Technique for false-profile lateral radiograph and measuring anterior centre edge angle. The anterior centre edge angle is calculated from a false-profile radiological view of the pelvis. The subject stands at an angle of 65 degrees oblique to the x-ray beam, with the foot on the affected side parallel to the x-ray cassette. The focal distance is 1m. The tip of the greater trochanter forms the horizontal centre, and the vertical centre is midway between the symphysis pubis and the anterior superior iliac spine. A vertical line through the centre of the femoral head subtends the anterior edge angle by connecting with a second line through the centre of the hip and the foremost aspect of the acetabulum.

A retroverted acetabulum can be identified through the ‘cross-over’ sign (Figure 7.7.4). The cross-over sign is seen when the anterior rim of the acetabulum ‘crosses over’ its posterior rim, as their outlines are traced from proximal to distal on the radiograph. Retroverted acetabulae have been correlated with radiological evidence of osteoarthritis of the hip. A comparison of six radiographic projections to assess femoral head/neck asphericity demonstrated that the Dunn view in 45-degree or 90-degree flexion or a cross-table projection in internal rotation best show femoral head/neck asphericity, whereas AP or externally rotated cross-table views are likely to miss asphericity.
Fig. 7.7.3
Common radiographic angles. Acetabular angle (of Tonnis) or Sourcil angle normal value 0–10 degrees. Vertical centre edge angle (of Wiberg) normal value ≥25 degrees; note small cam lesion left hip.

Fig. 7.7.4
The cross-over sign in acetabular retroversion. A) Preoperative film shows cross-over sign, dotted line represents anterior rim of acetabulum. B) This patient was treated successfully for a pincer lesion with acetabular rim resection and labral refixation. The anterior dotted line and posterior solid line meet at the sourcil edge as they should in normal hips.

Computed topography
Computed tomography (CT) is useful in assessing the congruency and coverage of the femoral head and as an aid to preoperative planning for osteotomy.

CT can provide detailed information on bony architecture and any subtle pathology such as cam lesions (Figures 7.7.5 and 7.7.6). It also can assess version and is extremely helpful in imaging grossly abnormal anatomy.

Fig. 7.7.5
Coronal CT image of pelvis. A cam lesion is evident in the left hip. Note the cyst at the superior lateral margin of the acetabulum, this almost certainly indicates underlying labral or chondral pathology.
Magnetic resonance imaging

This is used valuation of painful hip and exclusion of other sources of hip pathology. It allows for assessment of concavity of head neck junction. The angle of Notzli (Figure 2.7.7.7) is used to confirm cam lesion. A normal alpha angle is approximately 40 degrees while patients with FAI have average alpha angles of 74 degrees. The gadolinium enhanced magnetic resonance imaging of cartilage has the potential of predicting outcome of Bernese pelvic acetabular osteotomy by assessing the integrity of the cartilage.

Fig. 7.7.7

Alpha angle (of Notzli). A is the anterior point where the distance from the centre of the head (hc) exceeds the radius (r) of the subchondral surface of the femoral head. Alpha angle is then measured as the angle between A–hc and hc–nc, nc being the centre of the neck at the narrowest point. A) shows a hip in a normal subject and B) a typical deformation resulting from a Cam lesion.

Femoroacetabular impingement (Figure 7.7.8)

The concept of FAI started to become widely accepted at about the same time that enthusiasts of hip arthroscopy started to publish their experiences and results. One of the main indications and supposed benefits of hip arthroscopy was the diagnosis and debridement of labral tears. Unfortunately, results were disappointing due to the fact that the labral tear was not the underlying pathology but usually a result of FAI which itself went untreated. The study by Beck and colleagues has shown that cam impingement in particular leads to extensive damage to the acetabular cartilage and that separation between the labrum and the cartilage arises because the cartilage is ripped off the labrum. The tear of the labrum is only part of the pathology and is secondary to impingement.

The aim of surgical treatment for FAI is to improve the femoral head–neck offset thereby improving joint clearance and preventing abutment of the femoral neck against the acetabulum. The open surgical approach pioneered by Ganz and colleagues involves dislocation of the femoral head through a trochanteric flip osteotomy and allows full visualization of the femoral and acetabular articular surface. Excision osteoplasty is performed to regain a spherical femoral head and appropriate head–neck offset; acetabular rim excision is performed where there is a prominent anterolateral rim and any damage to the labrum can be addressed. Open dislocation of the femoral head involves technically challenging surgery with a long learning curve. Complications following open dislocation of the hip include heterotrophic ossification (37%), failure of trochanteric fixation, incomplete trochanteric union (27%), and sciatic nerve injury. The approach is extensile and requires sacrificing the ligamentum teres and 6–8 weeks of non-weight bearing with crutches until the trochanteric osteotomy unites.

Hip arthroscopy has recently become popular, but even in experienced hands cam lesions, and in particular acetabular rim trimming and labral refixation, can be technically very difficult. Complications following arthroscopic treatment include sciatic and femoral nerve palsy, perineal injury, and intra-articular breakage of instruments. Arthroscopic treatment of FAI is said to have results comparable to the open procedure although outcome measures were unclear and the methodology unclear.

Treating impingement of the hip through a direct open approach is not a novel idea. Even the authors behind the Bernese surgical dislocation of the hip routinely open the hip joint through a modified Smith–Petersen approach to assess for any impingement following periacetabular osteotomy, and, when necessary, undertake a resection osteoplasty of the femoral head–neck junction.
direct anterior approach allows for easy access to the site of impingement and correction of cam, pincer, and labral lesions. This can be performed after intra-articular assessment and treatment by hip arthroscopy or on its own. At the Royal National Orthopaedic hospital it is the senior surgeon’s preference to use a mini-arthrotomy based on the Heuter approach.

Resection of the cam lesion by whatever technique should not exceed 30% of the femoral neck as the risk of femoral neck fracture becomes unacceptably high.

