesiae chiefly occurring with forearm muscle contraction. Patients can complain of pain in the volar aspect of the proximal forearm. Phalen’s test is generally negative. The pronator compression test, involving compression applied at the junction of the pronator heads with resulting dysaesthesiae and tingling in the median nerve distribution, may support this diagnosis. Flexing the elbow with the forearm in supination while simultaneously applying resistance can indicate compression at the lacertus fibrosus. If paraesthesiae occur while resisting forearm pronation with full elbow extension, the pronator site is indicated. The occurrence of median nerve tingling while the examiner resists isolated proximal interphalangeal joint flexion of the middle finger can indicate entrapment of the median nerve below the arch of the flexor digitorum superficialis muscle. Electrodiagnostic testing is essential.

Conservative treatment is to modify forearm and wrist musculature activity, possible through the use of a volar neutral position wrist splint. Occasionally heat and massage, as well as non-steroidal anti-inflammatory medications, can improve the condition. Surgical release of the median nerve in the proximal forearm may be required. Of the four sites which should all be checked during...
surgery after the median nerve is identified, the lacertus fibrosus and arch of the flexor digitorum superficialis appear to be most commonly associated with visual compression of the median nerve. The large blood vessels immediately adjacent to the median nerve should be protected during surgery (Figure 6.10.2). If a patient has had a previous carpal tunnel release without symptom relief, pronator syndrome should be considered but is still rare.

Fig. 6.10.2
After release of the lacertus fibrosus and pronator musculature, the relationship between the median nerve and adjacent vascular structures is easily seen.

**Anterior interosseous nerve syndrome (Box 6.10.5)**

Isolated compression of the anterior interosseous nerve branch of the median nerve occurs but, again, rarely. The condition results in loss of motor function without sensory loss, usually seen with the loss of the ability actively to flex the distal interphalangeal joint of the index finger and the interphalangeal joint of the thumb (loss of the OK or ring sign). Patients may also experience non-specific aching and discomfort in the volar proximal forearm. Occasionally, the pronator quadratus can be deemed weak by testing resisted pronation with the elbow fully flexed to reduce the effect of the proximal pronator teres.

Anterior interosseous nerve syndrome is generally treated conservatively for 3–6 months, since most patients will recover spontaneously. If patients present with pain in both forearms or with symptoms extending proximally in the limb, transient brachial neuritis or Parsonage–Turner syndrome should be considered. The indication for surgical release of the anterior interosseous nerve is the lack of active flexion return in the distal interphalangeal joint of the index finger and that of the thumb, but the timing of surgery is controversial and almost always can be avoided. On rare occasions, only one of the thumb or index finger is involved, generally indicating a more distal compression of the anterior interosseous nerve; one must be careful not to confuse this diagnosis with that of an isolated tendon rupture to either the flexor pollicis longus or the flexor digitorum profundus of the index finger especially in rheumatoid patients who can have isolated rupture of the flexor pollicis longus tendon. Flexion of the interphalangeal joint of the thumb when pressure is applied firmly to the flexor pollicis longus muscle belly in the forearm confirms that the tendon is intact.

**Box 6.10.4 Pronator syndrome**

- Rare
- Due to proximal median nerve compression
- Must exclude carpal tunnel syndrome
- Diagnosis requires neurophysiology.

**Box 6.10.5 Anterior interosseous syndrome**

- Uncommon
- Mostly viral
- Classically patients cannot make the ‘O’ sign
- Most patient recover spontaneously in approximately 6 months.
Cubital tunnel syndrome (Box 6.10.6)

Cubital tunnel syndrome, or entrapment of the ulnar nerve at the medial elbow region, is the second most common peripheral nerve entrapment syndrome. The most common complaint is numbness and tingling in the little finger and ulnar half of the ring finger, commonly aggravated by repeated elbow flexion and extension, or by sleeping in a ‘fetal position’ with the elbows flexed. Weakness of the ulnar-innervated intrinsic muscles is a sign of severe or long-standing compression. Several other conditions may mimic cubital tunnel syndrome, though examination generally excludes cervical root entrapment, cervical rib or band, radiation plexopathy, and peripheral nerve tumours. If sensory symptoms involve the medial aspect of the forearm, the cause is probably proximal to the cubital tunnel.

</tbody>
</table>

Cubital tunnel syndrome can be distinguished from the much less common compression of the ulnar nerve at the wrist (Guyon’s canal compression syndrome) by involvement of the dorsal sensory branch of the ulnar nerve, by weakness of the flexor digitorum profundus muscle of the small finger and flexor carpi ulnaris muscle, and by localization of Tinel’s test to the cubital tunnel.

Conservative management includes a night elbow extension splint or, alternatively, wrapping a pillow with tape around the elbow in the fashion of a ‘doughnut’ to prevent elbow flexion during sleep. Steroid injection use at the cubital tunnel is best avoided due to a high incidence of fat necrosis, and non-steroidal anti-inflammatory drugs are ineffective. Surgical decompression is indicated if conservative treatment fails or if muscle weakness or wasting is present.

The various operative procedures used for treatment of cubital tunnel syndrome all appear to provide 85–90% improvement of symptoms. Surgical procedures include simple decompression of the cubital tunnel, decompression with partial medial epicondylectomy, and transposition of the ulnar nerve anteriorly. Simple decompression alone is generally indicated if Tinel’s sign over the ulnar nerve at the elbow is localized to the cubital tunnel and the origin of the flexor carpi ulnaris. After simple decompression, the ulnar nerve must not sublux with elbow flexion and extension. If this does occur, partial medial epicondylectomy should be performed. Anterior transposition of the ulnar nerve is performed very variably depending upon surgeon preference. Indications include patients exhibiting significant involvement of the ulnar nerve with evidence of atrophy or weakness (Figure 6.10.3), especially in patients with fixed flexion deformities of the elbow. Since the nerve is being transposed anterior to the medial epicondylye, the medial intermuscular septum should be completely resected to avoid any ‘tenting’ of the ulnar nerve over this structure following transposition. The cubital tunnel release should be complete around the medial epicondylye, and the fascia, both deep and superficial overlying and within the flexor carpi ulnaris, needs to be completely released to prevent any further ‘kinking’ of the ulnar nerve distally. Transposition of the ulnar nerve can either be to the subcutaneous tissues above the fascia of the flexor pronator group, within the musculature of the flexor pronator group itself with the fascia repaired, or beneath the flexor pronator group with the origin repaired to the medial epicondylye. This is dictated by surgeon preference rather than scientific evidence.
A) During release of the ulnar nerve at the cubital tunnel prior to transposition, complete transection of the medial intermuscular septum and fascia of the flexor carpi ulnaris is required. Note the small branch of the medial antebrachiocutaneous nerve which should be preserved. B) After transposition of the ulnar nerve in an intermuscular fashion, superficial fascia is repaired forming an intermuscular tunnel.

Failure to achieve good results with these techniques may result from inadequate decompression, failure to ensure that the nerve is stable during elbow flexion/extension, or that it is free from compression in its new position.

**Guyon’s canal compression syndrome (Box 6.10.7)**

Compression of the ulnar nerve at Guyon’s canal (ulnar tunnel syndrome) is rare. Its numerous causes include space-occupying lesions (e.g., ganglion cysts), anomalous muscles, fractures of the hook of the hamate, thrombosis of the ulnar artery, repeated trauma to the heel of the hand (hypothenar hammer syndrome), and long-distance cycling. Symptoms may be motor, sensory, or both, depending on the location of the compressive lesion relative to the ulnar nerve branches. It can be difficult to differentiate from more proximal compression, i.e. at the elbow. The signs of proximal compression as noted earlier should be looked for, as should local nerve irritability, i.e. a positive Tinel’s sign over the ulnar nerve at the wrist.

The Allen test can often detect occlusion of the ulnar artery. Radiographic examination (e.g. computed tomography scanning) may identify a fracture of the hook of the hamate, while magnetic resonance imaging can define the nature and location of ganglia and other lesions.

**Box 6.10.7 Ulnar nerve compression at the wrist**

- Rare
- Often due to other local pathology
- Neurophysiology is essential
- Surgery should help.

Conservative management with rest and splintage is appropriate when compression arises from repeated local trauma or pressure. Since space-occupying lesions are so often the cause of compression within Guyon’s canal, operative treatment is commonly needed. No matter the compression site, the ulnar nerve must be traced through the entire tunnel so as to ensure complete decompression, a process that generally yields good results.

Occasionally patients are seen who have carpal tunnel and Guyon’s canal compression syndrome simultaneously. These patients can be treated by release of the carpal tunnel alone, since the procedure relaxes Guyon’s canal. Alternatively, the vertical septa to Guyon’s canal can be released through the same incision.

**Radial tunnel syndrome (Box 6.10.8)**

Entrapment of the posterior interosseous nerve produces two separate clinical pictures. In the first, a mass lesion around the neck of the radius may cause painless paralysis of the muscles supplied by the posterior interosseous nerve (see later). The second, termed radial tunnel syndrome, is a dynamic form of entrapment of the posterior interosseous nerve that cannot be unequivocally diagnosed following clinical and electrodiagnostic examinations.

Though a number of compressive sites have been described, the three most consistent are the fibrous edge of the extensor carpi
radialis brevis muscle, the proximal edge of the supinator muscle (the arcade of Frohse), and the recurrent leash of radial vessels (the leash of Henry) that cross superficial to the posterior interosseous nerve (Figure 6.10.4). Patients complain of a deep-seated aching in the proximal forearm after strenuous muscle activity. Deep palpation where the posterior interosseous nerve enters the supinator muscle will produce marked tenderness, sometimes with radiation to the proximal forearm. Radial tunnel syndrome should be differentiated from lateral epicondylitis since these conditions can coexist. Pain with resisted wrist extension is generally directed towards the lateral epicondyle itself, and focal pain directly over the lateral epicondyle is typically indicative of lateral epicondylitis. Pain on resisted middle finger extension is occasionally seen in patients with radial tunnel syndrome. An injection of local anaesthetic that abolishes the pain and gives a temporary wrist drop provides further evidence to support the diagnosis. Electrodiagnostic studies, although extremely helpful if positive, are frequently normal in this dynamic compression syndrome.

**Box 6.10.8 Radial tunnel syndrome/posterior interosseous nerve entrapment**

- Rare
- Often overdiagnosed
- Signs and symptoms are often vague
- Local anaesthetic injection may help diagnosis
- Neurophysiology is often unhelpful
- Surgery is unreliable.

Conservative management involves modification of upper-limb activity for 4–6 weeks and may be augmented by neutral wrist splinting. If conservative management fails, surgical decompression of the radial nerve, including the distal posterior interosseous nerve and sensory branch of the radial nerve, may be undertaken. Decompression should ensure release of the fascial tissues superficial to the radiocapitellar joint, coagulation and release of the recurrent radial artery known as the leash of Henry (ligating each vessel independently and sequentially), release of the fibrous edge of the extensor carpi radialis brevis, and, most importantly, release of the proximal edge of the supinator (the arcade of Frohse). In rare instances in which tenderness is also noted at the distal portion of the supinator preoperatively, release of the entire supinator or the distal edge may be required. Blunt finger probing along the radial nerve proximally and distally will exclude other areas of compression. The results of decompression of the radial tunnel have been quite variable. Coincidental undiagnosed lateral epicondylitis can lead to ‘failure’ of radial tunnel decompression so the lateral epicondyle should be addressed surgically if signs of lateral epicondylitis are present.

**Posterior interosseous nerve palsy**

Partial or complete loss of posterior interosseous nerve function may occur because of compression by a mass lesion within or at either end of the supinator muscle, most commonly caused by lipomas around the radial neck and rheumatoid synovial cysts. The diagnosis of a complete palsy is based on the loss of finger and thumb extension with weak and radial-directed extension of the wrist under the influence of extensor carpi radialis longus. Incomplete lesions, sometimes producing loss of extension of one or two digits, are easily confused with the much more common extensor tendon rupture. Operatively, the removal of the mass should be approached anterior to the proximal part of the supinator or posterior to the distal part.

**Wartenberg’s syndrome (Box 6.10.9)**

Compression of the radial nerve sensory branch in the middle and distal forearm is very uncommon. The sensory branch of the radial nerve normally courses underneath the muscle belly of the brachioradialis and emerges from below its tendinous portion in the distal third of the forearm (Figure 6.10.5), where irritation, compression, or tethering may occur. Occasionally, a tingling or shocking sensation in the territory of the sensory branch can be provoked by forcefully pronating the forearm for up to 60s. The most useful sign is a positive Tinel’s test directly over the sensory branch of the radial nerve as it enters under or exits from underneath the brachioradialis. Injection of a local anaesthetic can confirm the diagnosis. This condition is found more proximal...
than de Quervain’s stenosing tenovaginitis, which occurs at the radial styloid level.

**Box 6.10.9 Wartenberg’s syndrome**

- Uncommon
- Often clear from the clinical assessment
- Especially focal positive Tinel’s sign
- Surgery usually helps.

Conservative management involves the use of a volar neutral position wrist splint to try to reduce inflammation. Surgical management generally involves release of any fascial and constricting fibres at the junction of the extensor carpi radialis longus and brachioradialis. Careful release of the sensory branch of the radial nerve through a ‘no-touch’ technique should be undertaken to ensure complete removal of compression. Occasionally, the edge of the brachioradialis pushes into the sensory branch of the radial nerve itself, requiring resection of half of the brachioradialis tendon to decompress the sensory branch of the radial nerve and provide a blunter edge with less overall constriction. Early mobilization is generally used in these patients to stop secondary adhesions. The results of surgery have been variable.

**Recurrent peripheral nerve compression following failed decompression**

On occasion, patients present with symptoms that have persisted or recurred after surgical decompression for three possible reasons: incorrect original diagnosis; incomplete previous decompression; or psychological concerns related to issues of compensation in the workplace. In this case, psychological factors as well as the peripheral nerves and musculoskeletal system (to exclude further causes of entrapment) must be examined. If these examinations are unsuccessful, the area can be re-explored to ensure that the original decompression was complete. The results of such surgery may be disappointing unless the surgeon is able to release a tight structure that was missed at the first operation. Symptoms may recur because of new or recurrent pathological changes in the areas of compression. In general, patients who have had a period of excellent relief of symptoms followed by recurrence fare better with a secondary surgical decompression than those whose symptoms were never relieved.

The two common examples of recurrent compression, although fortunately rare, are following carpal tunnel and cubital tunnel release. Patients who have undergone open carpal tunnel release will generally have good relief of symptoms but after several years can suffer a recurrence, especially if there are underlying pathological changes, such as amyloid deposition in chronic haemodialysis or diabetes. Frequently, these patients can be treated successfully by open revision surgery.

Failure following decompression of the ulnar nerve at the cubital tunnel region can occur after any procedure. Commonly, the release of the ulnar nerve was incomplete at the first operation or other structures were not dealt with adequately (most importantly the medial intermuscular septum and fascia of the flexor carpi ulnaris). Revision surgery is typically performed by transposing the ulnar nerve anteriorly.

**Conclusion**

Entrapment of the peripheral nerves is a common cause of symptoms in the upper extremity. Isolating the exact area of
entrapment involves taking a careful history and a thorough physical examination to identify the nerve involved and to locate the site of compression. Conservative management can result in modest successes, especially if symptoms are of short duration and activities inciting the symptomatology can be curtailed for a period of time. Fortunately, surgical decompression also has met with a relatively high success rate if the diagnosis is accurate. Electrodiagnostic studies are an extremely helpful adjunct in establishing the diagnosis, but they can neither replace a careful history and physical examination nor make the diagnosis on their own. Isolated electrodiagnostic findings are not themselves an indication for surgery unless the diagnosis is supported by clinical evidence from the history and examination. With careful thought and planning, successful treatment of patients suffering from peripheral nerve entrapment is the rule rather than the exception.

Further reading

Summary points

- Neurophysiological assessment includes:
  - Clinical assessment
  - Sensory testing
  - Motor testing
  - EMG

- Sensory testing (SAP) is generally the most useful
- Motor studies – there are 4 main measurements
- EMG – looks for (abnormal) spontaneous activity. It is operator dependent.

Introduction

The skilled manipulation of objects, often with both hands simultaneously, is a unique feature of human behaviour. This is achieved through complex neural circuits involving direct and indirect corticospinal connections, rich feedback networks from muscle, skin, and joint receptors, and multilevel integration in the cord, cerebellum, and cortex. Therefore it is not surprising that dysfunction of these networks, due to peripheral nerve lesions, leads to impairment of hand function and considerable disability.

The accurate diagnosis of conditions affecting the nerve supply to the hand is clearly important, and clinical neurophysiology is the discipline, par excellence, which can deliver this. Not only can nerve lesions be localized accurately, but it is also possible to assess the duration of the condition, the underlying pathology, and the prognosis.

Clinical neurophysiology begins by taking the history and examining the patient. Simple nerve lesions, such as carpal tunnel syndrome, may be the presenting feature of a more generalized disease, for example, diabetic neuropathy, thyroid disease, acromegaly, connective tissue disease, etc. The neurophysiological examination is planned to maximize the information that can be gained, but to minimize the number of shocks or needle insertions for the patient.

This chapter will describe the methods whereby neurophysiological investigations are conducted and the neurophysiological diagnosis and prognosis of lesions affecting the nerve supply of the hand. Normal values in nerve conduction studies depend critically on the precise technique used, including the type and positioning of electrodes and the temperature of the limb, and each laboratory will have its own normal ranges. For this reason, precise normal ranges are not quoted.

Methods (Box 6.11.1)

Nerve conduction studies involve exciting, usually percutaneously, a peripheral nerve by electrical stimulation and recording either from the same peripheral nerve at a distant site or from a muscle supplied by the nerve. The latency from the stimulus to the start of the response, the nerve conduction velocity, and the amplitude of the response are the most pertinent parameters to measure. Conduction measurements may be made from sensory, mixed motor and sensory, or from purely motor responses.

Conduction measurements depend on age (amplitudes become smaller and conduction velocities slower with age). Conduction parameters also depend on temperature. In routine practice, it is often not necessary to control temperature rigorously, but if the patient has cold hands and equivocal abnormalities are found, then the study should be repeated after warming the hands to above 32°C.

Box 6.11.1 Neurophysiological assessment

This includes:

- Clinical assessment
- Sensory testing (generally the more useful)
- Motor testing
- Electromyography (EMG).

Box 6.11.2 Sensory testing
Stimulate the fingers and record proximally (SAP)

- SAP is dependent on:
  - Number of nerve fibres that are active
  - Synchrony with which individual action potentials arrive at the recording site.

**Sensory studies (Box 6.11.2)**

Ring electrodes placed around the fingers excite the digital branches of peripheral nerves which are, at this location, purely sensory. Recordings are made with surface electrodes from the skin overlying the relevant nerve. Because nerve responses are relatively small (in the microvolt range), electronic averaging may be required. The resulting nerve responses (Figure 6.11.1) are termed sensory action potentials (SAPs). The median SAP may be obtained by stimulating the thumb, index, middle, or ring fingers. The ring finger is usually split between median and ulnar innervation and hence the amplitude of response is smaller. The SAPs are usually obtained by stimulation of both digital nerves from each finger. They may also be obtained from stimulation of individual digital branches and even just recording in the finger but not the hand in order to localize any lesion. The radial sensory innervation of the hand and the dorsal branch of the ulnar nerve are tested by an antidromic technique.

The size of an SAP is principally dependent on two factors: the number of nerve fibres that are active and the synchrony with which individual action potentials arrive at the recording site. Thus patients with axonal degeneration-type peripheral neuropathies may have small or absent SAPs because of a reduced number of fibres; patients with demyelinating peripheral neuropathies may have small SAPs because of the dispersion of arrival times of action potentials at the recording electrodes.

In most nerve lesions likely to be encountered in the hand, sensory studies are more sensitive than motor studies.

**Mixed-nerve studies**

When a mixed nerve, i.e. one containing both motor and sensory fibres, is stimulated, action potentials propagate in both directions in all nerve fibres. Measurements can be made both proximally and distally. This is useful in helping localize nerve lesions and is particularly valuable for assessment of the ulnar nerve.

**Motor studies (Box 6.11.3)**

In motor studies there are four main measurements: the latency from distal stimulation to the start of the muscle response (distal motor latency); the conduction velocity in motor nerve fibres; the amplitudes of compound muscle action potentials evoked by maximal nerve stimuli, taken to be roughly proportional to the volume of active tissue in the muscle; and the conduction in the proximal segments of each nerve. Surface electrodes are placed over the belly and tendon of the muscle of interest. For the median nerve, the abductor pollicis brevis (APB) muscle is used and for the ulnar nerve, either the abductor digiti minimi (ADM) or first dorsal interosseous (DIO) muscles. Electrical stimuli are applied to the relevant nerve at two or more locations and the latency of compound muscle action potentials is measured. By subtracting these latencies and measuring the distance between stimulation sites, the maximum conduction velocity can be calculated (Figure 6.11.2). It should be emphasized that this technique only assesses the fastest conducting (A) fibres in the nerve; these may be preserved in the face of quite severe motor nerve problems. The compound muscle action potentials (CMAPs) from proximal and distal stimulation sites are normally very similar in waveform and have amplitudes differing by no more than 20%. In the presence of conduction block (neurapraxia), the CMAP from a stimulation site proximal to the block is smaller than that obtained distal to the block (see Figure 6.11.3).
Late responses

When a motor nerve is stimulated, action potentials propagate in both directions: distally to the muscle where they evoke a CMAP, and proximally to the spinal motor neurons. Some motor neurons are re-excited by invasion of their soma and discharge again down the motor axons to produce responses in the muscle. These are termed F waves. Their importance lies in the fact that the latency of F waves assesses conduction over the whole length of the motor nerve. Thus, a nerve showing a normal conduction velocity in its peripheral segment but prolonged F waves has slowing of conduction proximally, e.g. in the neck.

Box 6.11.3 Motor studies

- The relevant nerve is stimulated and response measure with a surface electrode:
  - Median nerve—APB
  - Ulnar nerve—ADM or first DIO
- There are four main measurements:
Electromyography (Box 6.11.4)

Much information can be gleaned by recording the electrical activity in a muscle through electromyography (EMG). The electromyographer relies as much on the sound of the activity as on its appearance. At rest, a normal muscle shows no spontaneous activity. Fibrillations, positive sharp waves, fasciculations, and complex repetitive discharges may be encountered and are searched for in several muscle sites. During voluntary activation, muscle activity forms what is referred to as the recruitment pattern. The activity is recorded with a fine-needle electrode consisting of a concentric wire insulated from the shaft of the needle. Conventional concentric needle electrodes used in EMG record from a volume of muscle of radius of about 1mm. This means that about 200 individual muscle fibres are within the pick-up area of the needle. If all these fibres are active, as during a maximal voluntary contraction, then the signal recorded by the needle is complex. However, if the patient is requested to make a weak contraction then individual motor unit potentials can be discerned. These derive from a group of muscle fibres all innervated by the same spinal motor neuron and constitute part of a motor unit. The potential recorded is referred to as a motor unit potential. The waveforms, amplitudes, and firing frequencies of motor unit potentials give important clues to the pathogenesis of weakness (Figures 6.11.4A and 6.11.5).

Fig. 6.11.4
A) The pick-up area of an electromyographic recording needle has a radius of about 1mm. Fibres belonging to one motor unit are indicated. The motor unit potential has an amplitude of about 1mV, a duration of about 10ms, and fires about 10 times per second when first recruited. B) In acute denervation, muscle fibres become supersensitive and produce spontaneous electrical activity in the form of fibrillations, positive sharp waves, or complex repetitive discharges. C) After a partial nerve lesion, degenerating axons (light line) are associated with fibrillating muscle fibres (open circles). Surviving axons (thick lines) are associated with normally functioning fibres (filled circles) produce nerve sprouts (dotted lines) to re-establish connection with the denervated fibres. The motor unit potential is complex, is of prolonged duration with satellite potentials, but is of normal amplitude. D) Nerve sprouts mature and the reinnervated fibres now assume the same fibre type as the parent fibres. The motor unit potential is now of long duration and high amplitude (say 10mV). E) In primary muscle disease, muscle fibres are lost and the motor unit potential is spiky in appearance and has a low amplitude (say 0.1mV).
Spontaneous activity recorded with an electromyographic needle in denervated muscle. Above are fibrillation potentials and below is a complex repetitive discharge.

Acute denervation of muscle is associated with spontaneous activity termed fibrillation, which is an electrical not a clinical sign. Traditionally this is described as sounding like rain on a tin roof. Fibrillations are potentials derived from single muscle fibres and are due to hyperexcitability of the muscle membrane. Acute denervation is associated with the proliferation of acetylcholine receptors on the muscle fibre membrane at sites outside the neuromuscular junction. Other forms of spontaneous activity having the same significance as fibrillations are positive sharp waves and complex repetitive discharges (Figure 6.11.4E). After an acute nerve lesion, fibrillations take 7–14 days to develop.

In complete nerve lesions, there is no possibility of reinnervation within the muscle and any recovery is by the process of nerve regeneration. This is a slow process and its success depends largely on the nature of the original injury and the distance of the lesion from the muscle.

In a partial nerve lesion, surviving motor axons in the muscle develop nerve sprouts which grow towards the denervated muscle fibres and establish neuromuscular junctions on them. These nerve sprouts at first conduct nerve impulses only slowly and so motor unit potentials recorded by a needle in the muscle show complex polyphasic waveforms of relatively low amplitude and may have satellite potentials. These potentials are sometimes referred to as ‘nascent’ and are a sign of early reinnervation (Figure 6.11.4C). As nerve sprouts mature, they conduct impulses faster and the satellite potentials now form part of the main motor unit potential. Thus, in chronic reinnervation, motor unit potentials are large in amplitude, and have relatively simple waveforms of longer than normal duration (Figures 6.11.4D and 6.11.6). The recruitment pattern in a chronically reinnervated muscle is incomplete due to the reduced numbers of motor units but the firing frequency of each motor unit is increased. This combination of reduced numbers of motor units with high amplitudes firing at high rates gives a characteristic sound on the EMG machine loud speaker which is easily recognized by the experienced electromyographer.

Box 6.11.4 EMG

- The electrode is placed in the muscle
- After acute denervation—fibrillations in 7–14 days
- Reinnervation—large motor unit potentials, and simple long waveforms.

Fig. 6.11.6
Electromyogram recording from the first dorsal interosseous muscle from a patient with a severe ulnar nerve lesion. The patient is making a maximal voluntary abduction movement of the index finger. The electromyogram recruitment pattern is severely reduced, there being only a few motor units under voluntary control. The surviving motor units are of high amplitude and fire at high rates.

In muscle disease, a condition only infrequently encountered in hand muscles, motor unit potentials are small and spiky and the recruitment pattern is full (Figure 6.11.4E).

Peripheral nerve lesions

Carpal tunnel syndrome

Sensory studies are usually more sensitive than motor studies. Diagnosis is achieved by demonstrating a slowing of conduction across the carpal tunnel. Orthodromic SAPs from the index finger to the median nerve at the wrist are compared with the ulnar SAPs from the little finger to the wrist (Figure 6.11.7). A median SAP peak latency more than 1.0ms greater than the ulnar value is taken as indicating significant median slowing. Occasionally, the middle finger is clinically more affected, and in this circumstance the SAP from the index finger may be normal but that from the middle finger delayed. Conduction velocity is calculated over the palm-to-wrist segment in the two nerves, and the ratio of ulnar to median conduction velocity is calculated; a ratio of greater than 1.25 indicates significant median slowing. Other protocols are in use but these are less reliable.
Sensory action potentials recorded from median and ulnar nerves at the wrist from stimulation of the digital branches in index and little fingers, respectively, in a case of carpal tunnel syndrome. The median sensory action potential (peak latency 3.6ms) is significantly delayed compared with the ulnar sensory action potential (peak latency 2.4ms).

Motor studies measure the distal motor latency from the wrist to the abductor pollicis brevis muscle and the conduction velocity in the forearm segment. In moderate to severe cases of carpal tunnel syndrome, the distal motor latency is prolonged above the upper normal limit (Figure 6.11.8). Forearm conduction velocity is sometimes reduced in carpal tunnel syndrome, presumably due to retrograde demyelinating changes advancing proximally from the site of entrapment. If marked slowing of velocity is found, conduction velocity in another nerve should be measured in case there is a generalized demyelinating peripheral neuropathy.

EMG can occasionally be useful in carpal tunnel syndrome. It may document the degree of denervation, allowing prognostic statements to be made about the degree and speed of recovery. A weak abductor pollicis brevis that is not wasted, does not show acute denervation, and has a normal distal motor latency will recover to a greater extent and more quickly than a muscle that is wasted, shows active denervation, and has a prolonged latency.

A grading scale (Table 6.11.1) for the neurophysiological severity of carpal tunnel syndrome (from 0–6) has been developed and validated and may be useful as a guide to management. It has been shown that patients with very mild entrapment (grades 1–2) may respond better to steroid injection rather than surgery. Similarly, patients with very severe (grade 5) or extremely severe (grade 6) entrapment will fare less well after surgery because there has been a significant degree of axonal degeneration in the median nerve.

Neurophysiological assessment after ‘failed’ carpal tunnel release is much more difficult. It is best performed in comparison with preoperative measurements. Thus some clinicians, especially neurophysiologists, would recommend all patients have preoperative neurophysiology but this is not standard practice.

Ulnar nerve lesions

Symptoms in the hand may arise from ulnar nerve lesions in the palm, wrist, forearm, or cubital canal, and in general are more difficult to localize neurophysiologically than median lesions. By far the commonest site of entrapment is at or just proximal to the cubital canal at the elbow. Clinical examination is usually indicative: proximal lesions, i.e. at the elbow, may have weakness of the long ulnar supplied muscles, i.e. flexor carpi ulnaris and flexor digitorum profundus to the ring and little fingers and reduced sensation on the dorsum of the hand not present in lesions at the wrist or hand.

There are various steps in assessing ulnar nerve electrical function. The first is measurement of the ulnar SAP from the little finger to the wrist and a comparison with the median SAP from the index finger; a small or absent ulnar SAP confirms loss of sensory axon function but is no help in localization. The next measurement is the SAP from the little finger to the elbow; if this is absent, the lesion must be in the forearm or at the elbow. This may be the only neurophysiological abnormality in mild ulnar nerve lesions. The third comparison is of mixed-nerve action potentials by stimulating the ulnar and median nerves at the wrist and recording at the elbow. An absent ulnar mixed-nerve action potential with a preserved median mixed-nerve action potential from wrist to elbow again implies loss of fibres. The fourth step required for localization are mixed-nerve studies obtained by stimulating the ulnar nerve at the elbow and recording in the axilla. The ulnar elbow-to-axilla mixed-nerve action potential is normally at least twice the size of the ulnar potential from wrist to elbow, but in ulnar nerve lesions at the elbow, the mixed-nerve action potential from wrist to elbow will be small in comparison with the elbow-to-axilla potential, which will be normal.

Conduction block in motor fibres is an important feature to search for. It may explain weakness of hand muscles in the absence of wasting. Motor conduction is measured by recording from the abductor digiti minimi muscle whilst stimulating the ulnar nerve at various sites: the wrist; below the elbow; above the elbow, and in the axilla (see Figure 6.11.3). In young individuals, the CMAP obtained by stimulating the nerve at various sites is almost identical in amplitude. In older people (> 45 years), the CMAP amplitude from more proximal sites may be slightly smaller, but never less than 80%. If, in the absence of significant slowing of conduction, the CMAP drops between two stimulation sites by more than 50% then conduction block can be confidently diagnosed. This technique also allows conduction velocity to be measured in the various nerve segments; in ulnar nerve lesions the velocity often drops by more than 20m/s across the elbow. The abnormality may be accentuated by placing the arm in full flexion and repeating the study. Because of the difficulty of accurately measuring distance in the short segment across the elbow, a fall in velocity of less than 10m/s should be regarded as of doubtful significance.

Lesions of the deep palmar branch of the ulnar nerve (Figure 6.11.9A) are demonstrated by showing that the latency to the first dorsal interosseous muscle from ulnar stimulation at the wrist is prolonged but that to the abductor digiti minimi muscle is within normal limits. The normal maximal latency difference between the two muscles is 4.0ms; differences greater than this suggest a lesion of the deep palmar branch, especially if there are also electromyographic signs of acute denervation in first dorsal interosseous muscle but not in the abductor digiti minimi muscle.
Lesions of the dorsal branch of the ulnar nerve are also occasionally encountered (Figure 6.11.9D). These are usually produced by pressure from, for example, handcuffs around the wrist. In this case, the sensory potential from the fifth digit to the wrist is normal, but the SAP in the dorsal sensory branch is absent. It is essential in these cases to compare the SAPs from the two sides.

Rarer lesions of the ulnar nerve at the wrist include ulnar nerve entrapment as it passes into the hand through Guyon’s canal at the base of the pisiform bone. In some cases, the lesion is distal in the palm in which case there will be denervation of abductor digitii minimi and first dorsal interosseous muscles but the ulnar SAP is normal (Figure 6.11.9B). Less frequently, the ulnar SAP is absent and there is denervation of the abductor digitii minimi muscle indicating a lesion proximal to the origin of the sensory branch in the fourth and fifth digits (Figure 6.11.9C).

The differential diagnosis of ulnar and median nerve lesions always includes cervical radiculopathy, and differentiation of this common condition is vital to prevent unnecessary operations being undertaken. The crux of the issue is to demonstrate denervation in muscles not supplied by the nerve in question. Thus, in the differentiation of ulnar nerve lesions from C8–T1 radicular lesions, it is essential to show that ulnar nerve conduction is within normal limits, and that there is denervation in median supplied muscles that derive their nerve supply from the C8 and T1 roots.

A cervical rib or fibrous band compressing the lower cervical roots can also simulate median nerve lesions. There is often thenar atrophy. In this situation, the median SAPs from the index and middle fingers are normal but the potential from the fifth finger to the ulnar nerve is small or absent, due to degeneration of sensory fibres in the T1 root. The distal motor latency to abductor pollicis brevis is normal but electromyography will show it to be partially denervated (Figure 6.11.10). The F-wave latencies in the ulnar or median nerves may occasionally be helpful in demonstrating proximal slowing in the ulnar nerve fibres.

Other conditions that can simulate ulnar or median nerve entrapments and in which neurophysiology is useful in differentiation include generalized peripheral neuropathies, conditions causing mononeuropathy multiplex (polyarteritis nodosa, Churg–Strauss syndrome, systemic sclerosis, diabetes mellitus, rheumatoid arthritis, amyloidosis), amyotrophic lateral sclerosis, and spinal muscular atrophy, which often present as painless wasting of hand muscles, neuralgic amyotrophy which can cause focal muscle weakness, brachial plexus lesions (radiation plexopathy or neoplastic infiltration of the plexus), dystrophia myotonica in which
EMG reveals characteristic myotonic discharges, and intrinsic cord lesions, especially syringomyelia. In this last case, because the lesion is central to the dorsal root ganglion cells, the SAPs from the fingers are preserved.

**Radial nerve lesions**

Lesions of the radial nerve are less common. In a complete radial palsy there will be wrist and finger drop and sensory disturbance over the dorsum of the hand. They may be traumatic, commonly due to fractures in the midshaft of the humerus or due to prolonged pressure as in ‘Saturday night palsy’. EMG in these cases can be useful prognostically in differentiating between axonal loss where recovery is likely to be slow and incomplete, from conduction block (neurapraxia) where the prospects for complete recovery are much better. If, some 2–3 weeks after the injury, there are no signs of denervation in the paralysed muscles, there is a good chance of recovery. On the other hand, if the finger and wrist extensor muscles show marked acute denervation then a favourable prognosis is less certain, especially if there are no motor units in the muscle that can be activated by volition. These changes also apply in assessing other nerve injuries following open wounds both following injury and surgery. Thus there is little role for neurophysiology acutely but after 2–3 weeks denervation changes may indicate a poor prognosis.

The superficial branch of the radial nerve in the forearm may be externally compressed and gives rise to sensory loss and/or dysesthesiae in the ‘anatomic snuffbox’. Comparison of the radial SAPs from the two sides is useful in demonstrating this lesion.

Rarely, the posterior interosseous branch of the radial nerve may be entrapped as it enters the forearm. Clinically there may be pain in the elbow and forearm, and weakness of the wrist and finger extensors. Nerve conduction studies are usually unhelpful because it is difficult, even with needle electrodes, to stimulate selectively the deeply sited posterior interosseous nerve. However, EMG can be useful in demonstrating denervation in finger and wrist extensor muscles, but normality of the brachioradialis, the branch to which arises from the radial trunk before it enters the forearm.

Tumours and hand reconstruction

Summary points

- Hand tumours are common
- The vast majority are benign
- Soft tissue – commonest Giant cell tumour of tendon sheath. Treatment marginal excision
- Bone – commonest – Enchondroma. Treatment – leave if incidental or curette +/- bone grafting
- Malignant – need full work up with detailed clinical examination, investigation, and planning in a multidisciplinary meeting
- Treatment is wide/radical excision often with partial amputation +/- plastic surgical reconstruction.

Introduction

A multidisciplinary approach which employs improvements in diagnosis, staging, adjuvant therapy, surgical resection, and particularly reconstruction has made limb salvage a viable option in the treatment of most upper-extremity malignancies. The adequacy of surgical resection should be paramount. However, reconstructive considerations should be contemplated during the phase of preoperative planning in order that the best possible functional and aesthetic outcome is achieved. Emphasis should be placed on a thorough evaluation by all members of the treatment team prior to the initiation of treatment. A broad range of techniques are available for both salvage and restoration of function.

In principle, the management of tumours of the bone and soft tissues in the hand and wrist differ little from those encountered elsewhere, except that vital neurovascular structures are more commonly juxtaposed and there is an inherent desire to preserve upper-extremity function. Certain tumours occur more frequently, e.g. ganglion cysts, epidermoid inclusion cysts, and giant cell tumours of the tendon sheath. Conversely, tumours common in other locations present rarely, e.g. metastatic carcinoma, lymphoma, and myeloma. The following guidelines may prove useful in the approach to the patient presenting with a mass in the hand:

- The majority of primary bone tumours of the hand are benign, but large deeply placed tumours in the soft tissues are frequently malignant
- The most common bone tumours in the hand are enchondromas and osteochondromas, except in the terminal phalanx where the most prevalent lesion is the epidermoid inclusion cyst
- The third most common site for giant cell tumours is the distal radius.

The approach to tumours of the hand and wrist incorporates the following principles:

- Clinical examination and investigations aimed at diagnosing and staging the tumour
- Biopsy
- Surgical resection
- Adjuvant treatment
- Reconstruction.

Principles of management (Box 6.12.1)

A multidisciplinary approach to management is mandatory for malignant tumours and some, typically larger, benign tumours. The initial goals of management include diagnosis and staging of the tumour prior to biopsy. The biopsy should be planned with the reconstruction in mind.

Box 6.12.1 Principles of management

The key steps are:

- Diagnosis:
  - Rarely from clinical examination or imaging
  - Tissue is required—incisional or excisional biopsy
- Staging: mainly through imaging, especially MRI
- Treatment:
Patients presenting with a bony mass may be investigated by means of plain radiographs, computed tomography (CT), and magnetic resonance imaging (MRI). The usual criteria for the radiographic analysis of bone tumours include size, shape, location, gross architectural alterations, disturbance of the bony cortex, and the radiological appearance of the matrices of these tumours.

### Staging of tumours of the hand and carpus involving bone or soft tissue

Most tumour surgeons employ the modified Enneking staging system for malignant neoplasms of bone (Table 6.12.1). This is generally also used for staging soft tissue tumours. This staging scheme depends on three primary determinants: the grade of the tumour (G), the anatomical location of the lesion (T), and the presence or absence of distant metastases (M). Benign tumours are usually designated G0, with low-grade malignant lesions classified as G1 and high-grade malignant lesions as G2.

The anatomical location is assessed by imaging studies including CT and MRI. The essential definition is whether there is preservation (T1) or violation (T2) of the involved compartment. For bony tumours, the involved bone fulfils the definition of a compartment, such that extraosseous extension is considered a T2 lesion. Soft tissue tumours that extend beyond the fascial compartment or involve the neurovascular bundle are considered to be T2 tumours.

For giant cell tumours of bone and chondrosarcoma, Campanacci (1976) has devised a grading system (Table 6.12.2). Giant cell tumours are graded into three radiographic types (calm, active, aggressive) and three histological types (typical, aggressive, sarcoma). Chondrosarcomas are also graded into three radiographic and three histological types (grades I, II, III). Cutaneous malignancies such as melanoma have their own unique staging scheme.

The American Joint Cancer Committee Staging System is usually employed in staging melanoma. This system is based primarily on tumour thickness and the presence of lymphatic metastasis. Tumour thickness and ulceration are the major determinants of prognosis. Subungual melanoma represents a specific clinical entity comprising 1–3% of all presenting melanomas. In these patients, tumour thickness is often difficult to determine due to fixation and biopsy techniques.

Staging workup

The approach to patients presenting with either bone or soft tissue tumours includes assessment of the grade of the tumour and the anatomical extent of the lesion, and determination of metastatic spread. The tumour is graded on the histopathology including special stains and even electron micrography. A working clinical diagnosis can usually be formulated on the basis of the physical examination, plain radiographs, and blood tests. This should enable the clinician to distinguish between benign tumours, primary malignant tumours, metastatic tumours, and lymphomatous deposits.

If the lesion is thought to be benign, an excisional biopsy without further workup is appropriate. Frozen section should be employed intraoperatively if there is any doubt. If the lesion is thought to be a primary malignant tumour, further imaging studies (CT or MRI) should be performed to stage the tumour accurately. MRI of the hand and wrist is accurate in the detection of mass lesions and can distinguish benign from malignant tumours in the most cases. In the case of suspected metastatic tumour, appropriate imaging of the probable primary source should be ordered. The focus of this search may be appropriately guided by the results of the biopsy.

Tumour resection (Box 6.12.2)

As a rule, neoplasms of the connective tissues spread locally by invasion of the adjacent vascular and connective tissues rather than by invasion of lymphatics. The adjacent normal tissues become compressed and may demonstrate a fibroproliferative response. This compressed fibroproliferative layer is known as the ‘reactive zone’. Histological analysis of the reactive zone will frequently demonstrate microscopic tumour invasion. Discrete nodular metastases formed within the same compartment are known as skip lesions. These are more frequent with high-grade neoplasms such as osteosarcoma. Several studies have demonstrated the correlation of survival and local recurrence with the adequacy of local control. Based on the proximity of the surgical margin to the tumour and the pattern of tumour spread within the compartment, Wolf and Enneking have devised four types of surgical procedure:
treatment of enchondroma by curettage

- **Marginal**: the surgical plane is in the reactive zone and there is a possibility of residual microscopic tumour or tumour satellite lesions. An example is the excision of a giant cell tumour of the tendon sheath.
- **Wide**: a significant cuff of normal tissue is left surrounding the tumour, but not all the contents of the compartment are resected. The width of the margin should counter the possibility of local satellite lesions but a skip lesion may be left behind. A ray amputation falls into this category.
- **Radical**: the entire compartment containing the tumour is excised en bloc. In theory, this entirely eliminates all local forms of recurrence, but is most costly in terms of loss of limb function. For tumours in the hand and wrist, this would constitute an above-elbow amputation.

**Box 6.12.2 Excision**

- **Intralesional**: e.g. enchondroma
- **Marginal**: e.g. giant cell tumour of the tendon sheath
- **Wide**: e.g. ray amputation for subungual melanoma
- **Radical**: for the hand this would be an above-elbow amputation

There are no set guidelines for deciding when each of these four procedures should be applied. Table 6.12.3 gives a reasonable approach based on the tumour grade.

Factors that may affect this decision include the age and wishes of the patient, functional demands on the limb, and adjunctive chemotherapy or irradiation. At operation, it is vitally important to limit the dissection, and to observe meticulous haemostasis, to limit potential seeding of tumour cells. The biopsy and subcutaneous tract should be included in the specimen. A bone weakened by resection requires protection or definitive reconstruction. If the reconstructive procedure requires the harvest of autogenous tissue, the two surgical sites should be kept separated until such time as the specimen has been removed.

Finally, the entire ablative procedure should be performed only after careful planning and preoperative consultation with the oncologist and the pathologist. Only after an oncologically sound plan has been formulated should consideration be given to the restoration of limb function and form.

**Primary bone tumours of the hand and carpus**

Primary bone tumours of the hand and wrist are uncommon. Of 1046 primary bone tumours in the Netherlands Bone Registry, only 64 (5.8%) occurred in the hand and 3 (0.2%) in the wrist (Table 6.12.4). Of the 420 benign lesions, 53 (12.6%) were in the hand and 3 (0.7%) were in the wrist. No malignancies involved the carpus, whilst eight (1.2%) were in the hand.

The classification of tumours is given in Table 6.12.5.

Table 6.12.5 Classification of bone tumors

- **Chondrogenic lesions**
  - Chondroma
  - Enchondroma
  - Osteochondroma
  - Chondroblastoma
  - Chondromyxoid fibroma

- **Osteogenic lesions**
  - Osteoid osteoma
  - Benign osteoblastoma
  - Osteosarcoma

- **Tumors of uncertain etiology**
  - Giant cell reparative granuloma
  - Fibrosarcoma
  - Ewing’s sarcoma

---

**Adjuvant therapy (Box 6.12.3)**

Postoperative adjuvant radiation therapy is usually employed in the management of malignant tumors when the surgical margin is narrow or for high-grade malignancy. Adjuvant radiation therapy should be considered in sarcomas larger than 6cm and where there is vascular invasion because of the poorer prognosis in these patients. Local recurrence of sarcoma with marginal resection and radiation is greater than with resection alone. The use of adjuvant radiation therapy diminishes local recurrence in extremity sarcomas. The use of preoperative adjuvant radiation therapy can be useful for diminishing tumour size prior to excision. In some patients presenting with sarcomas in the hand and forearm, adjuvant radiation therapy may facilitate limb-salvage surgery as an effective alternative to amputation.
Adjuvant therapy

- Radiotherapy is used but can give late stiffness
- Chemotherapy is used for specific malignancies.

Reconstruction (Box 6.12.4)

Soft-tissue reconstruction: a regional approach

More proximal lesions requiring division of branches of the brachial plexus should warrant a frank discussion with the patient as to the merits of amputation. Slow-growing soft tissue tumours seldom require additional skin coverage. The concomitant expansion of the adjacent tissues will usually ensure that skin closure can be achieved without difficulty. Reconstruction is more often required for rapidly growing tumours or where the provision of an adequate margin of resection dictates a greater need for skin coverage.

Digital coverage

Flap coverage following resection of small tumours in the digits is mandatory if such resection results in exposure of neurovascular structures or tendons. However, where the paratenon covering a particular tendon is intact, a full-thickness skin graft will often provide ideal coverage with minimal donor site morbidity. Where skin grafting is not an option, a local digital flap will provide good coverage of small defects. In principle, these are either harvested from the same finger (homodigital) or an adjacent finger (heterodigital). The use of heterodigital tissue for the reconstruction of a skin defect is only recommended following excision of benign tumours.

Thumb:
- Very important for hand function
- Length, stability, sensibility
- Many options

Dorsal hand: regional or free flaps

Palm:
- More specialist tissue
- May need tissue from sole of foot

Bone and joint: typically fusion for joint loss.

Thumb reconstruction

Amputation of the thumb constitutes a significant functional loss, rendering reconstruction a priority. The major goal of reconstruction is to provide a stable thumb of sufficient strength and length in the correct position. Lesser priorities for the reconstructed thumb are motion, sensibility, and appearance. Reconstructive alternatives following amputation of the thumb depend primarily on the length of the thumb remnant and the presence of the basal joint.

In subtotal amputations, metacarpal lengthening by distraction may provide adequate length. In total amputations, the options include osteoplastic reconstruction, pollicization, or toe-to-hand transfer. Which of these options is chosen depends on patient factors, such as compliance, suitability for microvascular surgery, and the level of the amputation, as well as surgical preference. Reconstruction of the thumb with tissue derived from the great toe gives the best results in patients suited to this procedure. This is by far the superior technique for thumb reconstruction. The tissue derived from the foot can be used in various ways. These include resurfacing of the skeletal thumb by the wrap-around technique, the trimmed great toe transfer, which minimizes the bulk of the great toe, and transfer of the second toe. Pollicization can yield excellent results, but in adults it is usually best reserved for the patient with pre-existent partial index finger amputation. Osteoplastic reconstruction, using a groin flap combined with bone grafting, is suitable for patients who are not candidates for microsurgery.

Dorsal hand coverage

In general the larger defects created by tumour ablation over the dorsum of the hand require flap coverage that cannot be satisfied by local tissue alone. One exception is where a fillet flap can be harvested from a digit to resurface a dorsal or palmar skin defect. The options include pedicled flaps from the groin or chest wall, regional flaps from the ipsilateral forearm, and free tissue transfers.
Based on the superficial circumflex iliac vessels, the groin flap has proved reliable for the resurfacing of dorsal hand defects. However, the use of the pedicled groin flap is limited to reconstruction following benign tumour resection. Although reliable, it commits the patient to a period of inactivity whilst the pedicle is attached, with the potential for stiffness in the small joints of the hand. Its use as a free flap obviates the need for a pedicle.

**Forearm flaps**

Flaps derived from the forearm include those based on fascioseptocutaneous perforating branches from the radial artery, the ulnar artery, and the posterior interosseous artery. They are referred to as the distally based radial forearm, ulnar forearm, and posterior interosseous flaps respectively, and are indicated for reconstruction following removal of benign tumours. Free tissue transfer is a better option for malignant tumours. Inherent in the use of local tissues for resurfacing skin defects is the concern about tumour seeding in the flap donor site. In the case of the radial and ulnar forearm flaps, there is the additional concern of deprivation of a major source of arterial inflow in the extremity. Donor site morbidity in the form of delayed healing is common, particularly where primary closure of the donor site is not possible. The posterior interosseous flap, although probably the least reliable of the group, has significantly less donor site morbidity.

**Free tissue transfers**

The ideal flap would provide durable coverage with the potential for a gliding environment without being too bulky. Broadly, the options include free muscle, skin, or fascial transfers. The success rate for free tissue transfer in large series now approaches, or equals, 100%. Cost analysis has demonstrated a significant saving with free tissue transfers compared with pedicled flaps.

There are many options with their own particular merits and limitations. They include: the gracilis and sartorius anterior as small to medium free muscle flaps; the latissimus and rectus abdominis as large muscle flaps; the contralateral ulnar flap, the free groin flap, and the scapular flap as skin flaps; and the serratus anterior fascia, the superficial temporal fascia, the lateral arm fascia, and the scapular fascia as fascial flaps.

**Coverage of the palm**

The uniquely sensate glabrous skin of the palm is ideally suited to prehension. The particular aim of reconstruction in the palm should be sensate skin which is of similar volume, texture, and colour. For smaller defects, a large variety of local pedicled or island flaps can be applied. The reconstruction of large palmar defects of the hand remains a difficult problem because of the specificity of the anatomic structures and the highly sophisticated function of the palm. Free tissue transfer remains the preferred alternative for larger defects with exposed tendons, nerves, or other essential structures. The medial plantar flap provides the capability of transposing glabrous skin from the non-weight-bearing instep of the foot to the palm of the hand. Occasionally, owing to the relative abundance of subcutaneous tissue in the palm, vital structures may be protected such that a full-thickness or thick split-thickness skin graft from the sole of the foot will suffice.

**Bone and joint reconstruction**

The treatment of benign tumours of the phalanges is usually intralesional treatment involving curettage only or curettage and bone grafting. Amputation is usually indicated for benign tumours with extraperiosteal spread or for malignant tumours. The rate of metastasis of chondrosarcomas presenting in the phalanges is very low, unlike those occurring elsewhere in the body. Treatment of this locally aggressive lesion may be by curettage rather than amputation if the latter may result in significant functional loss.

Reconstruction is generally required for tumours of the metacarpals, the distal radius, and the distal ulna that fall into one of the following three categories:

- Recurrent benign tumour
- Benign tumour with extraperiosteal spread
- Malignant tumour.

This applies to tumours in stages 2 or 3 of the Enneking grading system, or grades 2 or 3 of the Campanacci radiological grade.