Summary points

♦ Hip Dysplasia
  ▪ Despite screening programs, a large number of patients are affected by dysplastic hips and their sequelae
  ▪ An understanding of anatomical abnormalities is crucial
  ▪ Appropriate techniques and implants make arthroplasty feasible
  ▪ Complications are significantly higher than standard primary hip replacements

♦ Protrusio Acetabuli
  ▪ Technical difficulties include inadequate medial wall and restoring offset, hip centre and leg lengths
  ▪ Neck may need to be cut in-situ; bone graft is usually necessary and ideally should be taken from the femoral head
  ▪ Antiprotrusio cages or custom implants may be needed in cases with excessive bone loss

♦ Arthrodesed hip to total hip replacement
  ▪ Careful evaluation of the gluteal muscles is mandatory and predicts final walking ability and patient satisfaction
  ▪ Long-term effectiveness of total hip replacement in ankylosed hips is satisfactory but there is a higher complication rate

The dysplastic hip

Introduction

The severity of hip dysplasia varies widely and adults with dysplastic hips pose a number of technical challenges, ranging from the identification and preparation of the true acetabulum, preparation of the femoral canal, and stable reduction of the components.

Patients who have hip dysplasia are often young and active, and have had previous operations on their hip. Total hip replacement in such patients has been associated with high rates of complications and revision. It is therefore critical to understand the complexities of total hip replacement and to plan any intervention thoroughly.

Anatomy

The anatomical abnormalities depend on the severity of dysplasia. Characteristic features are listed in Box 7.8.1 (Figures 7.8.1 and 7.8.2).

Box 7.8.1 Characteristic features of hip dysplasia

♦ Acetabulum:
  ▪ In a low subluxation, the acetabulum is shallow but may have a wide, oval opening
  ▪ Anteromedially, the wall may be very thin
  ▪ In a high dislocation the affected side of the pelvis is smaller and the acetabular wall is thin, soft, and in some grossly antverted

♦ Proximal femur:
  ▪ Small head and short neck. Usually significantly antverted
  ▪ Usually significantly antverted
  ▪ Greater trochanter is posterior displaced
  ▪ Narrow, straight tapered femoral canal with a tight isthmus
  ▪ Increased neck-shaft angle

♦ Soft tissues:
  ▪ Shortened hamstrings, adductors, and quadriceps
  ▪ Horizontal orientation of the abductors from proximal migration of the femoral head
  ▪ Thickened hip capsule
  ▪ Shortened sciatic nerve, vulnerable to lengthening
Altered normal course of femoral nerve and profunda artery.

Assessment
Common symptoms and signs include:

- Pain
- Limb-length discrepancy
- Limp
- Referred knee pain
- Abductor lurch
- Compensatory lumbar lordosis
- Positive Trendelenburg sign.

Classification
Crowe and colleagues classified dysplastic hips radiographically into four categories depending on the extent of femoral head proximal migration. The Crowe classification system is the simplest and most widely used and allows comparison of operative techniques.

Crowe classification (Figures 7.8.3–7.8.5)
Grade 1:
- Proximal displacement less than 0.1% of pelvic height or less than 50% subluxation of the height of the femoral head

Grade 2:
- Displacement of 0.10–0.15% or subluxation 50–75% of the height of the femoral head
- Usually do not have leg-length inequality or loss of bone stock
- With low dislocation, the femoral head articulates with the false acetabulum which partially covers the true acetabulum; on x-ray there may be two overlapping acetabula
- Inferior part of the false acetabulum is an osteophyte which is located at the level of the superior rim of the true acetabulum; visible part of the true acetabulum can therefore be missed

Grade 3:
- Displacement of 0.15–0.20% or subluxation of 75–100% of the height of the femoral head
- Complete loss of superior acetabular roof
- May have thin medial wall; anterior and posterior columns are intact

Grade 4:
- Displacement greater than 0.20% or subluxation greater than 100% of the height of the femoral head
- True acetabulum is deficient but remains recognizable

Patients with Crowe grade 2 or grade 3 tend to develop degenerative changes earlier and proceed to total hip replacement at a younger age than grade 1 or 4.

Preoperative planning

Previous operations are common and add new surgical challenges. Previous femoral osteotomies make exposure more difficult and the procedure more technically demanding, but without significantly higher complication rates. Periacetabular and pelvic osteotomies may improve acetabular coverage but may alter available bone stock and careful assessment is necessary.
Retained metalwork and hardware can be problematic and its removal may be associated with significant morbidity. Some authors advocate the removal of hardware in the dysplastic hip setting routinely to avoid later difficulties with embedded or even intramedullary metalwork at a later date. In situ metal will need to be removed before a total hip replacement and specialized instruments and equipment may be needed. A staged procedure is sometimes necessary.

Preoperative planning is crucial in achieving a successful outcome. Useful investigations include:

- Radiographs
- Computed tomography (CT) scan can assess bone stock and degree of femoral anteversion
- A magnetic resonance image (MRI) scan can assess laxity of soft tissues around the hip.

**Templating**

- **Acetabulum:**
  - Position of true acetabulum should be identified
  - Need to decide whether to attempt to restore acetabulum to its original location or accept a non-anatomic (high hip centre) position
  - True acetabulum placement diminishes joint reaction force, facilitates limb lengthening, and improves abductor function
  - Assess degree of anteversion and adequacy of bone stock

- **Femur:**
  - Size of the femoral canal
  - Need for custom components
  - Need for rotational osteotomy. Consider if anteversion greater than 40 degrees
  - Need for relative equalization of leg lengths
  - Restoration of abductor function

- **Components:**
  - Estimate for size of components
  - Method of fixation
  - Need for bone graft
  - Special or custom made equipment.

**Operative procedure (Figures 7.8.6–7.8.12)**

**The approach**

Standard anterolateral or posterolateral approaches can be used with less severe degrees of dysplasia. Transtrochanteric or subtrochanteric approach may be necessary for high dislocation or where abductor retensioning is required. This approach affords excellent exposure at the cost of the difficulties and complications of trochanteric reattachment.
The acetabulum

Obtaining satisfactory acetabular coverage is crucial. At least 70% contact should be with host bone. Either bone graft or cement can be used to fill superior defects.

When there is only a moderate reduction in bone stock, small acetabular components may be used. Sochart and Porter reported 97% 10-year survival and 58% 25-year survival of extra small Charnley acetabular components (38mm or less) usually with 22-mm heads.