**Reconstruction of the distal radius**

The distal radius is a relatively common site for skeletal neoplasms and is the third most common site of giant cell tumours. Resection of the distal radius is indicated for malignant neoplasms, as well as for locally recurrent or invasive benign tumours. Many patients who fall into this category are relatively young and have high functional demands. The limited soft tissue coverage in this area and the proximity of neurovascular structures and tendons add to the difficulty in achieving clear marginal clearance of tumours of the distal radius. The pronator quadratus is a useful watershed on the volar aspect of the radius. Curettage remains the mainstay of management in cases where the tumour is confined within the radius. The resultant intramedullary bone defect can be filled with autogenous cancellous bone or methylmethacrylate cement, or it can be left unfilled. Oxytomy or phenol instillation is used in an attempt to reduce the incidence of local recurrence. Giant cell tumours are particularly prone to recurrence after curettage, especially in the distal radius where recurrence rates of 50% have been reported. Malignant change in recurrent giant cell tumour may be associated with irradiation. For these reasons, en bloc resection and reconstruction of the distal radius may be necessary.

In the reconstruction of the distal radius, the surgeon needs first to decide whether or not to retain wrist motion. Factors contributing to this decision include the proximity of the tumour to the joint, the tumour grade, and patient preference. The reconstructive options that retain wrist motion include excision arthroplasty, prosthetic replacement, ulnar translocation of the carpus, allograft replacement, and the use of a non-vascularized fibular bone graft or a vascularized fibular bone graft. Depending on
the nature of the bony defect, and if a decision has been made to sacrifice wrist motion, a vascularized or non-vascularized bone graft will usually be required at the time of the arthrodesis. However, recent reports have focused on the use of either osteoarticular allograft or vascularized bone grafts in the management of this difficult reconstructive problem.

The use of cadaveric osteoarticular allograft employs a size-matched fresh-frozen distal radial allograft. The advantages of this technique include the ability to provide an exact three-dimensional reconstruction and to reconstruct larger defects, including ligamentous reconstruction, and the absence of a donor site. Despite the encouraging results with this technique, non-vascularized autogenous bone grafts are predisposed to delayed union, stress fracture, resorption, and collapse.

The primary advantage of vascularized autogenous bone grafts is a lower fracture rate compared with large non-vascularized bone grafts or cadaveric bone grafts. Vascularized bone has a greater propensity to hypertrophy as well as a diminished tendency to non-union. Osteotomy sites heal in a fashion more akin to fracture healing than bone-graft incorporation. Furthermore, bony healing occurs irrespective of the dimensions of the vascularized bone segment. An additional advantage in the use of vascularized bone is the facility to provide skin as part of a composite skin–muscle reconstruction. In order to reduce the fracture rate further, the fibula can be double-barreled for additional strength and bulk. When harvested correctly, the donor site morbidity should not be significant. When used for upper-extremity reconstruction, the vascularized fibula may not be capable of the hypertrophy seen in the lower extremity, particularly where the fixation is rigid.

Distal ulna

As for the distal radius, T1 lesions of the distal ulna may be treated by curettage and bone grafting. Tumours that are not amenable to curettage may be resected en bloc with good functional results. Where the tumour extent allows subperiosteal resection, the ulnar collateral ligament and triangular fibrocartilage complex are amenable to reconstruction. This will significantly reduce the incidence of instability following resection. An ulna-stabilizing procedure may be necessary for the patient with demonstrable ulna instability following resection.

Outcome analysis

Standard systems have been derived for the evaluation of outcome following reconstructive procedures after tumour excision. It is recommended that these are used to facilitate comparison of reconstructive techniques.

Ganglia of the wrist and hand

Summary points

- Ganglia are common; typically age 20–40, in women more so than men
- Cause: unclear but associated with underlying ligament or tendon ‘irritation’ or joint osteoarthritis
- Diagnosis: usually obvious. Investigations are generally not needed
- Most recover spontaneously especially in children
- Good operative techniques are generally successful.

Incidence

Ganglia have featured in medical literature for over 250 years. They represent approximately two-thirds of all hand swellings and are most commonly seen between 20–40 years of age. However, they may be found in any age group. Annual incidence rates for ganglia of the wrist and hand are approximately 25 per 100,000 and 43 per 100,000 for males and females respectively.

Pathology

Ganglia present as smooth round swellings which vary in consistency from soft to bony hard, depending on the pressure within them. They may be single or multicellular but are seldom attached to skin.

Histologically, the ganglion wall consists of compressed collagen fibres lined by a few flat cells. There is no true epithelial or synovial lining membrane. The typical clear mucinous fluid within the cyst contains high concentrations of hyaluronic acid, together with glucosamine, globulin, and albumin.

Several lines of evidence indicate that the contents of ganglia originate from synovial cavities (i.e. joint or tendon sheath) nearby, but it is unclear if ganglion fluid is simply synovial fluid which has escaped from the joint or if it is formed by cells in the synovium at the origin of the ganglion. Ganglion fluid closely resembles synovial fluid in its composition. Ganglia are almost exclusively found near a joint or tendon sheath, with which a communication can often be demonstrated. Arthrographic and cystographic studies have shown that dye will frequently pass from joint to ganglion but, in the few cases studied, not in the reverse direction. The classical study of Angelides and Wallace (1976) examined the capsular attachments of 64 dorsal wrist ganglia under magnification in situ. In all cases, the ganglion arose from the dorsal surface of the scapholunate ligament. After dissection of the capsular portion of the ganglion from the scapholunate ligament, a small quantity of ganglion fluid seeped from the surface of the ligament in every case. Examination of this area under magnification showed that small gaps appear between the transverse ligament fibres in dorsiflexion and close in flexion. The capsular origin of the ganglion contained many small cystic spaces that were shown by serial sections to be parts of a tortuous continuous duct that connected the ganglion cyst with the joint. The hypothesis is that synovial fluid passes from the scapholunate joint along a continuous duct that acts as a one-way valve between the scapholunate ligament and the main ganglion cyst. Whether similar mechanisms operate at other sites of ganglia is unknown. The predilection for the four typical sites in the hand and wrist has not been explained. There is no good evidence to support traumatic or inflammatory aetiologies.

Clinical features

Patients present with swelling which may be accompanied by pain, stiffness, or weakness of the associated joint. Variation in size over time, especially a reduction in size, is virtually diagnostic of ganglion. Large ganglia may show the sign of fluctuance and may be transilluminated.

Obscure wrist pain is sometimes caused by an occult ganglion; there is local tenderness at one of the typical sites (usually the dorsum of the wrist) but the ganglion is too small to be visible or palpable. Occult ganglia can be identified by ultrasound or magnetic resonance imaging (MRI).

Ganglia resolve spontaneously in around 40% of cases. They may produce symptoms by extrinsic compression of adjacent structures such as the ulnar nerve in Guyon’s canal and the median nerve in the carpal tunnel. Pressure on the terminal branch of the posterior interosseous nerve at the wrist may account for the pain caused by dorsal wrist ganglia.

Ganglia are most usually classified according to their site of origin (Table 6.13.1).

Dorsal wrist ganglion

The most common type of ganglion arises from the wrist capsule over the dorsal surface of the scapholunate ligament. The pedicle that connects the ganglion with its articular origin may pass some distance beneath the extensor tendons before coming to the surface, so the ganglion itself may present some distance from the scapholunate area (Figure 6.13.1). When planning the removal of a ganglion that is not located in the typical site, the possibility of a connection with the scapholunate ligament should be borne in mind, so that an incision can be designed to allow access for excision of the pedicle (the key to successful surgical treatment) without leaving an unsightly scar.

Palmar wrist ganglion

Palmar wrist ganglia typically present at the proximal wrist crease between the radial artery and the flexor carpi radialis tendon (Figure 6.13.2). Two-thirds originate from the radiocarpal joint at the scapholunate interanel, the remainder arise from the scaphotrapezial joint. Ganglia arising from the scaphotrapezial joint may track along the tendon sheath of flexor carpi radialis and come to the surface some distance from their origin. Palmar wrist ganglia may occur in older patients in association with scaphotrapezial osteoarthritis. In these cases, the risk of recurrence is high unless the underlying arthritis is also treated by arthrodesis or excision arthroplasty. The symptoms seldom justify surgery of this magnitude.
Fig. 6.13.2
Palmar wrist ganglion presenting between the flexor carpi radialis tendon and the radial artery.

These ganglia may be closely related to the radial artery and require careful dissection from it. A preoperative Allen test and tourniquet release before skin closure should be considered when excising palmar wrist ganglia.

Palmar wrist ganglia may be more extensive than clinical examination suggests. An extensile surgical approach is advisable, so as to deal with possible extensions under the thenar muscles, into the carpal tunnel, and along the sheath of flexor carpi radialis tendon. Excision of palmar wrist ganglia should be approached with caution. Small subcutaneous nerve branches are prone to produce painful neuromas if injured in this region. It is not always easy to identify the pedicle of the ganglion, the scar may be unattractive, and the recurrence rate is higher than for dorsal wrist ganglia (Table 6.13.2).

**Flexor sheath ganglion**

A 2- to 5-mm-diameter ganglion, also known as volar retinacular ganglion or seed ganglion, commonly arises from the A2 pulley of the flexor tendon sheath at the proximal digital crease.

Patients complain of accurately localized pain when gripping objects such as the steering wheel of a car or when carrying objects. The ganglion is small, hard, and tender. It sits on the external surface of the tendon sheath in the midline or just to one side it and does not move with the tendon. The ganglion may be punctured with a fine needle inserted in the midline of the digit, so as to avoid the digital nerves, and its contents dispersed by firm massage. If the ganglion persists or recurs, it may be excised together with a small disk of tendon sheath. Care should be taken to preserve the major part of the A2 pulley. Recurrence after excision is very uncommon.

**Dorsal digital ganglion**

Ganglia arising from the distal interphalangeal joint are sometimes known as mucous or myxoid cysts. They occur in older individuals and are often associated with early osteoarthritis of the distal interphalangeal joint. Pressure from the ganglion on the germinal matrix may produce a furrow in the fingernail; the furrow may appear before the ganglion is evident (Figure 6.13.3).
The ganglion arises from the joint capsule between the collateral ligament and the extensor tendon, presenting just to one side of the midline, typically between the distal joint crease and the eponychium but occasionally proximal to the distal interphalangeal joint. The overlying skin may become very thin, giving the ganglion a pearly appearance and leading to occasional discharge of clear viscous fluid.

Operative excision requires removal of the cyst in continuity with a block of joint capsule between the extensor tendon and collateral ligament. The nail matrix should be protected. A local synovectomy and removal of osteophytes may help to prevent recurrence. Small defects in the thin skin overlying the ganglion will heal spontaneously. In the rare case of a large defect, a full-thickness skin graft or dorsal advancement flap may be required. The risk of recurrence is probably less than 5%.

**Intraosseous ganglion**

Intraosseous ganglia are uncommon. The most frequent site is the radial border of the lunate (Figure 6.13.4), where a communication between the lesion and the scapholunate joint is usually found. Computed tomography (CT) examination and operative exploration often show a communication that is not evident on plain radiography. The predilection of intraosseous ganglion for bones on each side of the scapholunate joint suggests that intraosseous and soft tissue ganglia share a common, as yet unknown, pathogenesis.

**Intraneural ganglion**

Intraneural ganglia are rare. The ganglion is usually located within the nerve sheath and may extend for some distance above and below the point at which it is clinically obvious. The cause of intraneural ganglia is not clear. One theory is that synovial fluid gains access to the epineurial sheath where an articular nerve branch enters the joint capsule and runs proximally into the main nerve.
trunk. Mucoid degeneration and fibrous tissue metaplasia have also been proposed. Although the most common site is within the common peroneal nerve at the knee, intraneural ganglia have been reported in the radial, median, and ulnar nerves (Figure 6.13.5).

Fig. 6.13.5
Intraneural ganglion cyst of the ulnar nerve at the wrist

**Investigation**

A confident diagnosis of ganglion is usually possible on the clinical features alone. If necessary, the diagnosis can be confirmed by aspiration of the typical ganglion fluid. Ultrasound can demonstrate the cystic nature of the swelling. MRI is helpful in the diagnosis of occult wrist ganglia and in delineating the site and extent of ganglia that present in unusual locations.

Plain radiography is useful in excluding other causes of wrist pain and should be performed before a ganglion is treated operatively. CT imaging may be useful in diagnosis of intraosseous ganglion and identification of a communication with an adjacent joint.

**Treatment**

The management of ganglia is influenced by several facts: ganglia are harmless; some ganglia disappear spontaneously; recurrence is possible after aspiration or excision; and excision is not without complications.

The options for treatment of ganglia are reassurance, aspiration, and excision. Some patients are concerned about the development of a mass, but have few symptoms and are content with reassurance that the swelling is harmless.

Aspiration of ganglia requires a wide-bore needle, taking appropriate care of adjacent structures such as the radial artery. Studies of aspiration of ganglia have shown quite disparate rates of recurrence that may be explained by differences in case mix. Palmar wrist ganglia appear to have a significantly higher risk of recurrence after aspiration (Table 6.13.3). Aspiration may be accompanied by attempts to puncture the cyst wall with the needle or by instillation of steroid, or followed by immobilization. It is uncertain if these manoeuvres reduce the risk of recurrence after aspiration. Ganglia that recur after aspiration tend to do so within 3 months. Flexor sheath ganglia are too small for aspiration but can be dispersed by firm pressure after puncturing the cyst wall with a needle.

</tbody>
</table>

Successful excision of wrist ganglia depends upon the identification of the pedicle connecting cyst to joint. The pedicle should be excised together with a disc of surrounding joint capsule. Closure of the capsular defect is difficult, unnecessary, and may restrict movement of the wrist. Contrasting evidence exists regarding the use of immobilization after surgical excision. Most authors recommend that movement should begin as soon as possible postoperatively, since immobilization may lead to stiffness.

Arthroscopic excision of dorsal wrist ganglia is no more reliable at reducing recurrence rates than open excision.
Although recurrence is much less frequent after excision than after aspiration (Tables 6.13.2 and 6.13.3), the benefits of excision must be considered against the risks. The mere presence of a ganglion is not an indication for surgery. In addition to general risks of haematoma and infection, local complications such as tender or hypertrophic scars, injury to superficial sensory nerves, and loss of wrist motion occur in up to 8% of patients. These may mar the result. The small but real risk of complications should tilt the decision away from surgery unless the ganglion is persistent and the cause of significant symptoms.

Further reading

Summary points

- Common
- Typically with common bacteria: *Staphylococcus* or *Streptococcus*
- Typically in common sites:
  - Fingertip
  - Tendon sheath
  - Deep palmar spaces
- Atypical infections such as MRSA becoming more frequent.

Introduction

Hand infections can result in severe disability, including stiffness, contracture, and amputation, particularly if treatment is inappropriate or delayed. Modern antimicrobial medication and prompt surgical intervention have made most infections in the hand treatable with the expectation that normal, or near normal, hand function will return. This expectation should not lead to complacency as infections in the hand can present in a myriad of ways and unusual organisms can sometimes evade definitive diagnosis by even the most astute clinician.

Incidence

This is difficult to determine and relates to the specific type of infection involved. One recent study of patients requiring admission to hospital in the United States found that human bites were the commonest infection (51%) followed by cellulitis (17%) and septic arthritis (11.8%). Paronychia was responsible for only 0.45% of admissions, although this is widely held to be the commonest hand infection overall.

Anatomy

The unique anatomy of the hand results in certain typical presentations of infection and dictates the principles necessary for subsequent surgical drainage. Dr Allen Kanavel, a Chicago general surgeon, treated hand infections in the preantibiotic era and undertook detailed studies of infection in the hand. The findings from these studies still underpin our understanding of how infections spread in the hand and how they may be effectively treated.

Fingertip

The fingertip is made up of multiple small compartments divided by connective tissue trabeculae. These trabeculae provide mechanical support to the fingertip pad and are filled with sweat glands that open in the skin and allow bacteria to enter. The nail complex consists of special tissues that are difficult to replace. The nail bed, below the nail plate, consists of the sterile and germinal matrix. Proximally the nail plate lies below the nail fold and to either side of the nail plate lies the eponychium.

Tendon sheaths

Tendon sheaths are double walled with a visceral layer closely adherent to the tendon (the epitenon) and a surrounding parietal layer adherent to the pulleys. These tubular structures are joined at their ends, forming a closed system that is a conduit for bacterial spread. The index, long, and ring finger tendon sheaths start at the distal interphalangeal joint (DIPJ), end at the A1 pulley in the palm, and drain into the midpalmar space. The thumb and little finger, however, have tendon sheaths that extend proximal to the transverse carpal ligament as the radial and ulnar bursae, respectively. These two bursae may communicate with each other, and enter the forearm, through Parona’s space. The tendon sheaths are very close to the skin over the volar proximal interphalangeal joint (PIPJ) and DIPJ creases.

Deep palmar spaces

These were originally described by Kanavel. The spaces are bound by bones and soft tissues septae that dictate how infection spreads. The midpalmar space encompasses the area from the base of the palm to just below the web space and is bounded by the middle metacarpal bone radially and by the hypothenar eminence ulnarly. The thenar space is the area between the thenar eminence and middle metacarpal bone while the hypothenar space is over the hypothenar eminence.

Deep subfascial spaces

There are three more spaces in the hand that can become infected: the dorsal subcutaneous space (superficial to the extensors),
the dorsal subaponeurotic space (between the extensors and the metacarpals), and the interdigital web space. These spaces are less well defined anatomically but infection here may present in a similar fashion to that of the deep spaces.

**Box 6.14.1 Pathophysiology**

- **Systemic features** e.g. immunocompromise, diabetes
- **Local features** e.g. repetitive insults, tissue damage
- **Changing pathogens**—MRSA becoming more common.

### Pathophysiology (Box 6.14.1)

#### Systemic factors

Individuals who are immunocompromised for any reason are at greater risk of developing acute, chronic, atypical, and life-threatening hand infections. As a result, they require more aggressive and prolonged therapy than other patients. Diabetics and drug abusers probably represent the commonest patients in this category but the very old and very young can also be affected.

Individuals with peripheral vascular disease resulting in poor blood flow to the extremities are also predisposed to infections, such as patients with scleroderma.

#### Local factors

The hand has natural barriers to infection, but local conditions can weaken these defences. Direct skin penetration from trauma or bites can introduce a variety of pathogens. Repetitive microtrauma or repeated environmental insults can also weaken defences and predispose to various chronic infections. Gross contamination, or crushing, results in devitalization of tissues that can allow opportunistic infections to occur. Surgical incisions and implants are other risk factors.

#### Changing pathogens

*Staphylococcus aureus* is the most common cause of skin and soft tissue infections in the hand, as elsewhere in the body. Methicillin-resistant strains have increasingly been identified (MRSA). In some institutions, upwards of 50% of cases were caused by MRSA. It is important to recognize this changing pattern, modify antibiotic regimens appropriately, and obtain definitive microbial cultures whenever possible, even in apparently simple cases. Liaison with the microbiology team is advised. Human and animal bites are frequently infected by unusual, often more virulent, bacteria.

### Clinical evaluation

#### History

A thorough history is essential, and suggests the likely organism(s) and best course of treatment. Careful enquiry must be made as to the mechanism of any precipitating injury, the environment in which the injury occurred, the time since injury, and any treatment that has been given. Risk factors for immune compromise, tetanus status, work activities, and hobbies should all be ascertained.

#### Examination

This should start with an assessment of any systemic signs of toxicity including temperature and vital signs. The regional lymph nodes should be palpated. The hand and forearm should then be inspected methodically, bearing in mind the anatomical considerations discussed earlier.

In an acute infection look for wounds and skin breaks, warmth, erythema, oedema, tenderness, and fluctuant collections. Differentiate uncomplicated cellulitis from that overlying an abscess or infected joint. All potential spaces should be palpated for tenderness, keeping in mind the possibility of spread along a defined space. For example, it is important to palpate the forearm in a little finger infection and palpate the midpalmar space in a middle finger laceration. It is sometimes useful to mark the extent of any erythema on the skin with a marker pen to allow subsequent comparative assessment.

**Box 6.14.2 Assessment**

- **History:**
  - Typically diagnostic
  - Time from inoculation is critical
- **Examination:**
  - Classical features, e.g. red, swollen, tender, pus
Check for extension
Beware deep infections.

In chronic infection the signs may be less florid with solid feeling, indurated tissues, sinuses, and ulcers.

Some infections have very characteristic appearances whilst other conditions can closely mimic infection. Some examples of this are discussed later in this chapter.

**Common sites of infection (Box 6.14.3)**

**Fingertips**

**Paronychia**

Paronychia affects the eponychial folds around the fingernail. Only refractory cases usually present to the hand surgeon.

**Acute paronychia**

Acute paronychia usually follows local trauma to the nail fold from biting nails, aggressive manicuring, or a hangnail. Pus below the nail plate can cause pressure on the germinal matrix and temporary or permanent arrest of nail growth.

Most acute paronychia are mixed infections. *Staphylococcus aureus* is the commonest bacterial isolate but other aerobic organisms such as *Streptococcus* spp. and *Eikenella corrodens* are also frequently present. Anaerobic species are also frequently isolated such as *Peptostreptococcus* spp. and *Bacteroides*.

Investigations are rarely needed.

Early acute cases can be treated with warm saline soaks, oral antibiotics (co-amoxiclav covers most of the common bacterial pathogens) and rest. Once an abscess develops it should be drained under ring block anaesthesia. If pus is found below the nail plate this should be removed to facilitate drainage.

**Chronic paronychia**

Chronic paronychia is a multifactorial inflammatory reaction to irritants and allergens often with superadded infection. The patient presents with a well-circumscribed, indurated, retracted, and rounded nail fold. The patient (92% female) often gives a history of frequently soaking the hands in water. Housewives, bartenders, dishwashers, nurses, swimmers, and children who suck their fingers are often affected. Diabetics and patients with psoriasis can also develop this condition. Surgical exploration reveals no collection of pus.

**Box 6.14.3 Common soft tissue sites for infection**

- **Paronychia**—nail fold:
  - Acute and chronic
  - Typically *Staphylococcus*

- **Felon**—pulp infection
  - Typically *Staphylococcus*
  - Very quick onset of marked pain
  - Pus needs releasing

- **Flexor sheath**:
  - Usually follows puncture wound
  - *Staphylococcus* or *Streptococcus*
  - Surgical emergency to avoid tendon problems

- **Deep palmar infections**:
  - Uncommon and easily missed early
  - *Staphylococcus*
  - Requires surgical drainage.

In chronic paronychia, *Candida albicans* is implicated in up to 97% of cases. Subacute, superadded bacterial infection may also occur with normal nail fold colonizers such as *Pseudomonas aeruginosa*. 
With a prolonged history, radiographs to exclude osteomyelitis and blood markers of inflammation (such as C-reactive protein) can be useful. If a fungal infection is suspected biopsy, Gram stain, or culture may be necessary.

Treatment includes activity modification and prolonged application of a topical antifungal. Oral antifungals are an alternative but neither approach consistently heals more than 40% of lesions. Eponychial marsupialization (excision of a crescent-shaped piece of skin proximal to the nail fold) should be considered if medical treatment fails.

Complications include stiffness, tenderness and hypersensitivity, nail growth disturbance, osteomyelitis, and recurrence. In chronic cases, nail discolouration may occur following secondary *Pseudomonas* colonization.

### Felon

A felon is an infection of the palmar pad of the finger.

Often the patient gives a history of a minor injury to the fingertip such as a fingerstick test for glucose estimation. Due to the tight compartments in the pulp, pressure rises rapidly in this condition and results in severe pain, swelling, and throbbing of the digit. Tissue breakdown can occur with progressive ischaemia and osteomyelitis is a risk if the condition is not rapidly treated.

The commonest organism isolated is *Staphylococcus aureus* with methicillin-resistant strains being reported.

If the felon is treated very early, antibiotics and elevation may suffice when no collection of pus has formed, otherwise treatment involves incision and drainage under ring block anaesthesia with antibiotic coverage. The incision must be planned carefully to avoid a painful scar in an important functional area. A longitudinal, midaxial incision is usually best. Avoid the digital nerve, ensure that the incision enters all the affected compartments of the pulp, and leave the wound open after a thorough irrigation.

Complications are similar to those for paronychia but also include pulp necrosis and DIPJ septic arthritis.

### Flexor sheath

Acute infections in the closed system of the flexor sheath can rapidly destroy the smooth gliding surfaces necessary for normal tendon function. Infection can also impair the blood supply to the tendon resulting in necrosis. This condition is a surgical emergency if devastating loss of function is to be avoided.

There is usually a history of a puncture wound on the volar side of the finger that can be very small. Animal and human bites can also be causative. Haematogenous spread rarely occurs and is most frequently gonococcal.

Kanavel described four cardinal signs of tenosynovitis:

1. Tenderness over the entire flexor tendon sheath
2. Swelling of the digit
3. Semiflexed position of the digit
4. Severe pain on passive extension of the digit.

*Staphylococcus aureus* and *β*-haemolytic streptococci are the most commonly isolated organisms. *Pasteurella multocida* is frequently found in association with animal bites. Other unusual organisms should be considered in the diabetic or immunocompromised patient.

This is primarily a clinical diagnosis, but blood tests and radiographs may be undertaken to monitor treatment and exclude foreign bodies, joint involvement, and unsuspected fracture.

Joint infection and inflammatory conditions, such as rheumatoid arthritis or gout, can mimic this condition.

Immediate drainage is almost always indicated for this condition. Ideally, microbiology specimens should be obtained prior to commencing antibiotics. Opening both ends of the flexor sheath via transverse skin incisions over the transverse palmar crease and the volar DIPJ crease and washing out using a paediatric feeding catheter is a useful technique. The catheter can be left in for sheath irrigation on the ward if necessary. Midaxial incisions are recommended if further exposure is required. Postoperative elevation and early motion are essential. Repeated washouts can be necessary.

Complications include stiffness and tendon necrosis.

### Deep spaces of the hand

These infections present with swelling of the whole hand, particularly the dorsum where the fascial attachments are looser. There is often a history of penetrating injury. Local areas of exquisite tenderness may overlie a deep collection. The thenar space is the most commonly affected deep space and the interdigital webspace (collar button abscess) is the most commonly affected subfascial space. A characteristic of webspace infection is abduction of the adjacent digits caused by pus between the bases of the fingers.

Blood tests and radiographs should be obtained. Ultrasound can be helpful in localizing an abscess but should not delay treatment when there is sufficient clinical suspicion of a collection. *Staphylococci* are the commonest isolated organisms.

These infections are surgical emergencies. Various approaches have been described but in all cases adequate exposure is required whilst avoiding subsequent contracture and iatrogenic injury. A thenar space infection is best drained through volar (thenar...
crease) and dorsal (transverse parallel to the edge of the web space) approaches. A combined approach is also used for a collar button abscess. Postoperatively, the wounds are left open to drain with strict elevation, regular dressings, intravenous antibiotics, and early motion. Repeated washout can be necessary.

Complications include tendon adhesions, scarring, joint contracture, skin necrosis, and iatrogenic injury.

**Joints (Box 6.14.4)**

Septic arthritis is characterized by a purulent exudate within a joint caused by the introduction and proliferation of pyogenic bacteria. Rapid articular destruction can ensue frequently, making this condition a surgical emergency.

In the hand there is usually a history of penetrating trauma from a bite or foreign body. Joint arthroplasty infection can present acutely early after implantation. Many inflammatory conditions can mimic a septic arthritis and this should be borne in mind when taking a history. Common mimics include gout, pseudogout (particularly in the elderly wrist), rheumatoid arthritis, and reactive arthritis.

Symptoms of septic arthritis can include systemic sepsis, decreased range of motion, and severe pain on joint movement. With a longer history, in smaller joints, the findings can be less florid.

*Staphylococcus aureus* and *Streptococcus* spp. are the most commonly isolated organisms but Gram-negative and mixed infections can also occur.

Blood tests, including cultures, and x-rays should be obtained. A joint aspiration can be useful when the diagnosis is in doubt, particularly in the wrist. Visible organisms confirm the diagnosis.

**Distal interphalangeal joint**

This usually presents with an established infection where the articular cartilage is already destroyed. Surgical exploration is often not necessary as symptoms will settle on 6 weeks of oral antibiotics.

**Box 6.14.4 Joint infection**

- Common, especially DIPJ
- Usually a puncture wound
- Radiography is suggestive
- Aspiration is confirmative
- Typically *Staphylococcus*
- The more distal the less need for washout, especially DIPJ
- Antibiotics for 6 weeks.

**Proximal interphalangeal joint**

Arthroscopy is performed through a midaxial incision with excision of the accessory collateral ligament to gain access to the joint. Dorsal wounds or sinuses put the central slip at risk and this area should be explored if necessary to avoid a subsequent boutonnière deformity.

**Metacarpophalangeal joint**

Any wound on the dorsum of this joint should be assumed to be related to a punch injury and therefore be treated as a human bite and explored early. A dorsal longitudinal or curved incision is used, either splitting the tendon or opening the sagittal band to gain access to the joint. Look carefully for joint damage or retained fragments of tooth.

**Wrist joint**

A thorough arthroscopic washout can be used to treat this joint or an open arthrotomy between the third and fourth extensor compartments.

Wounds are left open postoperatively to heal by secondary intention. Strict elevation, regular dressings, and early motion (passive and active) are essential if good results are to be achieved. Repeated washouts can be necessary. The length of antibiotic treatment depends on patient factors and the organism identified. Intravenous antibiotics for 2 weeks followed by 4–6 weeks of oral therapy are usually suggested but consultation with the microbiology team is advised.

Results correlate with the durations of symptoms before treatment is started. Joint stiffness is very common as is joint arthrosis. Other complications include tendon adhesions and osteomyelitis. Salvage procedures include arthrodesis, resection arthroplasty, or amputation, depending on the site.

**Bones (Box 6.14.5)**

Osteomyelitis is rare in the hand because of the excellent normal blood supply. The commonest bone affected is the distal
A history of penetrating trauma or a contaminated open fracture is usually obtained but postoperative infection also occurs as does haematogenous spread, particularly in children. The presentation is with local signs of infection with or without a collection. Soft tissue signs may predominate and a high index of suspicion needs to be maintained, particularly with immunocompromised hosts. Systemic signs can be present.

The most common organism isolated is *Staphylococcus aureus*. Coagulase-negative staphylococci have been isolated in conjunction internal fixation devices and polymicrobial infection can occur with open fractures or in the immunocompromised.

**Box 6.14.5 Bone infection**

- Uncommon except with joint infection or following surgery
- Radiography may be diagnostic
- Aspiration is confirmative but often not needed
- Typically *Staphylococcus*
- Most settle with antibiotics for 6 weeks
- Surgical excision and reconstruction may be required.

Blood tests and baseline x-rays should be obtained. Soft tissue swelling is the earliest radiographic sign with osteopenia, osteosclerosis, and a periosteal reaction occurring at least 14 days after the onset of infection. Ultrasound, magnetic resonance imaging (MRI), and labelled white cell scans can be useful adjuncts but again this is primarily a clinical diagnosis.

Treatment classically requires thorough surgical debridement with the wounds left open and reinspected regularly until the infection is under control. Bone and soft tissue reconstruction may be required at a later stage but concerns over the ability to cover tissue defects should not be allowed to result in inadequate removal of infected tissues. Four to six weeks of intravenous antibiotics are commonly required but discussion with the microbiology team is essential.

Complications are common and include stiffness, deformity, loss of function, chronic pain, and cold intolerance. Amputation is sometimes necessary, depending on the site.

**Subcutaneous tissues**

**Cellulitis**

Cellulitis is a process of acute inflammation of the skin and subcutaneous tissue in which there is hyperaemia, oedema, and white cell infiltration. Successful bacterial proliferation has the potential for systemic spread in the blood or the lymphatic system and therefore requires adequate intravenous antibiotic therapy and high arm elevation.

The most commonly isolated organisms are Gram-positive streptococci and staphylococci but multiple pathogens can be causative, particularly in the immunocompromised, which should be treated aggressively.

**Necrotizing fasciitis**

This is a rapidly advancing infection of the skin, subcutaneous tissues, and fascia. It is associated with severe systemic sepsis and a high mortality rate. Risk factors include diabetes (particularly insulin dependent), HIV infection, and intravenous drug abuse but it can occur in previously well patients. A fulminant course is usually observed with severe pain and skin changes occurring progressively from hour to hour.

Two subgroups are identified. Type 1 infections are caused by mixed aerobic and anaerobic infections (80% of cases). Type 2 infections are caused by Group A streptococci alone or in combination with staphylococcal species.

Baseline blood tests including a clotting screen should be obtained, but aggressive surgical debridement and antibiotic therapy should not be delayed for any reason. Secondary thrombosis of the digital vessels can occur. A finger fasciotomy may help prevent loss of the digit in this circumstance. Supportive treatment is frequently necessary, often on the intensive care unit.

Complications include soft tissue reconstruction, difficulties with stiffness, and functional compromise. Mortality rates can approach 60% when chest wall involvement occurs.

**Gas gangrene**

This is fortunately rare. The history often includes trauma with a significant crush element. The clinical presentation is similar to that of necrotizing fasciitis but the formation of hydrogen sulphide and carbon dioxide in the soft tissues is characteristic. The gas can be visible on plain radiographs and results in palpable crepitus in the affected tissues. Muscle necrosis also occurs.

Various species of Clostridium have been implicated with *C. perfringens* being the most common.

Treatment is similar to necrotizing fasciitis but hyperbaric oxygen has a more established role.
Animal bites

Dog bites

These are the most common animal bite, frequently affecting children under 12 years of age.

Infection manifests as erythema around the bite wound and malodorous discharge. Polymicrobial growth of aerobic and anaerobic bacteria is common. Pasteurella spp. were the most common isolates in one study with aerobes such as streptococci and staphylococci and anaerobes such as bacteroides also identified. The possibility of rabies and tetanus should be borne in mind.

Treatment includes irrigation of the wound, thorough debridement of any dead or infected tissues, and appropriate antibiotics.

Cat bites

Cats have needle sharp teeth which effectively inject any organisms deep into the tissues resulting in much higher subsequent infection rates.

Mixed flora are often encountered with Pasteurella multocida commonly isolated. The possibility of cat-scratch fever, caused by Bartonella henselae, should be kept in mind.

Treatment is similar to that for dog bites.

Marine organisms

These are more commonly associated with chronic infection but acute infection with Staphylococcus, Streptococcus, Pseudomonas, Aeromonas, and Enterobacter have occurred following penetrating injury. Occasionally a venom is injected, resulting in immediate severe throbbing pain at the site of inoculation. In some cases severe local reactions can occur.

Leeches

Aeromonas hydrophila infection can be seen in association with the medicinal use of leeches to relieve venous congestion. This can result in cellulitis, myonecrosis, abscesses, endocarditis, and sepsis.

Human bites

Most of these injuries occur in relation to fighting. A puncture wound over the metacarpophalangeal joint following a punch to the mouth with a clenched fist is a particularly common presentation. The injury typically occurs with the fingers flexed fully but the patient presents with the fingers only partially flexed. The skin will therefore be in different relative position in relationship to the underlying joint and superficial exploration may not reveal the true depth of the injury. All such wounds should be thoroughly explored to actively exclude joint involvement.

The human mouth contains up to 190 species of aerobic and anaerobic organisms. Staphylococcus, Streptococcus, and Eikenella corrodens are the most common organisms isolated.

Transmission of viral disease, such as hepatitis B, C, and HIV, has been documented through human bites.

Prosthetic infections

Joint replacements in the hand are frequently carried out in the immunocompromised rheumatoid patient with infection rates up to 3%.

Organisms vary and tissue specimens should be obtained to guide antibiotic treatment.

Apart from very early infections, treatment almost always requires removal of the prosthesis and a thorough debridement of the affected tissues. Intravenous antibiotic therapy is required for a similar time period to osteomyelitis.

Late reconstruction or, rarely, amputation is considered when blood tests have normalized, all signs of infection have resolved, and the skin and soft tissues are supple. Late reconstruction may not be necessary if a reasonably stable, if stiff, scar joint develops.

Infections in intravenous drug abusers

The hand and forearm are common sites for attempted injection by drug abusers. They frequently present with infected abscesses, often at multiple sites. Many will present late with associated systemic sepsis. Underlying immunocompromise and concomitant infection with hepatitis B, C, and HIV should be borne in mind.

Polymicrobial infection is common. Staphylococcus aureus is the commonest isolate with methicillin-resistant strains rapidly becoming predominant. Microaerophilic streptococci and other anaerobes are also commonly found.

Ideal treatment includes aggressive surgical debridement, regular dressings, appropriate antibiotics, and early motion.

Complications are common in this group, who are often poorly compliant, and include osteomyelitis, necrotizing fasciitis, amputation, septicemia, and endocarditis

Infections in HIV patients
Upper-extremity infections in patients with HIV are more common in those patients with a concomitant history of intravenous drug abuse. The clinical presentation is similar to that of patients without HIV but the natural history of the infection is often more severe, particularly when AIDS has been diagnosed. AIDS patients may also have fingers that are red with painless erythema and perungual telangiectasia. Nails may be blue or show clubbing. Abscesses and spontaneous infection, such as with septic arthritis, are common. Necrotizing fasciitis is also more frequently encountered in this group.

Pyogenic organisms, including staphylococci and streptococci, respond well to standard aggressive surgical treatment. Viral herpetic infections also occur and often do not run a self-limiting course but require oral or intravenous antiviral therapy to be resolved. Unusual infections, including atypical mycobacteria and fungi, also occur in HIV patients and maybe helpful in indicating the onset of AIDS.

**Herpetic whitlow**

This is caused by herpes simplex virus (HSV) 1 and 2. The infection can occur in children and adults. HSV-1 infections usually occur following contact with infected saliva (finger sucking in children and occupational exposure in dentists, for instance). HSV-2 infections occur following genital contact. The incubation period is 2–14 days.

Early in the course of the disease there is intense throbbing and pain in the affected digit. Tingling can also occur. Erythema and mild swelling develop followed by the appearance of clear vesicles that gradually coalesce. The clear fluid may become turbid mimicking a purulent infection. The lesions gradually resolve over a 3-week period. Superadded bacterial infection can occur.

The Tzanck smear can be performed on vesicular fluid but is less sensitive than viral cultures at confirming the diagnosis. Immunofluorescent serum antibody titres can also be diagnostic.

No active treatment is usually indicated but attempts should be made to avoid autoinoculation and transmission. Deroofing the vesicles may provide some symptom relief and partial nail excision can be carried out for subungual pressure symptoms but this should be performed with care. Misdiagnosis and treatment as a bacterial felon can increase local complications and some authors have mentioned a risk of inducing viral encephalitis with this treatment. No recent studies have confirmed this. Recurrence can occur and can be severe in the immunocompromised.

**Anthrax**

This is caused by infection with Bacillus anthracis, a Gram-negative spore-forming bacterium. A history of direct contact with infected animals or animal products 2–7 days prior to symptoms and signs developing is characteristic.

Ninety-five per cent of cases present with the cutaneous form of the disease. Small, painless, red macules gradually progress to papules over 48–72h. These then become vesicular, rupture, ulcerate, and form a 1–5-cm diameter brown or black eschar which is painless. Tender regional lymphadenopathy, fever, and malaise with surrounding oedema may occur. Pulmonary and intestinal forms also occur.

Antibiotics do not affect the progress of the skin lesion but do sterilize the ulcer. Penicillin is the first-line choice, initially given intravenously. Surgical debridement is contraindicated because of the risk of spreading the infection.

Complications include malignant oedema, septicemia, shock, renal failure, and death in 10–20% of untreated cases.

**Mimics of acute infection**

Many conditions can mimic acute infection in the hand.

Gout and pseudogout can present as a pyarthrosis or local soft tissue collection.

Acute calcific tendonitis presents as severe, acute pain over tendons or ligaments. This is often characteristic on plain x-ray.

Pyogenic granuloma presents as a raised, red friable lesion with a history of minor trauma. This is often characteristic on plain x-ray. Silver nitrate applied to the surface may resolve the swelling but often takes several applications. For larger or persistent lesions curettage of the base under local anaesthetic is curative.

Pyoderma gangrenosum is a progressive, necrotizing, and ulcerative disease of the skin often, but not always, associated with inflammatory bowel disease or myelodysplastic syndrome. No organisms are grown on culture. Treatment is with oral steroids. Surgery risks precipitating a rapid deterioration of the condition. Complete healing should be expected.

Bony metastatic tumours can present acutely in the hand. The primary is most commonly the lung and the commonest affected bone is the distal phalanx. Soft tissue tumours also occur in the hand but usually present chronically. They include squamous cell carcinomas, basal cell carcinomas, melanomas, and keratoacanthomas.

**Specific chronic presentations**

Chronic infections in the hand occur infrequently and can present in numerous of ways. A high index of suspicion and a careful history are vital if an early diagnosis is to be made. Close liaison with the microbiology department is helpful if atypical infections are to be diagnosed and treated most effectively.
Mycobacteria species

Tuberculosis is still the commonest mycobacterium causing a chronic hand infection in less developed countries but Mycobacterium marinum is the commonest species in the developed world. M. marinum is commonly found in fish tanks or similar environments and such exposure should be sought in the history.

Mycobacterial infections present in an extremely varied fashion that can involve the skin, subcutaneous tissues, tenosynovium, bursae, joints, and bone. In the hand the commonest presentation is with chronic tenosynovitis, wrist joint infection, or dactylitis. Mycobacterium leprae presents very differently and is fortunately rare in the West.

Blood tests and x-rays should be obtained but inflammatory markers are frequently not raised. Microbiology specimens require specific handling and culture techniques for successful growth of organisms. Tissue specimens need to be cultured for aerobic and anaerobic bacteria, typical and atypical mycobacteria, and fungi. Polymerase chain reaction testing of tissue samples can sometimes be useful to confirm the diagnosis. Tissue should also be sent for histology as characteristic caseating or non-caseating granulomas can be diagnostic. If there is a history of travel to developing countries, protozoa and parasites may also need to be considered.

Treatment principles involve obtaining tissue to establish the diagnosis and prolonged antibiotic therapy, depending on sensitivities. Resistance is emerging so liaison with the microbiology team is important. Surgical debridement may be necessary if prolonged antibiotic treatment does not resolve the infection.

Cutaneous

This commonly presents as a nodular or pustular lesion or as a chronic paronychia.

Tenosynovitis

The flexor tendons are most commonly affected, presenting with a characteristic ‘sausage digit’ or carpal tunnel syndrome that can mimic rheumatoid tenosynovitis. Rice bodies may be palpable subcutaneously. Constitutional symptoms and inflammatory signs are usually absent. There may be a history of previous trauma, a surgical procedure, corticosteroid injections, or water contamination.

Complications include tendon infiltration and rupture, with bone involvement if the diagnosis is delayed for several years.

Arthritis

Pain is an early feature of this condition with swelling and a reduced range of motion. A monoarthritis is most frequent. Deformity and sinuses may occur over time.

Progressive x-ray changes occur with early soft tissue shadowing followed by subchondral cyst formation on either side of the joint and osteopenia. Later, joint destruction, subluxation, and ankylosis may occur.

Treatment consists of synovial biopsy for diagnosis followed by prolonged antibiotics (several months). More aggressive surgical debridement is restricted to cases that respond poorly to this regimen. Arthrodesis may be necessary in the long term.

Osteomyelitis

This typically occurs in the phalanges or metacarpals with local discomfort and pain and occasionally a pathological fracture. Fistulae may form.

Radiographic findings can resemble a tumour with bone destruction and honeycombng but preservation of articular cartilage. In a child the physis can be affected resulting in developmental deformity.

Hansen’s disease (leprosy)

This is caused by Mycobacterium leprae and affects peripheral nerves and skin, particularly of the cooler peripheries. The highest incidence occurs in Asia and Africa with smaller numbers in South and Central America. Spread is probably from human to human via nasal droplet infection. In the upper limb the ulnar, median, and radial nerves are affected, usually in that order. The autonomic nervous system is also involved. Nerve damage is caused directly by infection, by immune reaction, and by compression of the thickened nerves. Cardinal signs are of an anaesthetic skin patch, nerve thickening, and a hypopigmented skin lesion. Without treatment, damage to anaesthetic digits may occur, deformity may arise from motor imbalance, and Charcot joints may develop.

Slit-skin smears (a cut in affected skin is scraped and smeared onto a glass slide) demonstrating acid-fast bacilli are diagnostic.

Treatment with multidrug therapy eradicates the bacteria. Later in the disease process, pain relief, nerve decompression, restoration of sensation, treatment of deformities, and rehabilitation may all be necessary.

Viral infections

Warts (human papilloma virus)

Human papilloma viruses (HPV) infect cutaneous and epithelia cells. In the hands 95% present as raised cauliflower-like lesions and 5% are flat. They are seen predominantly in children but adults, whose hands are frequently exposed to moisture, can also be affected. In the immunosuppressed, multiple lesions may develop and occasionally transform into squamous cell carcinoma (SCC).
In addition, recent evidence points to infection with certain subtypes of HPV as being a cofactor with ultraviolet light exposure for developing SCC.

In children, 90% resolve spontaneously within 5 years. If therapy is indicated treatment with salicylic acid, as a keratolytic agent, has the best evidence of efficacy with a 73% clearance rate. Curettage and surgical excision are alternatives for recalcitrant lesions.

Complications include iatrogenic injury (e.g. to the nail germinal matrix) and recurrence.

Orf

Orf is caused by a pox virus that is endemic in sheep and goats. In animals it produces weeping lesions around the mouth and nose. It is transmitted to humans by direct contact, predominantly affecting farmers and slaughterhouse workers. Orf produces a red weeping nodule 1–2cm in diameter, 95% of which occur on the fingers, hand, wrist, or forearm. The lesions can be very large in the immunocompromised. A crust forms on the surface of the nodule. The lesion heals spontaneously after 4–6 weeks.

Diagnosis is confirmed (if necessary) by electron microscopy of suspensions from the lesions. Treatment is directed at preventing secondary bacterial infection, which may cause scarring, while the lesion heals. Giant lesions may require surgery.

Fungal infections

Fungal infections can be broken down into cutaneous, subcutaneous, and deep infections. Microscopically, fungi can be unicellular yeasts or moulds with multinucleated filamentous hyphae. Cutaneous and subcutaneous infections may occur in the general population but deeper infections occur most frequently in an immunocompromised host. These infections should be suspected in any patient who has an infection that does not respond to antibiotics, drainage, and debridement or with non-diagnostic cultures.

Cutaneous infections

These infections are caused by fungi that metabolize keratin. The nails or macerated skin, such as can occur between digits or in the clenched fist of patients with an upper motor neuron disease, are affected.

The diagnosis is confirmed by nail or skin scrapings with potassium hydroxide staining. Candida albicans and trichophytosis (ring worm or tinea) are the commonest organisms encountered. Treatment is with careful hygiene and topical antifungals.

Subcutaneous infections

This includes chronic paronychia (discussed earlier), sporotrichosis (rose thorn disease), and phaeomycotic cysts.

Sporotrichosis is caused by inoculation of Sporothrix (Sporotrichum schenckii) into the skin and subcutaneous tissues by a rose thorn or cat scratch. At the site of inoculation an erythematous nodule arises which becomes ulcerated with raised edges. Characteristic linear nodules appear subsequently along the course of the local lymphatics and lymphadenopathy ensues. A cycle of healing, ulceration, and discharge can continue for years if the diagnosis is not made. Biopsy and specific stains are required to confirm the diagnosis. Treatment is with oral antifungals.

Phaeomycotic cysts are rare and may arise following infection with fungi present on an implanted wood splinter. They usually require surgical removal.

Deep infections

These may affect the tenosynovium, joints, or bone, often with sinuses or ulcers, usually in an immunocompromised host. Organisms include Aspergillus spp., Blastomyces dermatitidis, Candida spp., Coccidioides immitis, Cryptococcus neoformans, Histoplasma capsulatum. Sporothrix schenckii may also present rarely in an extracutaneous form, often acquired through the lungs with a concomitant pneumonia. Aggressive therapy and close collaboration with the microbiology team are vital if treatment is to be successful.

Bacterial infections

Actinomycosis

This is caused by Actinomyces israelii, a normal inhabitant of the oral cavity. Only 2% of cases occur in the upper extremity. A closed fist injury is the commonest cause with the oral flora impacted into the metacarpal head. Persistent sinuses that drain yellow sulphur granules are characteristic. These granules are conglomerations of the microorganisms. Treatment is with penicillin. For late or recurrent infection with deformity, surgery might be required.

Mycetoma

Mycetoma is a chronic granulomatous infection caused by traumatic inoculation of a bacterium (actinomycetoma) or fungus (eumycetoma) present in the environment—as opposed to the endogenous human flora causing actinomycosis. The infection generally remains localized with swelling, nodule formation, and drainage through sinus tracts. Characteristic granules are discharged that can be black, white, yellow, pink, or red depending on the exact organism involved. Actinomycetes are advanced aerobic bacteria with some characteristics of fungi and are found in association with woody plants and soil. The commonest species are Pseudallescheria and Nocardia. Only 2–10% of mycetomas affect the hands, the majority occur in the feet. Males are five times more commonly affected than females and are usually not immunocompromised.
Treatment depends on definitive identification of the causal organism from the granules. Actinomycetoma should be treated with antibiotics. Eumycetomas should be widely excised initially with antifungal therapy to follow.

**Brucellosis**

*Brucella* spp. are widespread in animals and exposure to cattle, goats, or sheep is necessary for human infection to occur. The disease is endemic in the Mediterranean, Middle East, and South America. Presentation can be with osteomyelitis, septic arthritis, or dactylitis. Treatment is with a 4-6-week course of antibiotics.

**Syphilis**

Primary disease may present as an ulcer on the tip of the finger or as a paronychia with enlarged local lymph glands.

Secondary disease presents as dactyilitis.

Tertiary disease presents with gummata that are chronic granulomatous swellings in any tissue from the skin to the bone.

Congenital syphilis may present as bilateral metacarpal and phalangeal dactylitis with sclerosis and bone destruction.

The causative organism is *Treponema pallidum*. Diagnosis is by serology and microscopy of the exudate from a lesion. Treatment is with antibiotics guided by local sensitivities.

### Conclusion

Despite modern antibiotics, hand infections with a variety of organisms continue to be a source of morbidity and mortality. While *Staphylococcus aureus* continues to be the most common cause of infection, resistant strains and other organisms are increasingly being seen. Successful treatment requires identification of the infecting organism, appropriate antibiotic therapy, and proper surgical treatment, although aggressive surgery is less often required in the hand than the lower limb. The treating physician must have knowledge not only of the infecting organism, but also of the host factors contributing to infection. Microbiological advice should be sought for unusual organisms or organisms resistant to initial treatment.

Approaches to the hip

Summary points

- The development of safe and reliable approaches has allowed hip replacement surgery to be undertaken successfully
- There are four main approaches, each with their inherent advantages and disadvantages
- Awareness of the structures at risk with each approach reduces the risk of iatrogenic injury
- All of the approaches have been modified and improved upon to address specific weaknesses.

Introduction

Hip surgery has evolved from simple techniques, through excision arthroplasty and the development of modern total hip replacement surgery. As the operations have become more complex, visualization of the proximal femur and, in particular, the acetabulum has become increasingly important. An accurate and reliable approach is critical to the success of any primary or revision hip replacement. In order to achieve this, a variety of approaches have been pioneered and improved upon. Each has its own advantages and disadvantages and none can claim to be perfect (Table 7.2.1). There are a multitude of modifications but they can be grouped into four areas in order to simplify their comparison as listed in Box 7.2.1.

Box 7.2.1 Approaches to the hip for total hip replacement

- Anterior
- Anterolateral
- Direct lateral/transgluteal
- Posterior

The anterior approach

The anterior approach uses the intermuscular interval between sartorius and tensor fascia lata, supplied by the femoral and superior gluteal nerves respectively. It was popularized by Smith-Peterson, who first described it in 1917, and further described its application in ‘mold arthroplasty of the hip’ in 1949. Subsequently, it has been adapted to allow for ‘mini-open’ femoro-acetabular impingement surgery and been incorporated into minimal invasive hip replacement surgery. It is performed supine, making bilateral surgery easier. It allows excellent views of the anterior femoral head and neck though is limited in acetabular exposure and visualization of the proximal femur can be difficult. In order to extend the approach, extensive dissection of the abductors from the ilium is required to expose the acetabulum in its entirety and division of the external rotators allows delivery of the proximal femur into view. In addition, the approach requires division of both origins of rectus femoris. The lateral femoral cutaneous nerve crosses the incision and should be preserved, as its division often produces a tender neuroma.

Less invasive surgery has modified the approach to include just the central portion of the incision and preserve the rectus femoris intact. Keggi and colleagues report excellent results with this minimally invasive surgical (MIS) approach. It does not require osteotomy or transection of any muscle belly or tendon so is proposed to allow quicker return to full function, reduced bleeding, and shorter hospital stay. It remains a matter of controversy with studies at other centres finding high complication rates, particularly with respect to component malposition, femoral fracture, and failure of femoral component fixation.