Changes in the centre of hip rotation alter hip biomechanics. Acetabular placement can be non-anatomical or anatomical.

**Anatomic (low hip centre)**

- Better bone stock at site of true acetabulum
- May restore Shenton's line but acetabular coverage may be limited
- Use the transverse ligament as a landmark
- Loosening 13% at fifteen years (Linde and Jansen)
- May not be possible if hip is very stiff
Large superior defect in superior wall can be filled with femoral head autograft and held with screws (Fig. 7.8.7-B and 7.8.8).

Uncemented fixation may be advantageous for implant survival but needs good coverage.

If acetabular component is small due to limited bone stock 22mm femoral heads can be used.

Fig. 7.8.7
Three alternative techniques that have been used for acetabular reconstruction during total hip arthroplasty in hips with a low dislocation. A) Superior placement of the cup. The cup is placed in the false acetabulum, and the superior location of the centre of rotation of the artificial joint is accepted. B) The superolateral augmentation technique with the use of a structural graft. C) The cotyloplasty technique. Complete coverage and anatomical placement of the cup are obtained with controlled medialization. (Reprinted with permission from Hartofilakidis, G. and Karachalios, T. (2004). Total hip arthroplasty for congenital hip disease. Journal of Bone and Joint Surgery, 86A, 242-50.)

Fig. 7.8.8
Crowe grade 1 dysplastic right hip pre- and post-uncemented total hip replacement.

Dunn and Hess recommended a deliberate fracture of the medial wall (cotyloplasty) to place the cup within the available iliac bone plus or minus augmentation with a mesh. The defect is then reinforced with autogenous bone graft and a small cup cemented in. This procedure advances the acetabulum medially and shifts the weight-bearing axis distal to the acetabulum, whilst gaining good anterior and posterior coverage (Figure 7.8.6C).

Fig. 7.8.6
CT scan assessing bone stock and femoral neck anteversion.

The femur

Anteversion:
• Significant anteversion (greater than 40 degrees) may necessitate a derotational osteotomy or the use of a custom or modular implant in which version of the femoral neck can be varied

• Femoral shortening:
  • The femur may need to be shortened to protect the sciatic nerve, especially if the acetabulum is brought down to its true level
  • Lengthening of 4cm or more is associated with increased risk of nerve damage. Leg lengthening of <4cm—no nerve palsy; lengthening >4cm—28% develop a nerve palsy
  • Shortening can be carried out at the level of the trochanter or in the subtrochanteric region
  • Subtrochanteric shortening is indicated when several centimetres of shortening is necessary or if derotation osteotomy required
  • Femoral neck shortening is combined with release of the psoas and external rotators

• Narrow femoral canal and short femoral neck often demands the use of a small, short, straight component. In Crowe grade 1, 2, or 3 a conventional implant can usually be used as long as the size of the femur is taken into account

• Distortion from previous osteotomies must be considered.

The abductors

• Osteonecrosis and trochanteric overgrowth in dysplastic hips may result in the greater trochanter lying superior to the centre of the femoral head

• May be resolved with:
  • Appropriate femoral component and increased offset
  • Extensive capsular release, psoas release, gluteus maximus tendon transposition
  • Abductor slide: stripping abductors off ilium and advancing them on the superior gluteal neurovascular bundle

• If the greater trochanter or the abductors cannot be reattached they can be sutured to tensor fascia lata and immobilized in abduction for 6 weeks.

Complications and outcomes

Complications are consistently higher in dysplastic total hip replacements compared with osteoarthritis hip replacements.

• Nerve palsy: 3–15% in published series. Maximum lengthening 4cm for dysplastic hips

• Dislocation: 5–11%

• Trochanteric non-union: 11–29%

• Fracture of the narrow femoral canal

• Impingement: increased if high hip centre used, particularly if the hip is placed medially. The femoral component impinges on the anterior acetabular column in flexion and internal rotation and impinges on the posterior column in extension and external rotation. Reduced with increased offset and release of rectus femoris

• Infection: higher rates reported may be due to longer operating times and more extensive soft tissue dissection and stripping.

Protrusio acetabuli

Introduction

Protrusio acetabuli was first described by Otto in 1824 as an intrapelvic protrusion of the femoral head occurring as ‘an abnormal gouty manifestation’ in adult women.

Protrusio may be primary or secondary and is thought to occur from the result of remodelling of the weak, medial acetabular bone after multiple recurring stress fractures. It is defined as displacement of the femoral head medial to the ilio-ischial line. In the early stages this heals with no apparent bone defect, in later stages the bone is severely fragmented. The deformity may progress until the femoral neck impinges on the side of the pelvis. Technical difficulties are, thus, normally encountered with the medial wall of the acetabulum in total hip arthroplasty.

Primary protrusion (Otto pelvis):

• Is characterized by progressive protrusion in middle-aged women

• Bilateral in one-third of patients and causes pain and limitation of movement at an early age

• Varus deformity of the femoral neck and degenerative changes are common.

Secondary protrusio may be bilateral or unilateral and due to:

• Paget’s

• Marfan’s
- Rheumatoid arthritis
- Ankylosing spondylitis
- Osteomalacia
- Septic arthritis
- Central fracture dislocation
- Total hip replacement and migration of the femoral head or cup.

**Classification** (Figures 7.8.13 and 7.8.14)

Sotelo-Garza and Charnley measured the distance between the medial wall of the acetabulum and the pelvic brim (ilio-pectineal line) radiographically. They recognized three grades:

1. 1–5mm (mild protrusion)
2. 6–15mm (moderate)
3. Over 15mm (severe).

**Radiographic diagnosis:**

- If the medial wall of the acetabulum is 3mm or more medial to the ilio-ischial line in men and 6mm medial to it in women.

---

**Fig. 7.8.13**
Kohler's line and centre edge angle of Wiburg in a normal hip.

---

**Fig. 7.8.14**
Sotelo-Garza and Charnley method.

- If femoral head is medial to Kohler's line (line from medial border of ilium to medial border of the ischium)
- If centre edge angle of Wiburg is greater than 40 degrees (normal = 35 degrees).