Position

Supine.

Landmarks

Anterior superior iliac spine (ASIS) and the iliac crest.

Incision

‘J’-shaped incision, starting along the iliac crest and sweeping just below the ASIS and passing vertically along the anterior femur.

Procedure (Figures 7.2.1 and 7.2.2)

Identify and split the interval between sartorius and tensor fascia lata, erring towards tensor fascia lata to prevent damage to the lateral cutaneous nerve on the fascia of sartorius.
The interval between sartorius and tensor fascia lata used in the anterior approach. This exposes the underlying muscles—gluteus medius and rectus femoris. Detach the direct head of rectus from the anterior inferior iliac spine and the reflected head of rectus from the superior margin of the acetabulum. The reflected head has fibres which blend with the anterior capsule—these should be carefully dissected.

Rectus femoris can now be retracted medially and gluteus medius retracted laterally. The capsule is now visible with iliopsoas passing medially to its insertion on the lesser trochanter. Incise the capsule and the hip is exposed by adduction and external rotation of the leg.

The anterolateral approach

The anterolateral group of approaches all gain access through the interval between tensor facia lata and gluteus medius, utilizing a variety of methods of detachment of the hip abductors to expose both sides of the hip joint. It has its origins in the description by Watson-Jones in 1936 and was further advanced by McFarland and Osborne in 1954. It has been changed and applied to hip replacement by a multitude of famous hip surgeons, notably Charnley in the 1960s, Müller in the 1970s, and Hardinge in the 1980s. The patient can be positioned in either the supine or lateral decubitus position. The detachment of the abductors can be achieved in two ways: osteotomy of the trochanter (as popularized by Charnley) or transection of the anterior portion of distal gluteus medius and gluteus minimus tendon (as popularized by Müller). Both methods provide excellent access to both the acetabulum and the proximal femur and variations on the anterolateral approach remain very popular in total hip replacement and hemiarthroplasty of the hip.

As the posterior structures are maintained, the approaches allow inherently stable closure, reducing the rate of dislocation when compared with posterior exposures. Equally, both have disadvantages. Trochanteric osteotomy has an incidence of non-union, bursitis, and metalwork failure. The detachment of gluteus medius risks its denervation and the approach is associated with an incidence of Trendelenburg gait. Variations have been described in attempts to reduce the chance of a postoperative Trendelenburg gait; they propose avoidance of damage to the superior gluteal nerve (particularly the large and more significant superior branch).
Learmonth’s omega approach detaches the whole gluteus medius and minimus then splits vastus lateralis near its posterior border, avoiding denervation of most of it. Hanssen’s approach involves a longitudinal split in the fibres of gluteus medius but much further posterior than that described by Müller. These approaches are described as modifications of the anterolateral approach but many, particularly that of Hardinge, fall into the direct lateral group.

**Position**
Lateral.

**Landmarks**
Greater trochanter and shaft of femur.

**Incision**
Slightly curved, apex posterior, incision centred over the greater trochanter passing parallel with the shaft of the femur, across the centre of the greater trochanter. Typically the incision will be 12–20cm in length for primary surgery.

**Procedure (Figures 7.2.3 and 7.2.4)**
Incise fascia lata, distally, and tensor fascia lata, proximally, in line with the incision.

This reveals the greater trochanter, with attached gluteus medius proximally and vastus lateralis distally.

If a trochanteric osteotomy is to be used, the greater trochanter is removed with a saw, starting 1cm below the vastus tubercle and aiming for the junction of the greater trochanter and the femoral neck. If an osteotomy is not used, the leg is externally rotated to stretch the gluteus medius and minimus. Dissect gluteus medius and the underlying gluteus minimus tendon off the anterior border of the greater trochanter. Use blunt dissection to reveal the anterior capsule of the hip, with the reflected head of rectus femoris. Dissect the reflected head off the anterior capsule.

To reveal the femoral head, the capsule is incised, typically in a “T” shape centred on the femoral head and neck junction. The hip is dislocated by adduction and external rotation.

**The direct lateral approach**

The direct lateral approach does not use an intermuscular interval, rather it is muscle splitting. It creates an interval through splitting gluteus medius fibres proximally and vastus lateralis fibres distally. The approach was pioneered by Harris, in 1967, again for use in "mold arthroplasty". The patient is held in the lateral decubitus position. The upper femur is osteotomized between the vastus lateralis tubercle and the base of the superior surface of the femoral neck, keeping the abductors attached to the greater trochanter (as described in the anterolateral approach—see Figure 7.2.4). Again, this has been modified to avoid the need for an osteotomy: the so-called transgluteal approach was described in 1979. In this approach, the incision is between anterior third and posterior two-thirds of both gluteus medius and vastus lateralis. The incision continues to bone and the dissection is carried out through periosteum, elevating each flap without damaging muscle fibres. A similar approach, described by Hardinge in 1982, leaves a cuff of gluteus minimus intact upon the greater trochanter, helping reattachment. The direct lateral approach has the ability to provide excellent exposure of the femur and is easily extended distally. However, proximal extension is not possible as splitting of the gluteus medius greater than 3–5cm above the tip of the greater trochanter risks damage to the superior gluteal nerve. This limits its application in cases of complex acetabular reconstruction.
The orientation of a trochanteric osteotomy.

**Position**

Lateral.

**Landmarks**

Greater trochanter and shaft of femur.

**Incision**

Straight incision passing directly over the greater trochanter, parallel with the shaft of the femur. Typically, the incision will be 12–20cm in length and centred on the greater trochanter.

**Procedure (Figure 7.2.5)**

Incise fascia lata, distally, and tensor fascia lata, proximally, in line with the incision.

This reveals the greater trochanter, with attached gluteus medius proximally and vastus lateralis distally.

Split the fibres of gluteus medius in line with the incision in the fascia lata. Begin 2cm above the greater trochanter, passing across the anterior border of the greater trochanter and continue onto the most proximal 2cm of the vastus lateralis.

Continue to dissect to lift an anterior flap, consisting of gluteus medius and the underlying gluteus minimus. More distally this will include the most proximal fibres of the anterior of vastus lateralis.

The underlying capsule is now visible and is incised in a “T” shape with the bar of the “T” across the femoral head-neck junction.

The femoral head is dislocated by adduction and external rotation.

The posterior approach
The posterior approach is another muscle splitting exposure: longitudinal split of the gluteus maximus fibres is used but there is no associated denervation as the muscle is innervated far medial from the split. The joint is exposed through division of the short external rotators of the hip. The lateral position is used. The exposure was introduced by Moore in 1957 and further detailed in his paper of 1959. The posterior approach does not encroach upon the hip abductors, far reducing the incidence of Trendelenburg gait after surgery. In addition it provides good visualization of both the pelvis and the femur, being easily extensile in both directions. The approach has also been condensed to only its central portion, as the mini-posterior approach, a form of minimally invasive approach. In this approach, the gluteus maximus tendon is not incised and pronator quadratus, the lowest short external rotator, is unviolated. Disadvantages of either posterior approach include the proximity to the sciatic nerve, which requires careful protection throughout and the division of posterior structures, which can result in an increased incidence of dislocation. The resistance to dislocation is dependent upon adequate repair of the short external rotators. A significant advance in the posterior approach has been the development of an enhanced posterior repair method, reducing dislocation rates from 5% to less than 1%. This method relies on direct fixation to bone: drilling through the proximal femur and passing sutures through the external rotators then through these drill holes. When this technique is used, the rates of dislocation are comparable with those of the other approaches.

**Position**

Lateral.

**Landmarks**

Greater trochanter and shaft of femur.

**Incision**

Curvilinear incision centred on the posterior border of the greater trochanter. The proximal portion swings posteriorly, to lie parallel to the fibres of gluteus maximus, passing posterosuperiorly towards the buttock. The distal portion lies along the posterior border of the shaft of the femur.

**Procedure (Figures 7.2.6 and 7.2.7)**

Incise fascia lata in line with the femur distally; more proximally the fibres of gluteus maximus are encountered and should be split bluntly in line with the skin incision, i.e. parallel with the muscle fibres.

MIS, minimally invasive surgery.

This reveals gluteus medius, lying superficial and anterior to the short external rotators of the hip. By holding the hip in slight internal rotation and retracting under gluteus medius, the short external rotators are further exposed. Taking care not to damage the sciatic nerve, divide the external rotators close to their insertion on to the proximal femur. Continue this incision through the underlying capsule to reveal the hip.

The femoral head is exposed through internal rotation of the leg.

**Further reading**

Preoperative planning is essential to achieve successful results after total hip replacement.

Obtaining informed consent is important for both surgeon and patient.

The surgeon must have a comprehensive knowledge of the aetiology and treatment of the common associated complications.

Introduction

Preoperative planning is of the utmost importance in performing total hip replacement successfully and obtaining reproducible results. For the surgeon, meticulous planning allows for efficient utilization of resources, the selection of appropriate implants, the need for any special equipment, and the anticipation of intraoperative difficulties. It shortens the learning curve when performing relatively new procedures, and achieves consistent results. Because total hip replacement is an operation aimed at improving quality of life, emphasis must be placed on prevention of complications rather than salvage afterwards.

Patients undergoing hip replacement are often elderly. The approach should be a multidisciplinary one. Patient education, attention to psychosocial needs, and early assessment of home circumstances will assure timely discharge home and increased satisfaction (Box 7.3.1).

Box 7.3.1 Preoperative planning: patient factors

- **Patient education:**
  - Details of operation
  - Rehabilitation, physiotherapy
  - Complications

- **Discharge planning:**
  - Assess home circumstances
  - Need for extra home care

- Assess patient expectations, set appropriate goals.

Clinical assessment

The process begins with the careful evaluation of the whole patient (Box 7.3.2). The indication for hip replacement must be well founded and appropriate. It is important to clarify that the signs and symptoms for which treatment is sought is attributable to the hip, and not the adjacent joint or overlying soft tissues. Childhood conditions such as developmental dysplasia of the hip, slipped upper femoral epiphysis, and Perthes’ will have obvious consequences on the choice of implant due to altered anatomy, as will any previous surgery for these conditions.

Box 7.3.2 Preoperative assessment: history

- **Pain**
- **Function**
- **Deformity**
- **Childhood orthopaedic disorders**
- **Previous limb trauma**
- **Past medical history**
- **Drug history**
- **Early referral to anaesthetist/physician to optimize any potential anaesthetic risks.**

The preoperative examination (Box 7.3.3) should include assessment of the patient’s gait, as well as the spine and knee. Any...
conditions precluding the use of crutches or walking aids will have obvious consequences. Limb-length discrepancy, both true and apparent, should be established. The true limb length is measured from the anterior superior iliac spine to the medial malleolus; apparent length is from any midline structure, e.g. the umbilicus, to the medial malleolus. The commonest reason for apparent leg-length discrepancy is abduction or adduction contractures around the hip. When there is a difference between actual and apparent leg length, pelvic obliquity should be assessed with the patient sitting and standing. Pelvic obliquity due to causes above the pelvis, e.g. lumbar scoliosis, persists in the sitting position. Conversely, obliquity due to causes in or below the pelvis, e.g. gross arthritis, post-traumatic deformity of the pelvis, infection, or muscle contracture, resolves on sitting. In addition, leg-length discrepancy due to more distal causes, such as limb fracture, poliomyelitis, infection, and physeal trauma, should be excluded.

Box 7.3.3 Preoperative assessment: examination

- Gait
- Hip range of motion—active, passive
- Limb-length discrepancy
- Presence of scars
- Spine
- Knee
- Neurovascular status.

Correcting any leg-length discrepancy optimizes muscle function and provides the patient with improved gait and increased comfort, provided the stability of the hip replacement is not compromised, and sciatic nerve function not threatened.

Patients at high risk of postoperative dislocation, e.g. due to neuromuscular problems, should be identified. This may influence the choice of implant, e.g. the use of a larger femoral head to confer greater stability.

Radiographic review

The aim of implant positioning in hip arthroplasty is to restore the biomechanics (Box 7.3.4); templating helps to achieve this reliably and consistently. The traditional method of templating involves the use of transparent acetate templates held against hard-copy radiographs. The magnification of radiographs is generally in the region of 110–125%, and this needs to be known. Templates are usually supplied by the manufacturer.

Box 7.3.4 Successful hip arthroplasty: restoration of biomechanics

- Restore centre of rotation
- Restore leg length
- Restore femoral offset.

Acetabular templating

Templating usually follows the steps of surgery, and attention is first turned to the acetabulum to determine the centre of rotation, and the cup position and size. A horizontal reference line can be drawn through the base of the teardrops, which represents the true floor of the acetabulum; it is also helpful to identify two further key anatomic landmarks—the ilioischial line and the superolateral margin of the acetabulum (Figure 7.3.1). Correct positioning and orientation of the cup is essential for the stability of the hip replacement. The cup should be sized so that it lies in 45 degrees of abduction, the medial border approximates the ilioischial line, and there is adequate lateral coverage. The inferior border of the cup is placed level with the teardrop line (Figure 7.3.2). In cemented cups there should be a 2–3-mm uniform cement mantle. The centre of rotation should be marked, and compared with the contralateral hip, templating the contralateral hip is useful in the presence of bone loss. Any osteophytes that need removal and cysts that require curettage and grafting are noted. Special care must be taken to seat the cup in the anatomically correct position in the presence of protrusio acetabuli, a lateralized acetabulum due to medial osteophytes and the dysplastic acetabulum; the use of bone graft may be required to augment any defects in these situations.

Box 7.3.5 Radiographic assessment

- AP view of pelvis centred over pubic symphysis
- AP view of affected hip
- True lateral view of affected hip
- AP views taken with patient supine and hip in 10–15 degrees of internal rotation to counter the normal anteversion of the femoral neck.
Preoperative planning. The correct size and position of the acetabular component is chosen. The amount of acetabular bone that should be removed (left) and the hip center (×, right) are indicated.

Femoral templating

The aims of femoral templating are to restore femoral offset, optimize limb length and correctly size the stem. The anteroposterior (AP) view of the pelvis is useful to assess limb-length discrepancy. The teardrop line is used to orientate the pelvic axis; alternatively, a horizontal line drawn through the most distal part of the ischial tuberosities is also commonly used. The former is more accurate, as it lies nearer the centre of rotation of the hip joint. The vertical distance between this reference line and the most medial part of the lesser trochanters will enable measurement of any limb-length difference (Figure 7.3.3). The radiographic discrepancy should be compared with that measured clinically.
Preoperative planning. Determination of leg length on the pelvic view by drawing a line, which hits the most distal part of the os ischi. The most medial part of the lesser trochanter has to be used as a femoral landmark.

A line perpendicular to the femoral shaft at the level of the tip of the greater trochanter can be used to assess the desired level of the centre of rotation of the femoral head; caution must be exercised in the presence of coxa valga and coxa vara, as the true centre of rotation will then lie above and below the tip of the trochanter respectively. The stem size is chosen next, depending on the mode of fixation—for a cemented stem a 2-3mm cement mantle is desirable. For cementless fixation, adequate endosteal contact is required, either proximally or in the diaphysis, depending on prosthetic design. Finally, the femoral template is translated proximally or distally depending on the desired limb-length correction. The amount of limb-length change produced by surgery will be the vertical distance between the centre of rotation of the femoral component and the centre of rotation of the acetabular component.

The femoral offset should restore the offset of the normal hip; this can be judged from the contralateral hip if required. The offset is the horizontal distance between the centre of rotation of the hip joint and the longitudinal axis of the femur, and there is large anatomical variation (Figure 7.3.3). Failure to reproduce the correct offset will decrease the abductor moment arm, lead to a limp, increase joint reaction force and wear, and cause instability. Once again, the change in offset produced by surgery will be the horizontal distance between the centre of the femoral head and the centre of rotation of the cup on templating. Some stem designs allow for different offsets and neck-shaft angle. In addition, the angle and level of neck ostectomy can also be altered. In this way, it may be possible to adjust for anatomical variations in offset. Finally, when the surgeon is happy with the chosen size and position of the stem, the new centre of rotation and the position of the neck cut should be marked. Templating should usually aim for the middle range of neck lengths to allow for adjustment to a shorter or longer size of head intraoperatively if required.

The lateral view of the hip helps to plan the location of the femoral opening, and assess the femoral bow and the AP canal diameter. Any excessive femoral antversion can be detected on a true lateral view. An inaccurate femoral entry point can lead to eccentric reaming and concomitant shaft perforation.

Digital radiographic technology is increasingly being introduced into hospitals in association with Picture Archiving and Communication Systems (PACS). This has changed the traditional templating process; the central issue here is of variable magnification in the digital images. An external scale marker of known dimension attached to the patient at the time of imaging is therefore needed to assess the magnification. On-screen templating requires specific digital software, and are now commercially available, although at considerable cost. The sequence of steps involved in templating is similar to those outlined earlier. The hope is that these will make the whole process faster and more accurate, and translate to improved patient outcomes.

**Consent**

Informed consent is a legal requirement before any surgical procedure. Effective communication is the key to enabling patients to make informed decisions. Successfully consenting a patient to treatment revolves around three key issues: the patient must have adequate mental capacity to make the decision; have sufficient information upon which to base their decision (Box 7.3.6); and reach that decision voluntarily without undue duress.

**Box 7.3.6 Consent: patient information**

- Nature of patient’s condition
- Nature and purpose of the procedure
- Probability of specific/general risks
- Other operative/non-operative alternatives
- Prognosis with no treatment.

The surgeon should pass on that information which any reasonable patient would wish to know before giving consent. In the setting of hip replacement, this should include the common risks and complications. If cardiopulmonary or systemic condition places the patient at high risk, the patient should be fully informed and guided with relatives in deciding whether to undergo surgery.

The doctor who consents should whenever possible be the one carrying out the procedure, or at least be appropriately qualified and familiar with all the details involved. The explanation given to the patient is of paramount importance and the signing of the consent form is of secondary significance. Due consideration should be given to language ability, appropriate setting, and adequate time.

A structured verbal discussion of the information has traditionally been the mode of imparting the information. Alternatively, a written information sheet may also be employed, and this may enhance patients’ comprehension and recall of information.

The increasingly litigious environment at present may endanger the surgeon’s ability to practice. Good consenting practice is crucial both for the patient and for the surgeon. A recent review of malpractice claims of an insurance company that involved orthopaedic surgeons noted that all the claims involved elective surgery, and not a single emergency case. Poor communication was established as the critical factor linked to malpractice claims. Documentation in the surgeon’s notes that informed consent took place was associated with a decreased risk of indemnity payment; dictating even a brief description of the informed consent processes—whether part of the clinic notes or the operative notes—is deemed as more legally substantive.
Complications of total hip replacement

Patients undergoing total hip replacement often have significant medical comorbidities, and the general risks of surgery must not be forgotten when obtaining informed consent. Cardiovascular, pulmonary, and renal complications can occur, and patients should be counselled as to these (Box 7.3.7).

Box 7.3.8 Dislocation

- Reported incidence after primary total hip replacement: 0.2–7%
- Causes: surgical technique, prosthesis design and placement, and patient factors
- Treatment: closed reduction and bracing; revision surgery.

Box 7.3.7 Complications of hip replacement

- Dislocation
- Infection
- Thromboembolism
- Limb-length inequality
- Neurovascular injury
- Fracture.

Dislocation (Box 7.3.8)

Published reports of the incidence of dislocation after primary hip arthroplasty vary from 0.2–7%, the majority occurring within the first few months after surgery. Variables that influence postoperative instability can be grouped into: factors related to the surgical technique; factors related to the prosthesis; and factors related to the patient.

The surgical approach has commonly been cited as a risk factor for dislocation, with the direct lateral and anterolateral approaches reporting lower rates than the posterior approach. A recent meta-analysis, however, concluded that there was insufficient evidence in the published literature to support this claim. Others have stated that if repair of the posterior capsule and short external rotators is performed, the dislocation rate following the posterior approach is comparable to that of the lateral/anterolateral approach. Surgical experience may also affect dislocation rates, with more experienced surgeons having a lower incidence.

Proper orientation of the acetabular component is a very important factor for hip stability. Cup placement in 35–45 degrees of abduction and 15–25 degrees of anteversion has been generally accepted as ideal. Retroversion, excessive anteversion, or placement of the cup in a more vertical position can all lead to increased instability and accelerated wear. In addition, the aim should be to centre the primary arc range of the hip replacement in the middle of the patient’s functional range.

The use of larger femoral heads is another factor that may enhance postoperative stability. Larger femoral head sizes provide a more favourable head–neck ratio and therefore allow a greater arc of motion before impingement occurs. The use of constrained liners can also decrease instability rates; however, their use may be associated with increased polyethylene wear and loosening secondary to impingement.

Inadequate restoration of femoral offset results in decreased tension on the abductor musculature and subsequent instability. Preoperative templating should ensure that when the prosthetic stem is inserted, appropriate neck length and offset are restored. Restored hip mechanics confer stability via optimized abductor tension.

Finally, inherent neuromuscular disorders in the patient can affect hip stability by compromising soft tissue function. These can be grouped into central causes such as stroke, cerebellar dysfunction, Parkinson’s disease, alcohol abuse, and peripheral causes such as peripheral neuropathy and lumbar stenosis.

Most cases of dislocation can be successfully treated with closed reduction and abduction bracing. Patients who experience multiple dislocations may require revision surgery; it is then crucial to identify the cause of dislocation, as this leads to optimal results. Surgical options include revision for malpositioned components, use of constrained acetabular components, larger femoral heads, and trochanteric advancement.

Infection (Boxes 7.3.9–7.3.11)

The reported rate of deep infection after total hip replacement is now around 0.3–2%. Infection arises either by contamination at the time of surgery or later by haematogenous spread; the airborne route is probably responsible for most cases. The commonest organisms are Gram-positive, with Staphylococcus aureus (50–65%) and Staph. epidermidis (25–30%) accounting for the majority. The remainder consist of other bacteria, fungi, and mycobacteria.

Also important is the suppression or elimination of infection at remote sites before surgery. Dental procedures produce a bacteraemia in nearly all patients, and should be covered with antibiotics, although this remains controversial. Any chronic skin
ulcers should be treated prior to hip replacement. Patients should be screened to exclude concurrent urinary tract infections, and if identified, appropriate treatment instituted.

The use of ultraclean air and prophylactic antibiotics in combination has had a dramatic reduction in the rate of sepsis. The use of prophylactic antibiotics has been of paramount importance. Cephalosporins tend to be the antibiotic of choice because of their broad-spectrum activity. A preoperative dose at induction is always administered; the evidence for the recommended duration of prophylaxis thereafter is in favour of 24h, and not for longer periods.

**Box 7.3.9 Infection**

- Reported incidence after primary THR: 0.3–2%
- Causes: primary contamination, secondary blood-borne
- *Staph. aureus* and *Staph. epidermidis* account for majority
- The use of ultraclean air and prophylactic antibiotics are the most important preventive measures.

**Box 7.3.10 Patient factors predisposing to infection**

- Immunosuppression
- Long-term steroid therapy
- Diabetes
- Morbid obesity
- Rheumatoid arthritis
- HIV.

**Box 7.3.11 Infection: prophylaxis**

- Ultraclean air in theatre
- Prophylactic antibiotics
- Identify and treat concurrent infections preoperatively (dental, urinary tract, cutaneous, etc.)
- Limit number of individuals in theatre
- Closed-air exhaust suits
- Avoid unnecessarily prolonging operating time.

Evaluation of a patient with suspected infection should include the use of blood inflammatory markers, plain radiographs, bone scans, and white cell scans. The goals of treatment are the eradication of infection and restoration of function; treatment itself is usually operative.

**Thromboembolism (Box 7.3.12)**

Despite the use of thromboembolic prophylaxis for some time now, deep venous thrombosis continues to pose a significant risk after total hip replacement. In the absence of any prophylaxis, deep venous thrombosis rates are reported to be in the region of 40–60%, and the incidence of fatal pulmonary embolism about 0.5–2%; with prophylaxis, the corresponding rates are approximately 3–30% and 0.5 % respectively. Despite extensive research, the ideal agent for prophylaxis remains controversial; however there is agreement that some form of prophylaxis should be used. The results of randomized trials indicate that low-molecular-weight heparin, warfarin, and fondaparinux are the most effective agents, with or without the use of graduated compression stockings and/or intermittent pneumatic compression devices. Surgeons are concerned about bleeding associated with the use of prophylactic agents, as it can lead to haematoma formation, infection, and reoperation. Further controversy also surrounds the duration of prophylaxis; prophylaxis should, however, probably continue beyond discharge. The selection of a particular regimen depends on the experience of the surgeon and risk factors in individual patients.

**Limb-length discrepancy (Box 7.3.13)**

Limb-length discrepancy after total hip replacement may result in impairment of abductor function, pain, and a limp; it is one of the commoner reasons for significant patient dissatisfaction in an otherwise successful arthroplasty. The amount of disparity that causes a clinically significant or functionally relevant shortening remains unclear, and published data are conflicting. This is probably due to variation in individual patients; the presence of concomitant spinal deformity, pelvic obliquity, and contractures of the contralateral limb all have an influence on the patient’s functional leg length. Psychological issues and cosmesis are also important factors in the patient’s perception of leg-length discrepancy.
Thromboembolism

- Reported incidences after primary total hip replacement: deep vein thrombosis 3–30%; fatal pulmonary embolism 0.5%
- Ideal agent for prophylaxis remains controversial
- Low-molecular-weight heparins widely used, but there are concerns regarding bleeding.

Limb-length discrepancy

- Reported incidence in published literature variable
- Lengthening of more than 1cm may cause symptoms and patient dissatisfaction
- Preoperative templating and intraoperative assessment are both important to minimize incidence.

Preoperative radiographic templating, as outlined previously, should be used to minimize the possibility of creating a significant leg-length discrepancy. A method of intraoperative assessment of leg length is also essential. A variety of methods are available: iliac fixation pins, intraoperative calipers, and computer-assisted navigation have all been described. Leg length can be compared by assessing the equivalence of knee joints and the malleoli. Measurement of distances from the tip of the greater trochanter to the centre of the femoral head, and the distance from the lesser trochanter to the centre of the femoral head should be compared to preoperative measurements. The toggle or ‘shuck’ test, in which the hip is distracted in the neutral position, also indicates length restoration; in general no more than 2mm of distraction should be possible.

Leg-length inequality may respond to the use of a shoe raise; persistent symptoms or significant patient dissatisfaction may necessitate revision surgery.

Neurological injury (Box 7.3.14)

The overall incidence of nerve injury associated with total hip replacement is 1–2%. Sciatic nerve injuries are by far the commonest, accounting for about 80%, followed by femoral, with obturator and superior gluteal nerve injuries accounting for a very small number. The posterior approach to the hip is traditionally associated with injury to the sciatic nerve, but the lateral approach may also be responsible. The aetiology of injury is usually unknown in a significant proportion of the cases. Out of the known causes, traction, compression, haematoma, constriction by suture, and heat from cement polymerization are generally responsible. Traction injury may be from intraoperative manoeuvres including dislocation and reduction, or from leg lengthening. Lengthening of greater than 4cm is generally accepted as a risk factor for nerve injury.

The majority of injury to the sciatic nerve affects the peroneal division; it is at increased risk of damage because it is tethered at both the sciatic notch and the head of the fibula, and is also located more laterally than the tibial division. For the femoral nerve, mechanisms of injury are similar to those that can lead to sciatic nerve palsy, and include direct injury from retractor placement, leg lengthening, and extruded cement. Obturator nerve injury is rare, and is usually due to cement extrusion, and anteroinferior quadrant screw placement. Injury to the superior gluteal nerve is a complication of the anterolateral or direct lateral approach to the hip.

Vascular injury (Box 7.3.15)

Vascular complications after total hip replacement are rare—reported rates in the literature are in the order of 0.1–0.2%. They can either be perioperative, presenting with obvious haemorrhage, or late, causing pain or ischaemia due to a pseudoaneurysm. The commonly affected vessels are the common femoral, the external iliac, and the obturator. Vessels may be injured by direct mechanisms (scalpel, retractor, or reamer) or indirectly from a stretching injury, particularly in patients with atherosclerosis.

The use of screws to augment acetabular stability has also caused concern with regards to vascular injury. The quadrant system as described by Wasieleski and colleagues has become popular as a guide to safe screw placement (Figure 7.3.4). The acetabulum is divided into quadrants by two lines; the first from the anterior superior iliac spine extending distally through the centre of the acetabulum, and a second line perpendicular to, and bisecting, the first line. The anterosuperior quadrant risks
external iliac injury, and the anteroinferior quadrant risks injury to the obturator vessels. The posterosuperior and posteroinferior quadrants are the safest for screw placement, and generally have the best bone quality.

Fig. 7.3.4
Acetabular quadrant system. The quadrants are formed by the intersection of lines A and B. Line A extends from the anterior superior iliac spine (ASIS) through the center of the acetabulum to the posterior aspect of the fovea, dividing the acetabulum in half. Line B is drawn perpendicular to line A at the mid-point of the acetabulum, dividing it into four quadrants: the anterosuperior quadrant, the anteroinferior quadrant, the posterosuperior quadrant, and the posteroinferior quadrant. (Reproduced from Wasielewski et al. (1990).)

Periprosthetic fracture (Box 7.3.16)
The reported incidence of periprosthetic fractures after total hip replacement varies, being in the region of 1–3% with cementless femoral stem implantation; the incidence is much lower using cemented stems. Fractures to the acetabulum occur much less frequently than occur in the femur. A recent report from the Swedish National Hip Arthroplasty Register found the accumulated incidence for primary hip replacements to be about 0.4%.

The surgeon must keep in mind patient factors that increase the chance of fracture, including age, female gender, and osteoporosis. Routine follow-up of patients after total hip replacement is critical in identifying those at high risk of fracture.

Box 7.3.15 Vascular injury
- Rare in primary total hip replacement; reported incidence: 0.1–0.2%
- Commonly affected vessels are the common femoral, external iliac, and obturator
- The use of screws to augment acetabular stability is a risk factor.

Conclusions
In conclusion, careful preoperative planning ensures that the goals of total hip replacement are consistently and reliably achieved —the anatomical aims of restoring the centre of rotation, leg length and offset, as well as maximizing patient satisfaction. It ensures that the appropriate implants are available, shortens the learning curve for the surgeon, and minimizes the incidence of complications. Digital templating is gaining in popularity, and holds promise for the future.

The process of obtaining informed consent is an important component of the whole process, both for the surgeon and for the patient. Due attention must be given to the provision of adequate information to the patient, and appropriate documentation.

Finally, a comprehensive knowledge of the aetiology and treatment of complications associated with hip arthroplasty is necessary for safe practice. A hip replacement is an elective procedure that is very good at improving a patient’s quality of life; the patient rightly has very high expectations. A meticulous approach will ensure the surgeon anticipates potential complications and minimizes them.

Box 7.3.16 Periprosthetic fracture
- Reported incidence in primary total hip replacement: approximately 0.4%
- Most cases involve femoral component
Treatment options include: conservative management, fracture fixation, or revision arthroplasty.

Summary points

♦ Cemented fixation in total hip replacement set the standard and has stood the test of time
♦ Improved generations of cementing technique have led to improved results
♦ The long term results of uncemented implants have improved with better designs and materials
♦ The most important determinant of the outcome and longevity of the implant is the quality and accuracy of the initial implantation

Introduction

Cemented fixation has been used successfully in total hip replacement for over 40 years, but uncemented implants were developed because of the higher rates of aseptic loosening noted in young, active patients. In 1987 Hungerford mistakenly attributed this mode of failure to the method of fixation and coined the term ‘cement disease’ but it was later realized that the cause was, in fact, osteolysis resulting from the generation of polyethylene wear debris.

There remains much debate over which type of fixation—cemented, uncemented, or hybrid—offers the most reliable and durable results. As technology and manufacturing processes have developed, the results for uncemented fixation have improved, but at the same time cementing techniques have advanced.

The basic arguments over fixation have been overtaken by tribological issues, but discrepancies remain with regard to the results published in the literature, usually of a single implant or technique from a single centre by the surgeon who designed it, and the findings of the national joint registries. Issues such as age, weight, activity, pathology, bone quality, canal morphology, experience, and cost, must always be considered and there are differences between the philosophies and performance of individual implants within the cemented and uncemented categories.

Wear, leading to the development of osteolysis, is the ultimate determinant of outcome in modern total hip arthroplasty, but neither implant can be studied in isolation, because it is the performance of the entire hip system (implants, bearing, and cement, if used) that will determine the function and longevity of the reconstructed hip.

Fixation with cement

Polymethylmethacrylate (PMMA) bone cement has been used in arthroplasty surgery for over 40 years, with many publications and registries confirming excellent long-term results, even in young patients. The constituents and properties of the successful cements have remained essentially unchanged, but the ways in which they are prepared and used have improved (Figure 7.4.1).

Cement consists of a powder and a liquid (Box 7.4.1), which, when mixed together, produce an exothermic reaction (40–46°C), with polymerization as the cement hardens. Modern cements contain radiopacifiers and may also contain chlorophyll to impart a green colour in order to differentiate cement from the bone.

Box 7.4.1 Constituents of a typical bone cement
The type of cement used is not simply an afterthought and the Swedish registry has confirmed that the specific cement used has a significant bearing on the risk of revision. Cements are available with a variety of setting times and viscosities, with the high viscosity cements having a lower reported revision rate. Most contain antibiotics, usually gentamicin, which has been shown to further reduce the risk of revision.

If revising an infected arthroplasty the cement can be customized, based on the sensitivity of the infecting organism, by adding appropriate heat-stable antibiotics in powder form (less than 10% of the weight of the powder), and such cement can also be used to fashion a temporary spacer or beads for use in a two-stage procedure.

Bone cement has no adhesive properties and works as a grout, rather than a glue. During its insertion and working phase the cement is pressurized and interdigitates with the cancellous bone, hardening and creating a micro-interlock, forming a cement–bone construct, giving immediate stability. Meticulous preparation of the bony bed is essential and cancellous bone must be retained.

Pulse lavage removes debris or loose bone and the canal is dried to improve interdigitation and shear strength. Intramedullary bleeding is reduced by the local application of hydrogen peroxide, epinephrine, or chilled saline and by hypotensive anaesthesia.

The optimum cement mantle should be even and 2–4mm thick around the entire component, without any gaps, which would weaken it and allow wear debris to access the bony interface. Two interfaces are created (cement–bone and cement–implant), with cement being strongest in compression (93MPa) but weaker in shear (42.2MPa) or tension (35.3MPa).

The quality of the cement is important and the fatigue strength is increased by vacuum mixing or centrifuging which decrease the porosity. During cement insertion inclusions, voids, or laminations of fat, blood, or air should be avoided as this can reduce its strength by a factor of five.

A cement restrictor is placed 2cm beyond stem tip and a hollow centralizer should be used. Pressurization is maintained throughout to negate the effects of back bleeding, which forces the cement back out of the cancellous bone, and to take into account the initial cement expansion during the exothermic reaction and subsequent overall shrinkage (3–5%).

Cement must be stored at a constant temperature and should not be preheated or chilled because this makes its setting time unpredictable. Theatre temperature is important because a 1°C rise can reduce the setting time by up to 1min.

The type of cement, theatre, and storage environment and the quality of the cementing technique (Table 7.4.1) are crucial to the longevity of the arthroplasty, with the methods of bone preparation, cement insertion, and implantation differing between acetabulum and femur. Cemented fixation is demanding and time and care must be taken to ensure that all of the stages are performed as well as possible on each and every occasion (Box 7.4.2).

**Improvements**

| Mantle | NA | Yes | Yes | Yes |
| Cement quality | NA | NA | Yes | Yes |
| Stem position | NA | NA | NA | Yes |

Box 7.4.2 Barrack classification of femoral cement mantles

- Type A: complete filling of the medullary cavity, a ‘white-out’
- Type B: slight radiolucency (<50%) of the cement–bone interface
- Type C: 50–99% radiolucency, or a defective or incomplete mantle
- Type D: 100% radiolucency, or failure to fill the canal or cover the tip of the stem.

**Uncemented fixation**

The aim of uncemented fixation is to achieve initial press-fit stability with ‘macro-fixation’ of the component against the surface of the bone, which is prepared with a degree of under-reaming. Long-term stability is achieved by ‘micro-fixation’ with the subsequent ingrowth of the surrounding bone into the porous surface modifications of the implant. Hydroxyapatite (HA) can also be used to encourage this process, but initial stability is crucial, because excessive micromotion will prevent bony ingrowth.

Some early designs of femoral prosthesis were manufactured with gaps or surface irregularities to allow bone to grow through and anchor the prosthesis. One familiar example is the Austin Moore hemiarthroplasty, but in young or active patients this offered limited support and led to loosening. In others, HA was used to coat components, which had no other surface modifications, with the risk of the implants subsequently loosening if the coating separated from the implant or had been reabsorbed.

Modern uncemented implants feature coatings to part or all of their surfaces to encourage bony ingrowth, which will then provide long-term fixation. This process occurs within 6 weeks of implantation and some surgeons keep their patients partially weight bearing during this period. The initial fixation may be augmented by longitudinal flutes, spikes, fins, or screws (Figure 7.4.2).
The manufacturing of uncemented implants is more complex and time consuming than for cemented ones, as a result of which they are generally more expensive, but without significant improvements in prosthesis survival they will not be cost-effective.

**The cemented acetabulum**

Cemented high density polyethylene (HDP) acetabular components were popularized by Sir John Charnley as part of the low-frictional torque concept. The material of choice subsequently became ultra-high-molecular-weight polyethylene (UHMWP), with cementable highly cross-linked polyethylene (HXLP) implants only recently being made widely available, despite the fact that this material has been used in modular uncemented cups for many years.

Modern components incorporate a long posterior wall to reduce the risk of dislocation and a flange to improve cement pressurization, implant positioning, and to act as a potential barrier to wear debris (Figure 7.4.3). PMMA spacers may be used on the back surface of some designs to avoid bottoming out, but may affect the integrity of the cement mantle. Metal backing, initially introduced for more even stress distribution, has been discontinued due to generally poorer results.

![Fig. 7.4.3](image)

**Acetabular components: Top left clockwise: Flanged cemented, solid resurfacing, multi-hole uncemented, unflanged cemented.**

The process of bone preparation and cementing technique is crucial to long-term survival. The presence of a radiolucent line in zone 1 of the bone–cement interface on the 12-month radiograph is a predictor of early failure and represents suboptimal technique, rather than a fault in the philosophy of cemented fixation.

The bony bed is prepared by reaming to subchondral bone and the creation of multiple keyholes, increasing the surface area for cement interdigitation to provide fixation and rotational stability. The correct implant size is based on the size of the final reamer used and the preferred cement mantle thickness, following which the flange is trimmed, either by using a template or markings on the flange itself.

Charnley used three major keyholes (iliac, ischium, and pubis), with other cementing proponents advocating the use of multiple smaller ones, or a combination of both techniques.

The bone is washed and dried as thoroughly as possible and the use of a suction vent in the ilium, superior to the rim of the acetabulum, can assist with this. The cement is inserted and pressurized, avoiding laminations, with the cup being inserted at the appropriate time, then held and pressurization maintained until it sets. Any excess cement and osteophytes are removed to avoid impingement.

**The uncemented acetabulum**

Initial fixation can be achieved by press-fitting of a hemispherical component, or by the use of a threaded implant, screwed into the host bone.

The use of HA coatings without other surface modifications has now been abandoned, but HA continues to feature in modern designs. Threaded screw-in components were popular in mainland Europe, but have been superseded by the press-fit modular designs. These components may be either hemispherical or non-hemispherical and some have an expanded equator to enhance initial stability.

The press-fit cups are implanted by under-reaming of the acetabulum by 1–2mm, depending upon bone quality and prosthesis design, then the implant is impacted into place. The injudicious use of excessive impaction force must be avoided to reduce the risk of fracture.
If there are concerns regarding the quality of the initial fixation, augmentation can be achieved by additional screw fixation and components come in a variety of designs, some with no screw holes, and some with many (Figure 7.4.3). Screws must be accurately inserted to avoid tilting the prosthesis and distancing it from the surrounding bone. There will be one central hole in a modular cup for the insertion handle, and a cap is provided to occlude this prior to insertion of the liner. Some implants also feature spikes or fins to resist rotational forces, but solid resurfacing cups have no holes and a different design of insertion handle is required.

Modular cups were originally designed for use with polyethylene liners, but were associated with high rates of wear and osteolysis. This was more common with vertical implants (greater than 50 degrees) or when large heads articulated with thin liners. The phenomenon of backside wear was common, when a poor locking mechanism allowed motion to occur between the liners back surface and the inside of the metal shell. This is an example of type 4 wear between two surfaces which are not intended to articulate and the debris produced can access the bony interface via unplugged screw holes, leading to the development of pelvic osteolysis, in keeping with the concept of the effective joint space, as described by Schmalzreid and illustrated by computed tomography studies published by Engh.

Modern implants have improved locking mechanisms, polished inner surfaces, and caps to occlude the screw holes. The modular shells also permit the use of liners with different bearing materials such as highly cross-linked polyethylene, ceramic or metal, but long-term survivorship results of these implants are not yet available.

**The cemented femur**

The development of cemented femoral components has seen the divergence into two main categories, with the establishment of the composite beam (shape-closed) and taper-slip (force-closed) philosophies (Figure 7.4.4).

**Femoral components:** (L>R) – Cemented Charnley (composite beam), Cemented Polished triple taper, Uncemented fully coated calcar replacing, Uncemented fully coated, Uncemented S-ROM with proximal sleeve, Uncemented proximally coated metaphyseal filling.

Composite beam implants have rough surfaces to promote bonding with the cement and may have a collar designed to load the calcar. Once inserted the stem should not move and any debonding or subsidence, at the implant–cement or bone–cement interface, represents loosening and failure.

Taper-slip components are polished, collarless, and taper in two or three planes. There is no bonding with the cement and the stems are designed to subside within the cement mantle, which must therefore be regular, complete, and of the highest quality. Stems are collarless to permit subsidence and polished to avoid abrasion of the inner surface of the cement mantle and the generation of debris, which led to high failure rates in matt finished collarless stems. A hollow centralizer is used to optimize stem positioning, avoid the creation of defects in the cement mantle, promote controlled subsidence, and to eradicate end-bearing, which would lead to distal load transmission.

Subsidence utilizes the viscoelastic properties of cement in a process called creep, which is non-recoverable deformation under load. As the femoral prosthesis is loaded, the cement deforms and the implant subides within the mantle. The stem subides and becomes more securely fixed within the mantle, generating hoop stresses within it. These stresses are then transmitted to the surrounding bone, which, because it is being loaded, will not undergo stress shielding, which could lead to the eventual loss of proximal support and loosening. This is in accordance with Woolf's law and the aim of polished tapered stems is to load the femur as proximally and 'physiologically' as possible.

Good long-term results have been achieved with both composite-beam and taper-slip stems, but when the importance of the philosophies or the bone cement are ignored, unacceptably high failure rates can occur as was seen with the Capital hip femoral prosthesis or the use of Boneloc cement.

Cementing technique is crucial and has progressed from the original ‘first generation’ bowl mixing and finger-packing, to vacuum mixing, pulsatile lavage, restrictors, retrograde filling with a gun, pressurization, and the use of centralizers (Table 7.4.1).

The cement mantle should be even, with a minimum thickness of 2–4mm, and the stem in neutral alignment, filling more than half of the femoral canal. Varus alignment of the stem leads to a higher failure rate, but probably reflects a global failure in the surgical
technique and implantation rather than in the cemented philosophy.

Results from the Scandinavian joint registries have confirmed improved survivorship with the advent of each generation of cementing technique, confirming that the results of cemented arthroplasties are technique dependent.

**The unicemented femur**

There are two main categories of uncemented femoral components depending upon where in the femur the initial press-fit mechanical stability is achieved. The stems can be straight or curved, and feature a variety of porous coatings, beads or fibre-mesh (Figure 7.4.4). The implant may have a collar to prevent subsidence, whilst attempting to load the calcar.

The first category are the stems designed to provide metaphyseal fixation with fit and fill implants, which have porous coating only on the proximal part of the prosthesis. The distal stem may be polished or slotted to prevent distal loading and reduce the incidence of thigh pain.

The proximal coatings on early metaphyseal stems were often incomplete, leading to the development of osteolysis due to wear debris accessing the interface, but modern implants feature circumferential coatings to prevent this and aim to load the femur more 'physiologically' via the metaphyseal region.

Because of the success of metaphyseal filling designs and the realization that the distal part of the stem may, in fact, be redundant, shorter or stemless implants, also designed to achieve metaphyseal fixation, have recently entered the marketplace. These stems are often identical to the proximal portion of a design that has been in use for a longer period, but there are no long-term results available, and claims that they will achieve the same results as the stems upon which they have been based can not be supported.

The implants designed to achieve distal diaphyseal fixation are extensively porous coated along all, or most, of the intramedullary surface and may feature longitudinal flutes to enhance rotational stability.

These extensively coated implants obtain the majority of their fixation distally and therefore risk the development of stress shielding, with subsequent proximal femoral bone loss. Because of the extensive coating these stems may also be harder to revise without causing significant additional loss of bone, as a result of which specialized instruments may be necessary for their safe extraction.

Uncemented implants are associated with a greater risk of intraoperative femoral fracture, which if undisplaced and unrecognized can progress to a complete fracture in the early postoperative period. If recognized at the time of surgery the fracture can be stabilized with cerclage wires or cables and the patient kept non-weight bearing for a period. Thigh pain is more commonly reported with uncemented implants, particularly the larger, stiffer, extensively coated ones.

Uncemented femoral components are not recommended for use in patients with a stove-pipe or Dorr type C femur, but such femoral anatomy is also associated with a higher failure rate of cemented implants.

**Hybrid fixation**

Conventional hybrid fixation consists of a cemented stem with an uncemented cup (Figure 7.4.5). The uncemented modular shells were originally used with a polyethylene liner, but with the growing popularity of alternative bearings, different articulations, and larger head sizes are becoming more popular.

There has also been a recent trend towards the reverse hybrid (uncemented stem and cemented cup) with a metal or ceramic head articulating on a polyethylene bearing.

Good results of hybrid fixation using metal on polyethylene articulations have been demonstrated in the Scandinavian registries, but long-term results of reverse hybrid hips or alternative bearings have not been reported.
Conclusion

The use of a specific implant, whether cemented or uncemented, does not guarantee success. It is the process of implantation, with precise aseptic and surgical technique and the optimal use of the carefully selected components, which will reduce the risk of complications, improving the function and longevity of the arthroplasty.

The results of early uncemented designs were inferior to contemporaneous cemented implants, due to poor implant design and excessive wear of thin polyethylene liners, with many designs being withdrawn, replaced, or becoming obsolete long before any meaningful results could be established.

There is, however, a growing body of evidence from publications and registries that well-designed and well-performed uncemented implants can achieve equivalent results to well-designed and well-performed cemented ones, in most age groups.

The greatest influence on the outcome of any given design of total hip replacement remains the accuracy with which the surgeon implants the prostheses at the time of the operation and the technique of implantation will ultimately take precedence over the technology or specifics of the implant with respect to achieving the best long-term results.

- Types of bearings

Introduction

Until the mid twentieth century, degenerative disease of the hip joint could be treated by excision arthroplasty, arthrodesis, or interposition arthroplasty. Excision arthroplasty developed as a necessary strategy in the management of osteomyelitis and joint sepsis. Hip arthrodesis provided a painless and stable junction between trunk and lower limb, but created functional restrictions and increased the stresses and strains on the lumbar spine, contra-lateral hip, and ipsilateral knee. Interposition arthroplasty started as a simple surgical strategy in which a patient’s own muscle and fascia were interposed between the damaged articular surfaces. This was superseded by implantation of a shell over the reshaped femoral head (Smith–Peterson cup). Interposition cups were replaced by hemi–arthroplasties secured into the proximal femoral bone with varying degrees of rigidity and stability. The hemi–arthroplasties were superseded by articulating monobloc implants secured to both femur and acetabulum (Total Hip Replacement, THR). THR development has followed two fairly distinct paths. On one route, monobloc implants were adapted to minimize host bone resection. This has led to our current generation of metal-on-metal hip resurfacing and epiphyseal replacements. On the other route, monobloc implants have been modularized to provide devices that are optimized for fixation to host bone, and offer a variety of articular combinations with differing tribological advantages.

Half a century of THR development has created a cornucopia of hip replacement options to choose from. Today’s surgeons are required to treat patients who may seek hip replacement while still relatively young and with many years of active life ahead of them. Hip surgeons face a spectrum of clinical conditions all of which are best treated by THR. However, equally strong arguments exist for different implant combinations in different clinical conditions. Surgeons ultimately choose particular implants because of their unique interpretation of available scientific and clinical literature, their clinical experience, their willingness or desire to embrace potential advances in implant design, and patient demand for benefits that have been promulgated through conventional media and the internet. This chapter considers the evolution, merits and shortcomings of the different component fixation and bearing options that are available to current orthopaedic surgeons.

The early hemi–arthroplasties and first THRs were implanted without any defined strategy for fixation of the implant to host bone. In Norwich, cobalt chrome, metal-on-metal, uncemented hip replacements were implanted in the 1940s and in the 1950s. The need for better femoral component fixation to host bone was rapidly recognized, and in 1963, polymethylmethacrylate (PMMA), an acrylic material used by the dental profession, was introduced. Initial results were poor because the cement was used to secure the prosthesis rather than to provide a mantle that would stabilize the implant and facilitate even transfer of loading stresses on the surrounding bone. Once this concept was understood and its efficacy demonstrated, cement became widely used in the United Kingdom. Incremental improvements in cementing techniques have been introduced and PMMA cement can provide consistent and reliable, long-term fixation for cemented femoral stems.

Some authorities considered that the cement-stem interface would be a weak link. Indeed, in the USA, the Food and Drug Administration (FDA) were initially cautious about sanctioning bone cement for general use. As an alternative, cementless fixation strategies were developed to strengthen the mechanical bond between stem and the adjacent bone. Holes were drilled into femoral components such as the Austin Moore prosthesis. Besides making the implant less heavy and saving metal, it was hoped that this would create a mechanical lock between bone and implant. The strategy provided limited benefit and attention turned to creating microscopic irregularities on the surface of the prosthesis. Roughening of the prosthesis surface proved more effective and has led to the application of porous coatings to the component surface. More recently, accelerated osseous attachment has been demonstrated by application of hydroxyapatite, which is the crystalline component of natural bone.

In summary, excellent long-term results have been achieved using cement fixation of the femoral component, as shown by the Swedish hip registry and many other publications. Likewise long-term results of the uncemented stems have been published with excellent long-term survival.

The subject of the optimal bearing surface is widely debated. Experimental work has demonstrated that the coefficient of friction in an animal joint ($\mu = 0.02$) is lower than that of a skate sliding on ice ($\mu = 0.03$). This observation led to the search for a low friction bearing, and in 1966 a Teflon-on-Teflon (polytetrafluoroethylene) bearing was tried. Early results demonstrated that Teflon-on-Teflon bearings lasted only 2 years and acted as an irritant. This led to the concept of resection of the femoral head and insertion of a metal femoral prosthesis. Metal-on-Teflon bearings fared no better with marked Teflon wear and osteolysis. In the same group of patients it was recognized that a larger femoral head caused higher volumetric wear. However, a small head (22.25 mm) caused linear penetration into the Teflon cup, compromising joint stability. The use of Teflon was therefore abandoned.

In 1962, a high molecular weight polyethylene acetabular cup was introduced. This was used in combination with a stemmed, cemented femoral component and 22.25 mm femoral head. Patients were thrilled with the outcomes of the cemented metal-on-polyethylene hip replacement, and enjoyed dramatic improvement in their quality of life. The combination proved effective, with low
wear, and it was widely adopted as a result. The cemented metal-on-polyethylene hip replacement has provided the benchmark for subsequent developments and evolution of THR surgery. THR is one of the most successful advances in modern orthopaedic surgery, with over a 90% clinical success rate at 10 years.

Designs such as the Charnley, Exeter, Stanmore, and Lubinus femoral stems have excellent, long-term results published in the literature. However, minor modifications of these designs have provided significantly inferior outcomes. This finding led to the recognition that different designs of THR provide different mechanisms of fixation and load transfer. For example, the Capital hip prosthesis was promoted as a copy of the Charnley design. The device was developed in versions manufactured as both stainless steel and titanium. The latter option ignored the fact that most polished tapered stems with published long-term results had been made from stainless steel. The Capital stems manufactured from titanium performed significantly less well than the stainless steel variant. Another example was the use of the matte-finish Exeter stem, first used in 1976. The matt stem, revision rate for aseptic loosening was four times higher, at 10 years’ follow-up. As a result of these poor results, a highly polished surface was reinstated to the Exeter stem, with excellent long-term results.