**Preoperative planning**
Successful total hip replacement depends upon restoring:

- The medial wall
- The ‘hip centre’ position
- The correct offset and abductor function
- Leg length inequality

and preventing recurrent protrusio.

Operative procedure (Figure 7.8.15)

Minor degrees of protrusio can be treated successfully with a standard total hip replacement. Moderate or severe degrees compromise the medial wall and an alternative should be considered. In some cases the neck cut will need to be made ‘in situ’ rather than risking a fracture whilst trying to dislocate the hip.

Bone graft

Bone grafting offers an elegant solution to managing the medial wall defect in protrusio. Various techniques have been described. It needs to be intimately opposed to the irregular host bed and compressible to allow sufficient incorporation and remodelling. Bone wafers meet these criteria better than a single massive graft as described by Heywood in 1980. Wherever possible, bone should be taken from the femoral head and supplemented by cancellous curettings from the femoral neck and greater trochanter. Morcelized bone graft is used for contained defects and can undergo revascularization and remodelling; it strengthens with time. Bone graft also allows cement to be inserted and offers resistance to compression. Using cement alone against the weak medial wall provides poor containment and fixation, which in turn leads to premature loosening.

Acetabulum

Uncemented components can be inserted over the bone graft in a more lateral and anatomic position and secured with acetabular screws. Ideally an acetabular component should contain a peripheral flare, plus or minus peripherally placed screws, rather than a true hemisphere in order to prevent progressive medialization of the component. If a cementless cup is used, contact with host bone should be at least 50%. If contact cannot be made with at least 50% of host bone, then a cemented cup with a reinforcement ring or the technique of cementing into impacted bone should be used. In cases of extensive bone loss, antiprotrusio cages are necessary.

Reaming

It is essential not to deepen the acetabulum while reaming; the surgeon should ream to allow a good peripheral fit. The reamer can be used in reverse mode to mould and conform the graft to the acetabular floor.

Results

The adequacy of correction of the deformity and anatomical centre of rotation correlates with long-term prosthetic survivorship. Good results exist for grafted hips; cement or antiprotrusio cages alone may fail early and should be supplemented with bone graft to provide lasting support.

- Primary protrusio is uncommon and accounts for only a small percentage of cases
- Technical difficulties include inadequate medial wall and restoring offset, hip centre and leg lengths
- Neck may need to be cut in-situ; bone graft is usually necessary and ideally should be taken from the femoral head
- Antiprotrusio cages or custom implants may be needed in cases with excessive bone loss.

Conversion of arthrodesed hip to total hip replacement

Introduction

Hip arthrodesis can successfully provide long-term pain relief and will allow the resumption of manual labour and demanding activities.
physical activities. However, over time, it may be associated with a significant functional disability:

- Back pain:
  - Multilevel degenerate changes common
  - Leg-length inequality and fusion malposition exacerbate lower back pain
- Ipsilateral knee pain and instability:
  - More likely in an adducted fused position
  - Tendency for valgus deformity
- Contralateral hip pain: more likely if hip fused in an abducted position
- Painful pseudoarthrosis.

Conversion to a total hip replacement may improve these symptoms as well as restoring leg-length inequality and improving hip mobility. Conversion of an ankylosed hip does, however, introduce a number of challenges:

- The effect of previous operations on both bone and soft tissues
- Atrophy of periarticular muscles
- The initial disease and indication for fusion.

Mid-term results have been satisfactory but complications, failures, restricted postoperative motion, and instability are more frequent than after primary hip replacement.

Preoperative planning

- Appropriate radiographs:
  - Anteroposterior and lateral
  - Judet views may identify anterior or posterior column deficiencies
- CT scan to assess bone stock
- MRI can be helpful in assessing the proximity of neurovascular structures and abductor muscle mass
- Position of fusion: patients with abnormal positions of fusion are more likely to have clinically significant soft tissue contractures and may require further soft tissue releases
- Further abductor muscle assessment:
  - EMG studies: routine use in assessing abductor function may be questionable
  - Some authors suggest palpation of abductor muscle contraction

Take care in offering conversion to total hip replacement when gluteal muscles are not continuous and the hip is fused in a good position.

Operative technique (Figure 7.8.16)

Numerous approaches have been described. The authors prefer a standard posterior approach although the direct lateral or a transtrochanteric approach is commonly used with success.

Gluteal muscles are assessed and any internal fixation devices will need to be removed. The femoral neck and the site of the fusion between the ilium and femoral head needs to be clearly visualized and preoperative planning is helpful in achieving this. If in doubt, an intraoperative radiograph can be obtained. Heterotopic bone is removed with an osteotome and the femoral neck is cut with an oscillating saw. Adequate exposure is necessary to identify the inferior margin of the acetabulum.
Technical considerations

- Acetabular component:
  - Consider constrained liner, especially if poor abductors
  - Structural grafting is sometimes required

- Femoral component: routinely prepared using modular implants to restore soft tissue stability, hip mechanics and a stable reduction

- Soft tissues releases are frequently required:
  - Percutaneous adductor tenotomy
  - Psoas release
  - If no abductors, the proximal femur can be sewn to the tensor fascia lata anteriorly and the gluteus maximus and iliotibial band posteriorly.

Postoperative rehabilitation

- Routine thromboprophylaxis and prophylactic antibiotics
- ‘Slings and springs’ until muscle control and then weight bearing depending on the type of implant fixation
- If any doubt about abductors, then an abduction brace for 6 weeks should be worn.

Results

The effectiveness of total hip replacement following hip fusion has been demonstrated in a number of series. Back pain is often relieved (70–90%) and leg lengths can be improved. Ipsilateral knee pain is less predictably relieved. Success is often more reliable in patients with spontaneous ankylosis.

Complications

More complications are generally reported than after conventional total hip replacement:

- Dislocation:
  - More common if early fusion (less than 15 years) due to underdevelopment of the abductor muscles
  - Quoted rates vary from 2–6%

- Infection: 2–6%
- Nerve palsy: sciatic and femoral 2–13%
- Heterotopic ossification:
  - Up to 13%
  - Some authors advocate the routine use of non-steroidal anti-inflammatory drugs

- Careful evaluation of the gluteal muscles is mandatory and predicts final walking ability and patient satisfaction
- Long-term effectiveness of total hip replacement in ankylosed hips is satisfactory
- Patients should be counseled about the higher rate of complications
- Trendelenburg gait will normally persist but abductor function may improve for up to 3 years.