Many factors influence the longevity of a THR, including patient, surgical and implant factors. During the mid 1990s, there was growing awareness that the so-called, advances in prosthesis design did not necessarily provide additional benefits to patients. It was identified that many prostheses are marketed with little or no scientific evidence to support the claims that are made regarding their potential advantages over existing designs. A directive on medical devices of the Council of the European Communities recommended that implant performance and side-effects should be assessed by clinical trials (Council Directive 93/42/EEC 1993) and some form of clinical investigation has become obligatory before a new implant can carry a CE mark. In 2000 the National Institute for Clinical Evidence (NICE) introduced benchmark performance criteria for implant use in the UK National Health service, and this strategy has been further developed by the Orthopaedic Data Evaluation Panel (ODEP) who have developed benchmarking of implant performance at 3, 5, 7, and 10 years. It is now widely recognized that the introduction of new implants must be supported by reliable pre-clinical testing, phased introduction, and diligent post-market surveillance.

Box 7.5.1 Summary Box

- Degenerative disease of the hip joint—treated by excision arthroplasty, arthrodesis or interposition arthroplasty
- Total hip replacement evolved
- Cemented fixation
- Uncemented fixation
- Optimal bearing surface debated
- New device must have reliable pre-clinical testing, phased introduction, and diligent post-market surveillance

**Cemented stems**

The optimal cement mantle thickness is not proven; optimal thickness may vary with different stem geometry. High strength stainless steel appears to be a satisfactory material in preference to titanium. Collars and flanges must be avoided in order to allow the taper to subside and function properly. Stem positioning within the femoral canal is improved with the use of centralizers and stem cannulation. The stem should be polished and tapered so that it can subside within the cement mantle and generate minimal cement debris. Whether the ultimate design should be single, double, or triple taper is not yet known, although both single and double tapers are associated with excellent results. No long-term results are yet available for triple tapered stems.

Cemented femoral stems probably remain gold standard for total hip arthroplasty. Long-term results for the Charnley (>80% survivorship from revision for aseptic loosening and/or radiographic loosening at 25 years) and Exeter stems (91% survivorship from revision for aseptic loosening at up to 33 years) are currently the gold standards in femoral fixation. They have an excellent track record in older patients (more than 65 years), but are also used in younger patients with comparable results to the uncemented stems.

The cemented stem is particularly useful with the stove pipe femur, previous femoral fracture, or previous osteotomy where one would not expect to achieve a tight fit for ingrowth with an uncemented stem. Cemented stems are also indicated in cases of poor bone quality such as Rheumatoid arthritis, osteoporosis, or Paget’s disease.

Cement is used for fixation of the femoral stem in THR. The cement forms a seal around the femoral neck: this prevents the ingress of wear debris particles into the medullary canal of the femur. More importantly, cement allows stress transfer from stem to bone. In this respect, the femoral component can be viewed either as a composite beam or a load taper. To achieve optimal long-term results with a femoral component design, one must consider stem geometry, surface finish, and prosthesis cement interface.

The cement/implant interface may rely primarily on the intrinsic stability of the implant within its cement mantle (i.e. the shape of the interface). Alternatively, fixation may depend heavily on adhesion at the cement/implant interface. In either situation, cement/implant displacement of 0.5 mm or less is characteristic of a well-fixed device.

Box 7.5.2 Summary Box

- Optimal cement mantle still debated
Biomechanical theories of load transfer

Each cemented femoral stem design uses one of two mechanisms to transmit forces from stem to femur. A composite beam system requires strong stem/cement and cement/bone interfaces. In a loaded taper system, no bond between stem and cement is necessary. Both types of stem have performed equally well in the long term.

A composite beam requires all components to be rigidly bonded, with no movement between them. A tapered stem, however, must be capable of movement within its cement mantle. As a patient bears weight on a tapered, cemented femoral stem, the load is transmitted from the prosthetic femoral head and forces the taper to subside within the cement mantle. This subsidence generates radial compressive forces within the cement and subsequent hoop stresses within the bone. These forces are created throughout the length of the femoral stem, reducing proximal stress shielding.

Stem material

Cemented stems are fabricated from a variety of metals, including cobalt chromium, stainless steel, and titanium. Improved manufacturing techniques and the use of high strength stainless steel and cobalt chrome meant that stem fracture is now regarded as a thing of the past.

Stem length

Most conventional femoral stems extend to the isthmus of the medullary canal, to stabilize alignment and prevent varus migration. More recently, bone conserving joint replacements are emerging. Hip resurfacing, epiphyseal replacement, and mid head resection stems are being implanted and evaluated.

Stem offset

In a series of two hundred cadaveric femora, typical femoral offset was found to be 40–50 mm. Use of a short-necked femoral component can decrease offset in a reconstructed hip. This results in relatively medial abductor insertion, shortening the abductor lever arm, and reduced mechanical efficiency. Reduced offset increases the energy required for normal gait and may cause an abductor lurch, limit the range of motion, and decrease hip stability.

Increasing femoral offset lengthens the abductor lever arm, reducing the abductor muscle force required for normal gait. A lateral position of the femur also reduces impingement of the femur on the pelvis, and improves soft tissue tension. However, an increased offset may cause trochanteric bursitis due to increased pressure from the fascia lata. Also, an increased offset creates a larger bending moment on the prosthesis, which may increase strain in the medial cement mantle. This effect could contribute to early failure of the femoral component.

Stem shape

Before considering stem shape, it is helpful to consider the modes of loading, including axial forces, bending forces, and rotational forces. The mechanism of transfer of axial and bending forces is predominantly affected by the mid-frontal plane shape. The cross-sectional (horizontal plane) shape determines rotational stability of the stem and stress distribution within the cement mantle.

Collar or Collarless

Considerable debate has surrounded the need for a collar. A collar is a medial extension of the stem that projects at the level of the calcar cut. The collar of a cemented femoral component allows direct load transfer from the implant to the medial cement mantle and/or the bone of the medial femoral neck. The collar can decrease tensile stress in the stem and reduce migration. The second function of a collar is to control insertion when the stem is smaller than the broach, so that the implant reaches the same level as the broach. A collar should be considered only in composite-beam stems.

A collarless design should be considered in stems with a tapered design, which allows the stem to move distally and engage with the cement mantle. This increases compressive loading in the cement and reduces tensile and shear stresses and ultimately reduces calcar resorption.

Surface finish

Controversies exist with regard to the optimal stem surface finish for cement fixation. Polished stems with a roughness (Ra) of less than 1 micrometer create little abrasion with the cement mantle. Matt surface finish with a Ra of less than 2 micrometer will create abrasion with the cement mantle in the presence of excessive micromotion. In some cases, roughened stems have failed earlier than polished stems of the same design. Surface finish may be a critical factor in the durability of cement fixation with specific stem geometries. A Ra of greater than 2 micrometer is expected to cause excessive abrasion with the cemented mantle in tapered stems causing premature failure.
Stem alignment

Implant malposition can impair long-term survival of cemented THR, probably due to increased cement mantle stress.

There are two principal causes of malposition: implantation with the component in varus or valgus, and failure to centre the stem in the cement mantle. Implant positioning can be optimized with a stem centralizer or a cannulated stem.

Cement Mantle Stresses and optimal thickness

Control of mantle geometry is vital in controlling cement stresses. During normal weight bearing activities, cement stresses are highest in the proximal mantle and around the distal stem tip. When a stem subsides, it generates hoop stresses in the cement. Creep and stress relaxation dissipate hoop stresses, which are succeeded by radial compressive stress. In general, lower stem/cement friction results in increased cement loads in compression, and decreased shear forces. PMMA has greater compressive than tensile strength, so preferential loading in compression rather than shear is advantageous.

It has been demonstrated that stems with a 2–5 mm medial mantle have the best outcome, and that 3–4 mm cement mantles appear to have the best stress curves. However, this has challenged by others, and to a greater extent by the ‘French paradox’. Two French-designed cemented femoral components both fill the medullary canal of the femur.

Stress risers

Stems with a square cross-section have more rotational stability than oval stems. However, sharp edges create peak stresses in the cement, which can lead to microfractures particular in areas where the cement mantle is thin.

Cement plug

Pressurization of acrylic cement is necessary for optimal fixation. Although this is most frequently achieved with a cement gun, it is possible to pressurize the implantation site by converting it into a closed space, with an intramedullary plug. Plug performance varies with canal diameter: in larger canals, plugs are more prone to migration. A successful plug should resist a cement pressure of 50 psi in clinical use. This can be more difficult in canals of >14 mm diameter.

Box 7.5.3

- Optimal Stem offset 40–50 mm
- Reduced offset leads to reduced mechanical efficiency
- Increased offset leads to larger bending moment on the prosthesis
- Collars for composite beam stems
- Collarless for taper slip stems
- Polished surface finish

Pre-Op Planning for THR

Pre-operative templating of the hip can be undertaken to determine a number of factors. On the acetabular side to determine the centre of rotation, identify any issues around coxa profunda or dysplasia. On the femoral side determine the centre of the femoral head, femoral offset, neck shaft angle, and an impression of the femoral canal shape. Also the relationship of the tip of the greater trochanter to the centre of the femoral head. Be clear where the piriform fossa is in order to avoid varus placement of the stem.

Factors that may lead to inaccuracy during templating include external rotation of the femur giving the appearance of coax valga and altered impression of femoral offset. Coxa vara may lead to thoughts around post operative lengthening and hip instability. Limb length can be assessed radiologically by drawing a line at level of, and parallel to, ischial tuberosities and intersecting the lesser trochanter on each side. A comparison of the two points of intersection measurement differences will determine any evidence of limb shortening.

Bearing surface

Improvements in femoral and acetabulum implant anchorage over the last 20 years have significantly extended THR implant lifespan; the formation of wear debris, however, leads to resorption and osteolysis, considerably shortening implant lifespan in active patients. Most wear related particulate debris originates from the bearing surfaces.

Wear remains is a significant problem. Alternative bearing surfaces are constantly being developed with improved tribological properties to reduce the amount of biologically active particle generation that can lead to osteolysis and aseptic loosening. The bearing surface include highly cross linked polyethylene, metal-on- metal articulations, ceramic on ceramic surfaces and composite bearing surfaces.

Highly cross linked polyethylene
In the past, polyethylene cups were manufactured from ultra-high molecular weight polyethylene (UHMWPE) by extrusion, bulk compression moulding, or net shape moulding followed by gamma sterilization in air with wear rates approximating 0.1 to 0.2 mm/year.

In order to reduce wear rates highly cross-linked UHMWPE was introduced in 1998. Gamma irradiation in the order of two to four times that used in traditional UHMWPE and electron beam radiation are used in conjunction with thermal treatment to induce cross linking of polyethylene particles and reduce free radicals that oxidize and weaken the polyethylene. The highly cross linked polyethylene has improved resistance to wear. However, too much radiation can lead to the material becoming prone to fatigue fracture. Very highly cross-linked polyethylene (PE) shows very significant improvement in terms of wear at five years’ follow-up compared to conventional PE, but the behaviour of this new concept will need to be monitored in the long term.

Use of larger femoral head articulating with the cross linked UHMWPE provides the potential for increased range of movement, reduced frequency of dislocation and reduced risk of component impingement without volumetric wear.

The incidence of dislocation has been reported as 1–4% in primary THR and up to 16% in revision cases. Acetabular component with an elevated rim is thought to improve the postoperative stability. The presence of elevated liners can reduce the incidence of dislocation in primary THR from 3.8% to 2.2%. The largest benefit is gained in revision hip replacement surgery. The majority of dislocations are reported have been posterior caused by flexion, adduction, and internal rotation. Beware, that the elevated liners may increase the incidence of anterior dislocation due to impingement between the femoral neck and elevated lip of the liner during external rotation. In addition, they may also contribute to increased polyethylene wear.

If the femoral component is placed with adequate ante-version, excessive internal rotation is needed before the hip dislocates posteriorly. The abductors do not allow enough external rotation for the hip to dislocate anteriorly. Excessive anterpostion of the femoral component reduces the chances of dislocation, but also limits external rotation. Excessive retroversion may predispose to posterior dislocation.

**Metal-on-Metal Articulation**

Metal-on-Metal articulations were first introduced with the McKee Farrar hip replacement. The main advantage are seen both in vitro on wear simulators and in vivo with retrieved implants in which the wear rates are low and increased range of motion to impingement secondary to the availability of larger diameter femoral heads. Retrievals analysed after 21 years of implantation revealed acetabular linear wear rates of 4.2 μm/year, which was 25 times lower than the wear rate of traditional UHMWPE. However, as a result of imperfect manufacturing, the implants were vulnerable to seizure and subsequently loosen. More recently, improved manufacturing has led to better tolerances leading to lower wear rates. Wear rates of metal-on-metal bearings typically have 1 to 2 years run in period with wear rates of 20–25 μm/year; a steady state wear rate of only 5 μm/year is typically observed. Similarly, to the wear pattern, metal-on-metal bearings produce ion levels that are high initially during the 1 to 2 year run in phase and then decrease. However, the main concern around metal-on-metal articulations is the effects of the metal ions debris.

Concerns exist regarding the generation of metal ions seen in both the blood, serum, and urine of patients with metal-on-metal implants. As ion excretion is renal, use of a metal-on-metal bearings in significant renal impairment should be with caution. Metal particles (0.05 μm) are far smaller than polyethylene particles (~1μm) and can thus cross the placental barrier. Women of child-bearing age should be counselled accordingly.

Large ball metal-on-metal bearings are particularly susceptible to high levels of metal ion generation. Raised metal ion levels have been reported if the cups are implanted with high inclination angles (> 50 degrees). These metal ions have theoretical, although not proven, risks related to carcinogenic and biologic concerns. Additionally, concerns exist regarding hypersensitivity. In a few cases, a synovial reaction to Metal-on-metal articulations has been identified to cause ALVAL (Aseptic Lymphocyte dominated Vasculitis Associated Lesion.). This reaction has been reported to occur in approximately 1% of cases with a female preponderance. The patients may present with a pseudotumor or pain leading to muscle and neurological damage.

Although a metal-on-metal bearing may be considered a viable alternative to either polyethylene or ceramic implants, outstanding and unresolved issues continue to exist with this bearing, as they do with the alternatives.

**Ceramic on Ceramic**

Ceramic on ceramic bearing have been used since the 1970’s. Alumina-alumina friction couples are hard, scratch resistant and provide a low friction coefficient, with wear particles that do not cause any osteolysis. Alumina bearings have shown low wear rates of 0.025 mm/year comparable to those of metal-on-metal articulations and up to 5000 times lower than metal-on-polyethylene.

Ceramics are inert materials. The disadvantage of ceramic bearing is with their brittle nature. Improvements in manufacturing have reduced fracture rates down to 4 per 100,000 patients. Zirconia is a less brittle ceramic than alumina and fracture risk is theoretically lower. The current generation DELTA ceramic is a zirconia-alumina composite and is rapidly becoming the ceramic bearing of choice.

**Box 7.5.4 Summary Box**

- With Ultra High Molecular Weight Polyethylene Gamma irradiation and Cross linking can improve resistance to wear
- Metal-on-metal manufacturing has significantly improved
- Metal-on-metal concerns regarding metal ions, hypersensitivity, ALVAL, and pseudotumor
- New DELTA ceramic is a hard, scratch resistant bearing that provides a low friction coefficient
### Acetabular Biomechanics

The surgeon should aim to restore the normal hip centre during acetabular reconstruction which helps restore normal biomechanics. Reaming down to the true floor of the acetabulum will medialize the hip centre and may improve the efficiency of the abductors. Implantation of the acetabular component laterally, reduces the abductor arm moment and increases joint reaction forces. The final position of the cup is critical to allow physiological movement without impingement. Cup placed in 30–40 degrees of abduction and 15–20 degrees of anteverision are regarded as a safe range. When cups are abducted less than 30 degrees, impingement occurs in flexion. When a cup is abducted more than 50 degrees, the femoral head is vulnerable to sublux out of the acetabulum. The bearing surfaces are also susceptible to higher rates of linear and volumetric wear.

### Acetabular implant for hip replacement

Factors that influence the outcome of acetabular replacement are design materials, means of fixation, operative technique, and patient-related parameters. Threaded cups have failed to demonstrate any improvement in results and have been widely abandoned. The idea of metal backing has some theoretical advantages. However, metal backing has failed to provide any improvement when used for cemented cups. Presently, uncemented porous-coated or hydroxyapatite acetabular components are the most popular option but it should be noted that advocates of fully cemented cups do provide equally strong data to support their preference.

#### Cementless cup

Uncemented acetabular components usually have a coated or textured surface to encourage bone growth into the surface for biological fixation. The components may also have screw holes via which screws can be implanted, or spikes, pegs, or fins to help hold the implant in place until the new bone forms. Sufficient initial fixation is required for osseo-integration and secondary stability of the press fit components. Ideally the component surface should lie within 50 micrometers of the acetabulum to facilitate host bone attachment. Whilst screws provide additional fixation, there is a paucity of evidence to support that the screws act as sources of fretting, generating wear debris leading to osteolysis. By reducing the number of screws these mechanisms of wear debris are minimized. However, the unfilled screw holes also can act as conduits for wear debris generated from the liner to affect the attachment of the bone onto the cup surface.

#### Hemispherical and Rim Fitting cups

Cementless hemispherical cups are implanted in the acetabulum following 1–2 mm under reaming. Acetabuli should not be under reamed by more than 2 mm. Excessive under reaming of the acetabulum may lead to an acetabular fracture in. Cementless rim fitting (peripheral flare) cups are implanted in the acetabulum typically following size for size reaming. Either type of cementless cup usually has the option of supplementary fixation with screws. In addition, once the outer shell of the cup is implanted, the appropriate liner can be inserted.

Rim fitting cups may be more appropriate for protrusio or where the acetabulum has the potential to be over medialized. Failure to restore normal lateral offset in cases of protrusio may cause the greater trochanter to impinge off of the anterior edge of the acetabulum, potentially leading to posterior instability. Bone grafting the medial wall with cancellous autograft taken from the femoral head may be also required.

### Cemented Acetabular Component

Whereas improved cementing techniques have produced a marked reduction in the rate of femoral component loosening, the incidence of acetabular loosening has been only slightly influenced by such improvements.

### Box 7.5.5 Summary Box

- Restore the normal hip centre
- Cup placed in 30–40 degrees of abduction
- Cup placed in 15–20 degrees of anteverision
- Uncemented porous-coated or hydroxyapatite acetabular components available
- Biological fixation
- Hemispherical and rim fitting cups
- Cemented cups

### Cementless Femoral component

In the 1980s, new implant designs were introduced to attach directly to bone without the use of cement. The stem material tends to be manufactured from titanium which is less than 50% less stiff compared to cobalt chrome alloys which favours proximal load transfer. The proximal stem geometry in the majority can be either anatomical, trapezoid or rectangular. With respect to the distal stem geometry, cylindrical stems seat in the diaphysis and tapered stems allow metaphyseal seating.
The stems also have a surface that is conducive to attracting new bone growth. Most are textured or have a surface coating around much of the implant so that the new bone actually grows into the surface of the implant to provide secondary biological stability. The surface porosity is achieved via plasma-spray, grit-blasting, or bead sintering allowing bone ongrowth and fibre metal allowing bone ingrowth and hydroxyapatite encouraging osseointegration.

Precise preparation the femoral channel must match the shape of the implant itself very closely. New bone growth cannot bridge gaps larger than 1 mm to 2 mm. Cementless femoral components tend to be much larger at the top, with more of a wedge shape. This design enables the strong cortex of the bone and the dense, hard spongy cancellous bone just below it to provide support. The prosthesis should have minimal stiffness and maximum stability.

Risk factors for intra-operative fracture include female gender, rheumatoid arthritis, increasing age, osteoporosis, and altered bone morphology/deformity. Intra-operative fracture is more common in cementless than cemented stems.

Initially, it was hoped that cementless THR would eliminate the problem of bone resorption or stem loosening caused by cement failure. Although certain cementless stem designs have excellent long-term outcomes, cementless stems can loosen if a strong bond between bone and stem is not achieved.

Patients with large cementless stems may also experience a higher incidence of mild thigh pain. Causes of thigh pain include motion at the bone prosthesis interface, varus stem position in the presence of distal cortical hypertrophy, and excessive stress transfer from stem to host femur. Patients should be initially managed with time, since thigh pain may subside over the first 2 years.

Likewise, polyethylene wear, particulate debris, and the resulting osteolysis (dissolution of bone) remains problematic in both cemented and uncemented designs.

Cementless THR is most often recommended for younger, more active patients and patients with good bone quality where bone ingrowth into the components can be predictably achieved. Cementless stems are not the stem of choice for patients with stove pipe femurs, previous fracture, or previous osteotomy since these patients would not be expected to achieve a tight fit which is necessary for ingrowth. Poor quality bone stock is more likely to undergo plastic deformation and to allow subsidence of the femoral component.

---

**Box 7.5.6 Summary Box**

- Uncemented stems with surface coatings
- Interference fit and biological fixation
- Implant should have minimum stiffness and maximum stability
- Not ideal with stove pipe femurs

---

**Hybrid Total Hip Replacement**

A hybrid THR has one component, usually the acetabular socket, inserted without cement, and the other component, usually the femoral stem, inserted with cement. This technique was introduced in the early 1980s, so long-term results are just now being measured. A hybrid hip takes advantage of the excellent track record of cementless hip sockets and cemented stems.

**Femoral head**

The femoral head range in size from 22 mm up to 44 mm in THR. Larger femoral heads can be used in combination with resurfacing type acetabular components. The larger the femoral head, the larger the range of motion before impingement occurs against the acetabulum and therefore therefore has less dislocation risk.

---

**Longevity and Outcomes**

Hip replacement operations are highly successful in relieving pain and restoring movement. However, the ongoing problems with wear and particulate debris may eventually necessitate further surgery, including replacing the prosthesis (revision surgery) in damaged host bone.

---

**Future**

Improvements in the wear characteristics of newer polyethylene and the advent of hard bearings (metal-on-metal or ceramic) and bone conserving hip replacements may help resolve some of these problems in the future.

---

**Further reading**

Summary points

- Traditionally bearings were made from polyethylene and cobalt chrome. These bearings are still most commonly used for knee replacements. In hip replacements due to osteolysis caused by polyethylene wear alternative material combinations at the bearing surface are used.
- Highly cross linked plastics have been developed and have been shown to reduce wear. There are a number of different types available which differ in their performance.
- Metal on metal bearings first used in the 1960s have also been developed and show very low wear rates. These bearings are more susceptible to edge loading and the resulting metal ion release can result in adverse biological reactions leading to failure.
- Whilst ceramic on plastic surfaces have been used for a considerable amount of time the reduction in wear is not as great as with well functioning metal on metal bearings.
- Ceramic on ceramic bearings have been used for a considerable time and show even lower wear rates than metal on metal bearings. In the past there has been an incidence of catastrophic fracture of these bearings but developments in materials technology have considerably reduced these events.

Introduction

Joint replacements of the hip and knee are among the most successful of surgical procedures. The changing demography of the population means that in future more total joint replacements are going to be performed. For example, in 2003, the number of primary total hip replacements performed in the United States was around 220 000 and this is expected to increase to over half a million in 2030. The number of primary total knee replacements is expected to rise exponentially with the ageing population. Patients today are also generally more active than those of three decades ago when hip and knee replacements were first being developed. The success of total joint replacements also means that younger patients are being treated with these procedures.

Therefore extending implant longevity and improving function to meet the increased demands of today’s patients are important. One of the limiting factors to increasing the longevity of total joint replacements, particularly hip replacements, has been the performance of the bearing surface. In the 1990s, alternative bearings to cobalt-chrome on ultra-high-molecular-weight polyethylene (UHMWPE), such as metal-on-metal and ceramic-on-ceramic, saw a resurgence in use due to aseptic osteolysis, which is associated with the release of UHMWPE wear debris. Development of the materials and design of alternative bearings has continued in an effort to reduce problems associated with wear at the articulation. Alternative bearing surfaces have been used predominantly for total hip replacement with total knee replacements still using conventional UHMWPE on cobalt chrome. This chapter will focus on the problems associated with wear of UHMWPE and then concentrate on the development of alternative bearing surfaces.

Problems associated with wear of UHMWPE (Box 7.6.1)

In the 1980s, endosteal lysis was thought to be associated with the breakup of the cement mantle and release of cement debris. The use of uncemented stems was introduced because it was believed that cement was detrimental to the long-term fixation of components, particularly in younger active patients. It was not until the late 1980s that wear particles released from polyethylene bearings were identified as being the main contributors to aseptic osteolysis and long-term implant loosening. Small particles released from the plastic bearing surface are phagocytosed by macrophages, which then release a number of cytokines, the most important being tumour necrosis factor (TNF) alpha, interferon-1 and -6, and prostaglandins. These cytokines recruit other macrophages and also promote osteoclastic bone resorption. Macrophages can only phagocytose particles less than 8µm in size and larger polyethylene particles are engulfed by foreign body giant cells (Figure 7.6.1). This may well be one of the reasons why aseptic osteolysis for knee joint replacements is not as common as that seen in hip replacements.

Box 7.6.1 Conventional UHMWPE

- Wear of the bearing surface leads to the release of small particles less than 1µm in size.
- These particles are phagocytosed by macrophages, causing an inflammatory reaction which leads to activation of osteoclasts, aseptic osteolysis, and loosening of the implant.
- The average wear rate for hip replacements with a 22-mm head (linear penetration) is around 0.1mm/year.
- A threshold has been established of 0.05mm/year. Below this threshold, osteolysis rarely occurs.
- Frictional torque and sliding distance increase with larger heads and for this reason, bearings of less than 30mm have to be used.
Fig. 7.6.1
Simplified diagram of part of the biological response to wear particles; wear particles under 10μm are phagocytosed by macrophages. The macrophages secrete cytokines including TNF alpha, which lead to further inflammation and induces bone resorption by osteoclasts.