Other difficult primary total hip replacements

Paget’s disease (Figure 7.8.17)

- Characterized by increased bone resorption and secondary formation of abnormal new bone
- Deformed proximal femur and hypersclerotic bone are common
- Paget’s disease may be incidental or a consequence of Paget’s disease
- Degenerative changes in the hip joint are typically in the form of medial joint space narrowing compared to superior joint space narrowing in primary osteoarthritis
- If the acetabulum is involved, protrusio may occur in 25–50% of cases
- If the femur is involved coax varus and anterior or lateral bowing of the femoral shaft may occur
- As the disease progresses, the femur becomes sclerotic, and the intramedullary canal is sometimes obliterated
Potential for serious bleeding perioperatively

Consider cemented arthroplasty

Increased incidence of early loosening and heterotopic ossification.

Postacetabular fracture

Preoperatively:
- Ensure no occult deep infection
- CT scan to assess bone stock
- Assess sciatic nerve carefully

Fig. 7.8.17
Paget’s disease in the right proximal femur and a degenerate left hip.

Extensile approach necessary to remove hardware

May encounter altered anatomy

May have large bony defects requiring bone graft and cages

Higher postoperative complication rates because of scarring from previous surgery, retained hardware, and heterotopic bone

Successful results but associated with earlier loosening than total hip replacements for primary osteoarthritis.

Slipped upper femoral epiphysis

First described by Mueller in 1889

The displacement of the femoral head usually results in a varus and external rotation orientation between the epiphysis and the metaphysis. When the deformity is severe or there are secondary complications such as chondrolysis or osteonecrosis, secondary osteoarthritis is an early complication

Patients are often young and active and choice of implant is important; total hip replacement should only be considered when all other options have been exhausted.

Ankylosing spondylitis

Preoperative respiratory and cardiac evaluation are necessary

May be difficult to mobilize the hip joint if severe contractures or ankylosis; in situ neck osteotomy may be needed

Uncemented femoral components only if bone is of good quality—often the femur has a ‘stove pipe’ deformity with straight lateral walls, making it unsuitable for press-fit or porous coated stems

Heterotopic ossification only more likely if hip was completely ankylosed.

Osteonecrosis

Osteonecrosis can be idiopathic or secondary to other pathology such as sickle cell disease, alcohol, or steroids

Long-term studies show that patients with osteonecrosis who undergo total hip replacement are up to four times more likely to experience an overall failure from aseptic loosening or infection than those with osteoarthritis.

- Hip arthrodesis

Introduction

This chapter outlines the main surgical options for hip pain excluding total hip replacement. The aim of surgery is to relieve pain and delay or halt further degenerative changes, negating the need for total hip replacement or delaying the age at which it needs to be implanted. The choice of treatment is dictated by the patient symptoms, underlying disease process, hip deformity, past treatment, and future patient expectations.

Due to the myriad of underlying causes of hip pain and arthritis in the young patient (see Chapter 7.7) not all, and likewise, perhaps more than one of the following surgical options may be employed during the course of management of the arthritic hip in the young adult.

Surgical options

Intra-articular steroid and local anaesthetic

For pain relief in patients with rheumatoid arthritis, juvenile idiopathic arthritis, and synovitis of the hip joint in the presence of minimal joint degeneration and absence of mechanical symptoms.

Used in conjunction with arthrogram and examination under anaesthesia to assess range of motion of hip joint and assessment for suitability of osteotomy (femoral, acetabular, or both) as well as verifying intra-articular nature of pain.

Surgical considerations

Should be performed under strict aseptic conditions with intraoperative fluoroscopy for correct placement of the needle. An anterolateral or direct lateral approach may be used. Injecting Omnipaque 300 dye confirms the needle is in the joint and helps outline the articular surface and aids in assessing joint congruency.

Intra-articular steroid and local anaesthetic do not alter disease progression radiographically and improvements in pain typically last for 12 weeks. Conflicting evidence in the literature exists regarding increased risk of infection in patients who have a subsequent total hip replacement shortly after their injection.

Soft tissue releases

Any condition leading to significant muscle imbalance and spasticity can result in soft tissue contractures. This in turn can result in substantial acetabular erosion, femoral head subluxation/dislocation, and in the skeletally immature increased femoral neck anteversion and coxa valga. Neuromuscular conditions such as cerebral palsy and myelomeningocele result in intrinsic muscle imbalance with resultant contractures.
Spastic hip subluxation and dislocation are common problems in patients with cerebral palsy often leading to a painful joint with difficulties in mobility (in previously ambulating patients), sitting, personal hygiene, and care. The adducted hip can also result in pelvic obliquity and subsequent scoliosis. The adductor longus and variably the iliopsoas are contracted in these patients. Release of adductor longus is performed by a medial or percutaneous method. Release of iliopsoas at the level of the lesser trochanter or at the pelvic brim (to prevent loss of flexion power) is also performed. Soft tissue releases have proved to be beneficial in the prevention of spastic hip dislocation and progressive hip dysplasia.

In juvenile idiopathic arthritis, inflammatory synovitis leads to pain and muscle spasm with subsequent joint contractures. Effusion of the joint also leads to pain, the joint is then held in the position of maximal joint space, thereby reducing joint pressure, which in the hip joint is 45 degrees of flexion in neutral rotation. In the presence of fixed contractures, surgical release of psosas and the adductors relieves pain and increases mobility and function. More aggressive surgical release, including rectus femoris with or without open synovectomy, may also be indicated.

Hip dysplasia with marked subluxation or dislocation, adult acquired neurological diseases such as stroke or Parkinson’s disease, and patients with longstanding hip pain can all develop muscle contractures around the hip joint. Patients undergoing a total hip replacement in the presence of tight adductors or iliopsoas may also benefit from surgical release to prevent deforming forces and improve range of motion and stability of the hip replacement.