The main wear mechanism responsible for knee joint replacements is delamination which is a spalling of the plastic surface leading to the formation of large plastic shards which are engulfed by foreign body giant cells. In the hip joint, predominantly particles considerably less than 1 μm in size are released from the acetabular plastic bearing surface due to adhesive and abrasive wear mechanisms. Calculations have shown that millions of wear particles are released from the acetabular cup on a yearly basis. Examination of worn polyethylene hip and knee joints shows a contrasting appearance. The plastic articulating surface of worn tibial components due to delamination is characteristically rough and flaky. For UHMWPE acetabular components, the worn region is often finely polished and smooth (Figure 7.6.2). Clinically this leads to a linear decrease in the wall thickness of the acetabular cup which can be identified and measured on sequential clinical radiographs. The linear wear rate determined from a number of clinical studies using UHMWPE has been shown to be on average 0.05–0.1mm per year. For a 22-mm diameter cup this represents a volumetric loss of around 38mm3. This wear rate is associated with successful cases where there is little evidence of osteolysis. In any clinical series there is a distribution around a mean where in some instances the wear rate may be considerably higher and osteolysis evident. The concept of a wear threshold has been introduced by Dumbelton and co-workers. They suggested that a wear rate below 0.05mm per year would not cause osteolysis and this was based on the observation that osteolysis was rarely seen in patients with wear rates of 0.1mm per year.

Fig. 7.6.2
Photographs of worn acetabular cup (A) and worn tibial components (B). This shows the smooth worn region of the cup cause by abrasive and adhesive wear (w) and the thinner acetabular wall associated with the wear region (arrowed). The tibial plastic has worn down to the metal base plate and in contrast to the cup, the worn plastic has a flaky appearance caused by delamination wear.

A wear rate threshold implies that wear particles released in low numbers do not have any effect and this may be associated with the clearance of macrophages containing the particles from the joint via the reticular endothelial system. UHMWPE wear particles have been identified in regional lymph nodes (inguinal) and aortic lymph nodes as well as in the spleen.

When Sir John Charnley introduced polyethylene as a bearing surface for total hip replacements in 1963 he did so in combination with a specific design. He referred to the design concept as ‘low friction arthroplasty’, indicating the benefits of having a relatively small, 22-mm diameter head which reduced frictional torque and a thick plastic acetabular component which dissipated the stresses. For UHMWPE bearings there are advantages of having a small femoral head which is associated with the sliding distance imposed on the bearing surface as it moves. Relative to the acetabular cup, for a given range of movement a smaller head moves less than a larger head and consequently the sliding distance is less. This leads to reduced wear with smaller heads and is the reason why conventional UHMWPE bearings surface are restricted to below 30mm in diameter. The disadvantage with smaller head sizes when compared to larger heads, is that in theory there is a reduced range of movement due to earlier impingement of the femoral head on the rim of the cup. There is also a greater incidence of disarticulation due to the distance required for dislocation to occur, which is less with smaller heads.

Alternative bearings

Alternative bearing surfaces have been developed in response to the high wear rates of metal on conventional polyethylene and subsequent osteolysis caused by the generation of wear debris from these bearings.
These alternative bearings include:

- Cross-linked polyethylene
- Metal-on-metal bearings
- Ceramic-on-ceramic bearings
- Ceramic-on-polyethylene
- Metal-on-ceramic bearings.

### Cross-linked polyethylene (Box 7.6.2)

In the 1990s it was recognized that sterilization using gamma irradiation in air led to a gradual increase in the oxidation of the plastic. Work from John Collier's laboratory (Dartford, United States) showed that plastic components sterilized by gamma irradiation and stored in air over several years gradually developed a characteristic subsurface zone of oxidation (Figure 7.6.3). This was a result of the irradiation process which caused chain scission and free-radical generation (Figure 7.6.4). In air, these free radicals combined with oxygen resulting in embrittlement of the plastic. In retrieved components it was shown that this led to enhanced delamination and surface wear. Around this time it was also shown that irradiation in an inert environment had a beneficial effect. This was because the free radicals which were generated by irradiation cross-linked the polyethylene molecules, stabilizing the material. Hip simulator work showed that oxidation was detrimental and increased the surface wear rate, whilst cross-linking reduced wear. Largely driven by work from several groups in the United States, highly cross-linked polyethylenes (XLPs) have been produced. Generally these XLPs are made by irradiating UHMWPE with electron beam or gamma irradiation at relatively high doses (compared with those used for sterilization), followed by a heating step which eliminates the free radicals produced by irradiation, before machining the component and terminal sterilization. Elimination of the free radicals is an important step in reducing the long-term oxidative degradation and embrittlement of the XPEs. There are variations on this theme associated with the dose of irradiation, the temperature used to drive off the free radicals, and on the final sterilization step. Optimizing the amount of cross-linking has been a key consideration in the development of XPEs. A dose of up to 10kGy has been used clinically. This is around three times the amount of gamma irradiation used to achieve sterilization. However, high cross-linking promoted by increasing the dose of irradiation increases the number of free radicals produced. These free radicals have to be eliminated by a heating step which may reduce the fatigue strength and fracture toughness of the XPE, and the resistance to crack propagation is reduced compared with conventional UHMWPE.

#### Box 7.6.2 Cross-linked polyethylene

- Gamma irradiation causes the generation of free radicals which can cause both cross linking and oxidation
- XPEs are made using high doses of irradiation promoting cross-linking and by a heat treatment that drives off the free radicals
- There are a number of different XPEs available with different performances and material properties
- XPEs have been shown to substantially reduce the wear of the acetabular cup.

#### Fig. 7.6.3

Sections through part of a plastic component from a knee joint component (A) and an acetabular cup (B) showing subsurface embrittled regions caused by plastic oxidation. The embrittled plastic has been stained with a strong acid discolouring the oxidized polyethylene.
XPEs have been shown in hip simulator tests to have extremely low wear rates, even under adverse conditions associated with rim loading, abrasion of the femoral head, and mal-positioning of the implants. Some laboratory hip simulator studies where the wear of XPEs was compared with conventional UHMWPE showed that XPEs reduced wear by over 90%. Other studies on different XPEs have shown less improvement. Due to the low wear rate of cross-linked plastics it has been proposed that these materials can be used in large diameter (>32-mm) acetabular cups. Hip simulator studies even under extreme conditions have shown that XPEs can potentially be used for large diameter plastic acetabular bearings.

Laboratory and short-term clinical studies have provided strong evidence that XPEs improve the longevity of total hip arthroplasty; however, the application of this material to total knee arthroplasty may not be so beneficial. Due to the fact that knee joint replacements are not as conforming as in the hip, high contact stresses are generated on the tibial plastic. This is one reason that delamination wear and cracking of the plastic is seen in knee replacements and less frequently in hip replacements unless there is rim contact. The cross-linking process reduces the resistance to crack propagation which is associated with cracking and delamination, and this may limit the role of XPEs in total knee arthroplasty. This reduction in the resistance to cracking is related to the heating process which is required to remove the free radicals. Retrieval of some components has shown oxidation, delamination, and cracking of XPE plastic and residual free radicals have been detected. This is associated with one particular XPE where it is claimed the free radicals were not eliminated because the heating step only annealed the plastic and the temperature was not high enough to melt the material which drives off more free radicals.

Recent advances in processing XPEs addresses the problems associated with the reduction in the resistance to crack propagation. One development utilizes vitamin E which is infused into the XPE after the irradiation step. Vitamin E is an antioxidant and works by scavenging free radicals in the plastic. In this way, although heated, the plastic is not re-melted during the infusion of vitamin E after the initial gamma irradiation step. It has been proposed that in this process the benefits of cross-linking can be achieved without the detrimental effects associated with remelting. Polyethylene manufactured using the technique is known as ‘E-poly’. Another second-generation XPE utilize three relatively low-level irradiation steps, each separated by an annealing step to drive off the free radicals that are generated each time. In this way, a high level of cross linking can be achieved without reduction in the material properties. This material is known as X6 polyethylene.

**Metal-on-metal (Box 7.6.3)**

At the same time as XPEs were being developed, there was resurgence in the use of metal-on-metal bearings. The low wear rate associated with these bearings was another way of avoiding the osteolysis associated with conventional plastic acetabular cups. Metal-on-metal bearings have a long track record of use. Relatively small numbers of these bearings were successfully used in the McKee–Farrar hip replacement which was developed in the early 1990s. Contemporary metal-on-metal designs are different from the bearings used in the McKee–Farrar hip replacement. Modern designs utilize better manufacturing techniques enabling the femoral head to contact the acetabular bearing at the pole of the cup whereas, for the McKee–Farrar design, clenching of the bearing due to peripheral contact sometimes occurred. Provided the geometry and surface finish of the bearing surface is well controlled, modern designs may be lubricated by a fluid film. This is important because it cuts down friction and reduces wear of the bearing. Fluid film lubrication is related to the movement of the femoral head which captures a film of fluid that is drawn into the bearing as it moves. The clearance of the head at the equator of the cup is critical and this is known as the diametral clearance. Too large a clearance and a fluid film does not form under physiological conditions. Movement is also key; for a given range of motion, the larger the head, the faster the movement and the greater the entraining velocity (Figure 7.6.4). It has been shown that fluid films form less readily in small metal-on-metal bearings. For metal-on-metal bearings the wear rate is more sensitive to macrogeometry and lubrication than a metal-on-UHMWPE bearing.

**Box 7.6.3 Metal-on-metal hip replacements**

- Wear on metal-on-metal hip replacements is characterized by a run-in period of relatively high wear and then a steady state period where the wear is lower
- Very low wear rate
- Wear rate increases when the cup is inserted at high inclination angles
- Wear particles are small in the nanometre size range
- Corrosion of these wear particles and corrosion from the bearing produces increased levels of metal ions in the bloodstream.

The wear rates of first-generation metal-on-metal bearings have been shown to be two orders of magnitude less than a conventional metal-on-UHMWPE bearing. For second generation, numerous metal-on-metal hip replacements hip simulator testing has shown that a metal-on-metal has considerably less wear than a metal-on-UHMWPE couple. The volumetric wear in hip simulator tests of second-generation bearings has been shown to be less than 1mm³ per million cycles. Initially wear is relatively high but reduces to a steady state after about one million cycles. Metal-on-metal bearings are said to have a self-polishing capacity and bed-in over time. A million cycles represents about 0.5–1 year of use in patients. The wear rates measured from retrieved metal-on-metal bearings are higher than that seen in hips simulators but are still very low compared to metal on UHMWPE. In *vivo* wear of metal-
on-metal bearings cannot be measured using radiographs because there is no distinction between the bearing surfaces and the wear rates are extremely low. Retrieval analysis of second-generation metal-on-metal bearings has shown wear of 25mm³ for the first year, and as low as 5mm³ per year thereafter.

As with any other bearing articulations there are advantages and disadvantages with metal-on-metal. Wear particles released from metal bearings are between 20–100 nanometres and are an order of magnitude smaller than debris released from UHMWPE bearings. The smaller size metal debris per se is believed to be less aggressive than plastic wear particles. The lubrication of ceramic-on-ceramic bearing surfaces (Figure 7.6.4) is thought to take these small particles up into the cell by a different mechanism which does not lead to the release of cytokines associated with phagocytosis of plastic debris. However, wear of the metal-on-metal bearings is a major concern. In theory, under fluid film lubrication wear should be low but physiological conditions associated with movement and gait, as well as the surgical positioning of the cup, all lead to the release of metal debris and ions. The metal ions are generated either through direct corrosion of the bearing surface or by the corrosion of the metal wear debris.

In patients with metal-on-metal hip replacements, metal ions in serum have been shown to be three to five times higher than in controls (metal-on-UHMWPE). These ions are secreted from the body in urine; however, due to the continual release there is always a pool of ions in the blood. In line with the observation of bedding-in of the bearing seen in simulator studies, there is a higher level of metal ions in the bloodstream during the first postoperative year. Metal ion levels are higher in patients where the cup has an inclination (abduction) angle of greater than 50 degrees and this is attributed to edge loading. A small number of studies have also demonstrated a transitory rise in metal ion levels after patients have exercised. So, for example, a study from Oswestry, showed a significant increase in serum cobalt and chromium of over 10% immediately after the exercise. This is an important study because the rise in blood cobalt and chromium levels was immediate, indicating that metal ion levels may be a combination of direct corrosion and release of ions from the bearing surface and generation of wear particles that subsequently corrode. Current work is showing the importance of direct corrosion of the metal-on-metal bearing surface in contributing to ion levels in the bloodstream.

The long-term biological consequences of the exposure to ions and wear particles remain largely unknown; however, adverse physiological effects have been identified in the follow-up of patients exposed to cobalt-chromium implants. It has been shown that implants generally have the potential to cause structural chromosome changes in marrow cells and in circulating lymphocytes but the incidence is greater in patients with metal-on-metal bearings. The clinical consequences of these chromosome changes, which include aneuploidy, deletions, translocations, and fragmentation, in a small number of cells are unknown. It is difficult to link these chromosome changes to any increase risk of developing cancer. However, the risk of developing haematopoietic cancers in patients with metal-on-metal hip replacements may be very slightly increased.

In a relatively small percentage of patients, wear debris and metal ion release from metal-on-metal bearing surfaces has been linked to newly recognized condition which is characterized by local necrosis, deposition of fibrin, and the agglomeration of lymphocytes around blood vessels, often deep within the synovial capsule. This condition has been termed aseptic lymphocyte-dominated vasculitis associated lesion (ALVAL). This is also linked with the formation of soft tissue masses within the capsule and surrounding soft tissue which is referred to as a pseudotumour. These masses may contain fluids or be more cellular and the main histological features of these masses are extensive necrosis and lymphocytic infiltration. Pseudotumours may also be linked to a hypersensitivity response. Metal ions can initiate a hypersensitivity response. A delayed cell-mediated hypersensitivity can occur, in which cytokines are released by T lymphocytes and an increased activation of macrophages is seen. Metal ions, such as nickel and chromium, can initiate a hypersensitivity response and in the normal population the incidence of sensitivity to metal ions is around 10%. This number is doubled in patients with well-functioning total hip replacements and increased further in patients with loose implants requiring revision. Whether the increased metal sensitivity is a cause or effect of the loosening is not known.

Ceramic bearing surfaces (Box 7.6.4)

Ceramic-bearing surfaces have been used over several decades and ceramic femoral heads have been implanted for more than 40 years. Just like other bearing surfaces there has been a general improvement in their wear characteristics and performance over time. The key to the wear resistance of ceramic surfaces is their hardness which prevents scratching (Table 7.6.1). These materials are also hydrophilic, more wettable than cobalt-chrome surfaces, and hold onto a fluid film which may be important for the lubrication of ceramic-on-ceramic bearing surfaces (Figure 7.6.5). Ceramic bearing surfaces can be used either as ceramic-on-ceramic coupling or as a ceramic femoral head articulating with a UHMWPE socket. In the past this was conventional polyethylene but XPEs are being increasingly used.

The perceived problem with ceramic heads is their history of catastrophic failure which is associated with their inherent low fracture toughness and ductility. Zirconia oxide ceramic femoral heads were introduced approximately 20 years ago to address the problems associated with alumina fracture. At that time, zirconia oxide femoral heads were three times stronger than their alumina oxide counterparts; however, zirconia oxide hardness is lower.

Several studies have shown the wear rate of UHMWPE total hip replacement is reduced when the femoral head is ceramic, although some studies have conversely shown a high penetration rate of UHMWPE liners by zirconia oxide heads. Overall, the penetration rate is between two to three times lower with ceramic-on-UHMWPE than with a metal-on-UHMWPE bearing. A small number of other studies have described higher wear with zirconia oxide heads with penetration rates equivalent to those seen with metal-on-UHMWPE bearings. The reason why some zirconia oxide bearings demonstrate a contradictory behaviour may be associated with changes in the phase structure of the head. Paradoxically, zirconia oxide owes its strength to a material phase transformation from a tetragonal phase to the monoclinic phase. The natural state of pure zirconia oxide is the monoclinic phase but by a small addition of yttria during processing, a stabilized tetragonal phase is produced. A slight volumetric change occurs with this phase change which happens when there is a release of stress in the material. This is important for strength because the phase change compresses cracks in the material making them less able to propagate thus strengthening the ceramic. However, if this change happens on the surface, the monoclinic phase will increase the roughness of the femoral head increasing the polyethylene wear. This surface phase change can be accelerated by heating in an aqueous environment and this is one reason why zirconia oxide femoral heads should never be autoclaved. The phase change does not occur with alumina oxide femoral heads. Linear polyethylene wear against alumina heads is reported to be as much as a factor of the to ten times lower than metal versus polyethylene.

Although technology to prevent ceramic fractures is improving, an alloy has been developed composed of niobium and zirconium marketed as Oxinium. This alloy's surface can be transformed into a relatively thick (4–5µm) zirconium oxide (i.e., zirconia) ceramic-like material using a thermal process. This process combines the strength and toughness benefits of using a metal alloy head with the wear properties associated with zirconia oxide. The oxide layer is not a coating but rather the surface zone of the metal alloy. The oxide/metal interface is continuous, without pores or voids which might be detrimental to oxide adhesion. Laboratory studies have demonstrated the superior wear performance against UHMWPE with Oxinium heads generating significantly less volumetric wear compared with cobalt-chromium alloys. This technology can also be applied to the femoral component of knee joints. For knees, the femoral component does not contain nickel or chromium which may be beneficial in cases of metal sensitivity. Tests in a knee simulator comparing wear rates produced by Oxinium and cobalt-chrome femoral components against polyethylene revealed 42–85% less wear in the Oxinium group. Oxinium and cobalt-chrome femoral heads have also been compared under both smooth and roughened conditions in hip simulators; Oxinium heads exhibited lower wear rates.

Before discussing ceramic-on-ceramic articulations, it is important to understand how the advances made in manufacturing alumina oxide components have improved their fracture toughness and the strength. In the 1980s, femoral heads made from alumina oxide were produced using long sintering times which were necessary to produce alumina femoral heads with low porosity; however, this resulted in the growth of large grains in the material making it susceptible to fracture resulting in the catastrophic fracture of a small number of femoral heads. Thus in the 1970s a clinical fracture rate of one head per 2000 was reported or 0.05%. Additions of CaO or MgO prevented grain growth reducing the grain size and reducing the fracture rate by an order of magnitude. Reports on the rate of fracture of the second generation ceramics are considerably lower than first generation with rates as low as four per 100 000 or 0.004%. The latest developments (third generation) produce ceramics which are even stronger. These ceramics are composed of alumina oxide matrix combined with zirconia oxide giving the components both wear resistance (associated with
hardness of alumina oxide) and additional strength (associated with zirconia oxide component). Due to the development of pores during the sintering process, the size of femoral heads for second-generation ceramic was restricted to under 32-mm diameter but with the introduction of the newer ceramic mixtures the head size has increased to up to 40mm. The improvement in the manufacturing tolerances associated with the femoral spigot has also contributed to a decrease in the fracture rate.

If fracture of the femoral head does occur, the problems are substantial. Fragmentation of the ceramic usually means that it is difficult to clean out the joint during the revision procedure. The hard particles of ceramic that are left behind will increase the wear of the revision bearing. Often the tapers of the hip stem will be severely damaged, making it difficult to replace the head on the damaged taper, and in these situations the stem has to be revised.

Ceramic-on-ceramic wear rates are usually very low and in the range of 0.003mm per year; a factor of ten less than the lowest polyethylene wear rates. The wear particles that are released from ceramic bearings have been isolated and have been shown to be small, do not release ions, and are biologically well tolerated. There have, however, been reports that in series of successful ceramic-on-ceramic bearings there are often outliers where the wear is much larger. The reasons for this remain unclear but may be associated with the surgical technique in placing the acetabular cup, leading to edge loading. In these cases, wear is characteristically seen as a roughened region on the ceramic which is often linear at the periphery of the bearing area and in the form of a stripe, referred to as striped wear. Striped wear is caused by the ball slightly distracting from the socket and then impinging on the cup rim. Alumina acetabular components also have been susceptible to edge chipping and it has been recommended to place the acetabular component in the pelvis at 45 degrees to optimize the distribution of forces over the surfaces of the ball and cup, and to avoid neck-socket impingement.

Another concern regarding ceramic bearings which may be associated with stripped wear, edge loading, and poor lubrication is the development of a ‘squeaky’ hip. Various studies have indicated that the incidence of squeaking is low, at well under 1% in most clinical series, and that apart from the annoying squeak there are no other symptoms. Simulator tests have shown that squeaky hips are usually associated with dry bearings and in vitro squeaking can be reduced by lubricating the hip joint, but unfortunately this is not possible clinically.

**Metal-on-ceramic bearings**

Unlike the metal-on-metal and ceramic-on-ceramic bearings used for hip replacements, bearings used in other engineering applications are often made of dissimilar materials with one material being harder than the other. In this sort of bearing combination, relatively greater wear occurs on the softer member of the bearing pairing. Hip simulator studies have shown that although not as low as ceramic-on-ceramic, metal-on-ceramic pairings were found to have wear rates approximately 30–100-fold lower than the metal-on-metal pairings. In these hip simulator studies, most of the wear was generated from the metal acetabular cup and relatively little from the ceramic head. In simulators, metal particles from the ceramic-on-metal bearings were also smaller than from metal-on-metal bearings. Friction of ceramic-on-metal combination bearings was less than for metal-on-metal combinations which indicated reduced wear and greater fluid film lubrication. Clinical trials conducted recently, have also shown a corresponding decrease in metal ion release in the bloodstream in patients from metal-on-ceramic hip replacements when compared to metal-on-metal bearings. The wear particles from the metal-on-metal articulation were similar in composition and shape to particles found in retrieved tissues from around metal-on-metal prostheses. The use of differential hardness ceramic-on-metal pairings reduced the wear rate compared to metal-on-metal hip prostheses.

**Conclusions**

Undoubtedly the use of alternative bearing surfaces has reduced wear at the hip joint. Table 7.6.2 shows the advantages and disadvantage of different bearing combinations. These new and developing technologies have been applied more to hip joint replacement than to knee joints. The reason for this may be that the incidence of osteolysis in the knees is relatively low compared to hip replacements. This may be associated with the kinematics of the replaced knee where the crossover motion characteristically seen in hip replacements is much less. Also, with the recognition of the effect that sterilization in air had on polyethylene in the 1990s and with the subsequent improvements in processing standard UHMWPE used for tibial components, delamination wear was significantly reduced.
### Table 7.6.2: Advantages and disadvantages of bearing surfaces. Readings may vary according to the published study but these are representative. Note that for polyethylene articulations wear is expressed as linear penetration whereas for hard-on-hard bearings wear is expressed as a volumetric wear rate.

* Readings may vary according to the published study but these are representative. Note that for polyethylene articulations wear is expressed as linear penetration, whereas for hard-on-hard bearings wear is expressed as a volumetric wear rate.

** This is an estimate based on a number of studies which show variable results.

For orthopaedic surgeons the number of different alternative bearing couples available for hip joint replacements and the body of scientific information backing up and rationalizing each one makes the choice overwhelming. It should be remembered that, to a certain extent, the range of alternative bearings developed by manufacturers was a response to the considerable issues faced in the 1990s with aseptic osteolysis as a result of plastic wear, and these bearings have not yet stood the test of time. Although there is no substitute for clinical data, since the mid 1990s there has been considerable improvement in the way that these alternative bearings have been preclinically tested which provides safeguards to patients. The choices that surgeons make are often associated with the patients that they are treating, and in today’s environment, having a choice of different bearing surfaces is advantageous for both economical and performance-related issues.

### Further reading

Summary points

♦ Impingement:
  • Primary femoroacetabular impingement:
    ▪ Cam type
    ▪ Pincer type
    ▪ Combined cam and pincer
  • Secondary femoroacetabular impingement:
    ▪ Slipped upper femoral epiphysis (cam type)
    ▪ Protusio (pincer type)
    ▪ Retroverted acetabulum (pincer type)
    ▪ Malunited femoral head/neck fracture (cam type)
    ▪ Acetabular fracture (pincer type)
    ▪ Perthes disease (cam type)

♦ Instability:
  • Developmental dysplasia of the hip (treated/residual and untreated)
  • Dislocation
  • Subluxation
  • Dysplasia

♦ Inflammatory:
  • Juvenile idiopathic arthritis
  • Rheumatoid arthritis.

Aetiology of arthritis in the young adult hip

The cause of osteoarthritis of the hip can be viewed as a mechanical dysfunction resulting from either instability (hip dysplasia) or impingement, or a combination of both. Treatment is directed at the underlying disease process. Where there is no or minimal degenerative changes radiographically in a young patient who is normally fit and healthy, a reconstruction procedure is the preferred option (see Chapter 7.9). If there is evidence of severe osteoarthritis, an arthroplasty or salvage procedure should be considered.

History

Obtain the pertinent information: patient’s age; occupation; and onset, nature, and duration of pain. Are there any limitations of work or sporting activities? Past medical history of childhood illness or pain affecting the hip along with any previous operation should be documented, along with any positive family history. History of trauma or any other associated illness should be gathered.

It should be ascertained whether the pain is present on weight bearing or at rest, such as sitting. History of locking is very suggestive of intra-articular pathology, such as labral tears, loose bodies, or chondral flap.

Examination

♦ Assessment of gait pattern and sitting posture
♦ Abductor strength, neurovascular status, and limb lengths
♦ Active and passive range of motion.

Patients with hip dysplasia typically have good hip flexion and, due to femoral anteversion, good internal rotation. In femoroacetabular impingement (FAI), passive flexion of the hip to 90 degrees with adduction and internal rotation will be restricted and will elicit pain in the groin similar to the pain they are complaining of. This is the basis of the impingement test. In Perthes disease, abduction in extension will be severely restricted in the presence of hinge abduction.
Imaging

Radiographic (Figures 7.7.1–7.7.4)

The anteroposterior (AP) pelvic radiograph illustrates the femoral head and its sphericity. The position of the joint centre and any subluxation can also be noted by integrity of Shenton's line. The acetabular coverage of the femoral head is depicted as is the acetabular inclination, also known as the sourcil (the weight-bearing superior dome of the acetabulum), which should measure 0–10 degrees and is between a line parallel to the weight-bearing dome (sourcil) and a line parallel to the inter-teardrop line. Loss of joint space and version of the acetabulum can also be seen. The vertical centre edge angle of Wiberg should be greater than 25 degrees. The anterior or lateral centre edge angle quantifies the anterior cover of the femoral head, and angles of less than 20 degrees are considered abnormal. An AP projection may also show cyst formation at the superior lateral aspect of the acetabulum representing damage at the labrochondral junction.