Soft tissue releases have not shown to arrest or prevent degenerative changes in the hip joint radiographically or prevent the marked femoral neck anteverision seen in patients with juvenile idiopathic arthritis.

**Synovectomy**

Only a few conditions exist which solely affect the synovium around the hip joint, resulting in pain with or without mechanical symptoms. Juvenile idiopathic arthritis can lead to severe synovitis resulting in debilitating pain and decreased function. Open synovectomy results in significant improvements in pain, mobility, and walking ability.

Primary synovial osteochondromatosis of the hip is a rare benign condition characterised by multiple intra-articular osteochondral loose bodies and synovial hyperplasia, which may result in mechanical symptoms and degenerative arthritis if untreated. Open synovectomy can reliably remove the loose bodies and alleviate symptoms.

Pigmented villonodular synovitis of the hip is a rare disease. Synovectomy is generally accepted as the only surgical treatment for the disorder.

Synovectomy is traditionally performed through a Smith-Petersen approach or open dislocation of the hip. The latter has slightly better results in terms of recurrence of the primary disorder but is associated with increased morbidity. Synovectomy can also be performed arthroscopically.

**Acetabular osteotomy**

Reconstructive acetabular osteotomy is indicated in young active adults with symptomatic hip dysplasia and only mild arthritic changes as seen radiographically. Hip joint congruency is essential to the success of the operation and can be confirmed by preoperative imaging with either an anterior-posterior (AP) radiograph of the hip with the leg in abduction, on three-dimensional computed tomography (CT) reconstructed images. The false profile radiograph is a true lateral radiograph of the symptomatic acetabulum taken with the patient standing. The false profile radiograph is important as some patients who have dysplasia of the hip have nearly normal findings on AP radiographs and the lack of anterior coverage of the head is seen only on the false profile radiograph.

Examination under fluoroscopy with radio-opaque dye injected in the hip joint allows for a dynamic assessment of the joint congruency and can also help detect subtle labral pathology. The aim of the osteotomy is to return the hip joint to as near as normal anatomy and biomechanics, with improvements in pain and prevention of further degenerative changes. Reconstructive osteotomies include the Bernese periacetabular osteotomy, triple osteotomy and dial osteotomy. Where the hip joint is not congruent because of severely distorted anatomy, a salvage osteotomy is undertaken. These procedures rely on metaplasia of the capsule to fibrocartilage and therefore do not provide a long-lasting reconstruction. Common salvage procedures include the Chiari and shelf osteotomy.

**Contraindications**

Patients with inflammatory conditions; patients older than 50 years; the presence of arthritis or marked obesity. The presence of joint incongruence precludes any reconstructive osteotomy. Smokers should be cautioned of an increased risk of non-union

**Bernese periacetabular osteotomy (Figure 7.9.1)**

The Bernese periacetabular osteotomy developed by Ganz and colleagues in the early 1980s is currently the most popular reconstructive pelvic osteotomy. The numerous advantages of this procedure include the need for only one incision, the use of three straight and reproducible bony cuts, the large range of correction possible with medialization of the hip joint centre, anterior and lateral rotation, version correction, preservation of a portion of the posterior column allowing for early partial weight bearing, and minimal internal fixation and no change in the diameter of the true pelvis therefore not interfering with childbirth. The risk of non-union of the osteotomized fragment is negligible due to preservation of its blood supply. The procedure also allows for intra-articular assessment and repair if required of the labrum, as well as treatment of femoroacetabular impingement.

The longest follow-up to date by Ganz and colleagues at a mean 20 years, reports joint preservation of 60% at latest follow-up. Poor outcome was associated with pain and low functional scores preoperatively, severity of arthritis, positive anterior impingement.
test, limp, and age at surgery. Patient selection is therefore key to the success of this procedure. Previous Bernese periacetabular osteotomy does not compromise the results of subsequent total hip replacement.

Surgical considerations

The periacetabular osteotomy is performed through an abductor-sparing Smith-Petersen approach. Sequential soft tissue and bony steps as described by Ganz are performed which then allow for mobilization and correction of the acetabulum. The key aims in correction are:

1) Acetabular sourcil (weight-bearing surface) is repositioned to a more horizontal orientation
2) Lateral femoral head coverage improved with a goal of achieving 25–35 degrees centre edge angle
3) Translation of hip joint centre medially if required
4) Correct version (absence of cross-over sign)
5) Anterior femoral head coverage improved to 25–35 degrees on false profile view
6) The correction maintains or produces a congruent joint space and subluxation is corrected
7) Adequate head–neck offset is present or has been restored with osteochondroplasty
8) Adequate internal fixation with acceptable screw position
9) Hip flexion of =90 degrees and hip abduction =30 degrees.

Triple

The triple osteotomy includes cuts of the ilium, ischium, and pubis through three separate incisions. The acetabulum is then rotated to provide increased femoral head coverage. Although this is technically easier to perform than the dial or Ganz periacetabular osteotomy, the coverage it provides is less adequate (since the cuts are farther away from the acetabulum) and has the potential for non-union at the osteotomy sites because of inability to achieve adequate internal fixation. Steels osteotomy involves ischial cuts at a distance from the joint. The modified Tonnis osteotomy (see Figure 7.9.1) involves bony cuts closer to the joint. As the sacrotuberous and spinous ligaments are not violated, the mobility of the osteotomized fragment is limited. Large corrections with a triple osteotomy can result in pelvic deformity and as the posterior column is disrupted fixation of the osteotomized fragment can be compromised.

Dial

The dial osteotomy described by Eppright is one of a number of spherical osteotomies, mainly favoured in the Far East. It provides for excellent coverage with complete redirection of the acetabular articular surface. It is rarely used because it is extremely technically demanding and carries a high risk of penetration into the hip joint and resultant damage of the acetabular articular cartilage. Alternative surgical procedures, such as the Ganz periacetabular osteotomy, can achieve the same result with a less technically demanding and reproducible procedure.

Chiari

This procedure is reserved for non-congruent joints. The iliac bone is osteotomized just above the hip joint surface to the inferior part of the sciatic notch. The inferior segment of the pelvis is then displaced medially, resulting in increased femoral head coverage and medialization of the hip centre. Capsule is interposed between the femoral head and the proximal shelf of bone. This capsular tissue undergoes metaplasia into fibrocartilage. Long-term review of the Chiari pelvic osteotomy found that most patients had progressive degenerative changes and almost a third had severe pain at follow-up at 14 years. Outcome was enhanced when no preoperative arthritic changes were present, in younger patients, and a hip that was painless at the time of surgery. Chiari osteotomy has no adverse effect clinically or radiographically on later hip replacement. It did, however, require less bone.
grafting and achieved better coverage by host bone when compared with hip replacements in dysplastic hips.

**Box 7.9.1 Femoral osteotomy: indications**

- Non-union of femoral neck fractures
- Osteoarthritis
- Correcting post-traumatic deformity, slipped upper femoral epiphysis deformity
- Legg–Calve–Perthes disease
- Avascular necrosis.

**Shelf**

This procedure involves using a corticocancellous graft to augment the anterolateral aspect of the acetabulum and to act as a buttress, increasing joint stability. The hip joint centre is unaffected as is the relationship of the femoral head with the acetabulum. This procedure is typically used in children with incongruent joints. Recent study in adults who underwent shelf osteotomy for symptomatic hip dysplasia revealed a survivorship with conversion to hip replacement as an end-point of 86% at 5 years and 46% at 10 years. In patients who had slight or no narrowing of the joint space preoperatively, the survival rose to 97% at 5 and 75% at 10 years.

**Femoral osteotomy**

**Indications (Box 7.9.1)**

One of the original and, to this day, main indications for proximal femoral osteotomy is the treatment of non-union of femoral neck fractures. A valgus osteotomy converts a shear force across the non-union site into a compressive force and this induces healing. In one study, 93% of hips went on to heal using this technique.

Pauwel is credited for introducing the concept of varus and valgus proximal femoral osteotomies as a method of increasing the weight-bearing surface across the femoral head. He believed that ‘osteoarthritis results when abnormal forces act on normal tissue, or when normal forces act on damaged tissues’ and treatment should therefore be directed at increasing joint congruency, which in turn results in a greater surface area and decreased load per unit area of the articular cartilage. Bombelli later added flexion and extension osteotomy in the sagittal plane to further optimize joint congruency.

Other indications for the use of proximal femoral osteotomy include correcting post-traumatic deformity, and treating healed slipped upper femoral epiphysis (SUFE) using a flexion with or without rotation osteotomy. Acquired varus deformity with hinge abduction following Legg–Calve–Perthes disease is corrected with a valgus extension osteotomy. The treatment of hip dysplasia with a varus (derotation) osteotomy is usually performed in conjunction with a pelvic osteotomy.

In the management of osteonecrosis a variety of osteotomies have been described, varus, valgus, flexion, extension, combined, or rotational all with the intention of moving the osteonecrotic area away from where it would transmit weight.

**Surgical considerations (Figures 7.9.2–7.9.5)**

Careful and meticulous preoperative planning is required to ensure a successful result. The position of ‘best fit’ and ‘improved patient comfort’ is key to achieving this. During preoperative examination it is important to assess the degree of passive movement, in particular adduction and abduction across the hip. Following a varus osteotomy there will be loss of abduction, the minimum amount of abduction required prior to surgery is the amount of varus required plus 10 degrees, otherwise a fixed adduction contracture will ensue. Likewise, a valgus osteotomy will result in loss of adduction; therefore to avoid any abduction contracture postoperatively the patient should have at least the required angle in adduction.

![Fig. 7.9.2](image-url)
Valgus and varus proximal femoral osteotomy. A) Marked bilateral valgus hips preoperatively B) Varus osteotomy with resulting increased head coverage C) Severe varus deformity right hip preoperatively D) Valgus osteotomy with normalised neck shaft angle.

Fig. 7.9.3
Effect of proximal femoral osteotomy on hip joint centre. Valgus osteotomy causes lateralization and varus osteotomy results in medialization.

Preoperative imaging with an AP of the hip taken in adduction/abduction is necessary. A false profile lateral view also reveals any anterior uncovering which may require correction. Magnetic resonance (MRI) scans are useful in isolating the osteonecrotic area in a patient with osteonecrosis of the hip. CT scans and hip arthrograms are also extremely useful in planning the corrective osteotomy and used according to surgeon preference. The latter, however, gives a dynamic understanding of the hip joint and allows for accurate assessment of position of ‘best fit’.

Patients undergoing a varus osteotomy typically have lateral subluxation of the femoral head, associated with coxa valga. Following the osteotomy, the affected limb will be shortened and patients should be informed of this. Valgus osteotomy should result in reduced lateral impingement and an improvement in joint space on AP pelvis with the hip in adduction. It should also result in normalization of the relationship between the tip of the greater trochanter and the centre of the femoral head. In varus osteotomy the femoral shaft should be medialized, and in a valgus osteotomy the femoral shaft requires lateralization to avoid any alteration to the mechanical axis of the limb.

The affect on limb length and any resulting discrepancy following an osteotomy should be discussed in depth with patients preoperatively to ensure patient satisfaction.

Femoral osteotomy may distort the local anatomy which may jeopardize any future total hip replacement and this has to be taken into consideration by the operating surgeon. Best results are typically found in the young, non-obese patient with a good range of motion preoperatively.

Contraindications (Box 7.9.2)

Results of osteotomy

A study of 26 varus proximal femoral osteotomies for hip dysplasia in adults with a mean follow-up of 5 years reported no conversions to total hip replacement in the review period. There was significant improvement in symptoms and function with one case of non-union which was successfully revised. Best results were obtained in patients with long-leg dysplasia.

A review of intertrochanteric valgus-extension osteotomy performed for osteoarthritis reported 67% of the hips were good or excellent at final review. Better results were obtained in patients under 40 years of age with unilateral involvement and a mechanical (secondary) aetiology.

Rotational proximal femoral osteotomy for the treatment of osteonecrosis is associated with a high incidence of complications (55%). Another study of rotational osteotomy carried out in 18 hips in 17 patients at a mean follow-up of 5 years for osteonecrosis revealed satisfactory results in only three hips (17%) and 12 hips had been revised to total hip replacement; 83% of the patients had additional collapse. Varus and valgus osteotomies performed better with 74% and 85% good or excellent results respectively at medium-term review.
Box 7.9.2 Femoral osteotomy: contraindications

- Stiff painful hip
- Obesity
- Gross narrowing of joint space with sclerosis.

A previously osteotomized hip may be difficult to convert to a total hip replacement. Complicating factors include hardware removal, deformity of the proximal femur leading to inadequate prosthetic fit and fixation, or to intraoperative femoral fracture and risk of infection. In one large series of 305 total hip replacements in 290 patients who had a previous intertrochanteric osteotomy, it was noted that the operative time was longer and blood loss was somewhat greater than for primary total hip replacement. Technical difficulties were encountered in 23% of cases. The overall probability of failure at 10 years was 20.6%. The incidence of positive tissue cultures from the osteotomy site was 9%, and that of broken plates or screws 24.3% at the time of total hip replacement. Removing hardware as soon as bony union has been obtained as well as maintaining proximal femoral alignment with the femoral shaft on coronal and sagittal planes may facilitate and improve results of subsequent total hip replacement.

Hip arthroscopy

See Chapter 7.18.

Open surgical dislocation of the hip

See Chapter 7.7.

Hip arthrodesis

Once the preferred treatment of choice for end-stage osteoarthritis, the popularity of this procedure has faded as that of total hip replacement has risen since the early 1970s. The procedure is rarely performed today and most orthopaedic surgeons are inexperienced in its use, making it even less of an attractive option.

In adolescents and young adults with severe end-stage arthritis affecting a single joint, reconstructive and salvage procedures as discussed earlier may not be suitable. While total hip replacement offers the potential for immediate pain relief and good results in the short to medium term with regards to function, there remains considerable concern and reservation about the long-term outcome and durability of its use in the young active patient. Several long-term studies have shown that hip arthrodesis successfully relieves pain and allows patients to lead active lives.

The ideal patient is classically described as a young active male manual labourer who wants to return to work. In general, patients should be younger than 30 years of age and have end-stage monoarticular osteoarthritis. Ideal candidates are those with post-traumatic arthritis, osteonecrosis, and patients who have had sepsis such as tuberculosis. Patients should not have low back pain, ipsilateral knee pain, or contralateral hip pathology. MRI screening of the contralateral hip should be performed in patients with osteonecrosis to rule out early disease.

Surgical considerations

Hip arthrodesis can be achieved with the use of a Cobra plate applied to the lateral aspect of the femur and ilium. To gain access to the femoral head and acetabulum, a trochanteric osteotomy is performed which is then fixed over the plate. The Iowa technique involves performing a Charnley type osteotomy while the Vancouver technique avoids the need for this by medializing the socket.

Further techniques have been developed to avoid violation of the abductor mechanism which occurs using the earlier described techniques. Preservation of the abductors is important as the arthrodesed hip may be a stop-gap measure to delay a total hip replacement or a patient may choose to have a fused hip converted to a total hip replacement. Abductor-sparing techniques include the use of a dynamic compression screw and anterior plating (Figure 7.9.5). The hip should be arthrodesed in a position of 30
degrees of flexion, 5–10 degrees of adduction, and 10 degrees of external rotation. Abduction and internal rotation are associated with poor results.

**Fig. 7.9.5**
Hip arthrodesis using compression hip screw technique. Twelve-year-old female with painful arthritis of the left hip who grew up in Africa. Arthrodesis achieved with use of compression screw. Union was achieved at 8 weeks postoperatively.

**Discussion**

The functional limitations of hip arthrodesis relate to the loss of hip flexion, with difficulty in prolonged sitting in confined spaces, bending, putting on socks, and sexual activity. It is unclear whether patients today are willing to accept these limitations. The main long-term complication of hip arthrodesis is associated low back pain in up to two-thirds of patients, ipsilateral knee pain in half, and contralateral hip pain in a fifth of patients. Patients fatigue more easily due to the increased energy expenditure when walking. The main advantage is the relief of pain, return to active lifestyle, and preservation of bone stock.

Conversion of a fused hip to a total hip arthroplasty is generally associated with a favourable outcome. However, the technically demanding nature of the procedure should not be underestimated. Patients should be informed preoperatively of the possibility of a higher complication rate than that seen with primary total hip replacement.

**Further reading**

Summary points

- Total hip replacements (THRs) may fail in various ways. They may become infected, they may be subject to aseptic loosening, they may dislocate, or a periprosthetic fracture may occur. The patient with a failed THR must be thoroughly assessed before treatment is contemplated.
- Infection may be acute or chronic. Assessment involves clinical assessment, plain radiographs, blood tests (C-reactive protein and erythrocyte sedimentation rate), hip aspiration, and, sometimes, nuclear medicine. The acutely infected hip may be treated with one-stage revision. This involves thorough lavage, debridement, and exchange of all modular components as well as long-term antibiotic therapy. The gold standard of treatment for a chronically infected THR is a two-stage revision. Success rates of 80–90% can be expected.
- Aseptic loosening typically occurs at the cement bone interface in hips where a metal-on-polyethylene bearing couple has been used. Bone resorption takes place as a result of an inflammatory response to small wear particles. After infection has been excluded the treatment of choice is a single-stage revision.
- Dislocation may be the result of patient factors, implant factors, or poor surgical technique. It is imperative for the clinician to minimize the risk by selecting patients carefully, using the correct combination of implants and performing surgery accurately.
- The management of periprosthetic fractures depends on how well the implants are fixed and quality of bone stock. Treatment ranges from simple fixation of the fracture through to revision augmented with strut allograft.

Introduction

THR is a successful treatment for osteoarthritis of the hip in the vast majority of patients. It reliably abolishes pain and restores function. Complications can and do arise, however, and the purpose of this chapter is to discuss the modes of failure of THR. Infection, loosening, implant failure, and periprosthetic fractures will be discussed.

Infection

Deep infection is a devastating complication of THR often requiring revision surgery. The incidence of deep infection after THR is 1–2%. Risk factors include diabetes, obesity, sickle cell disease, rheumatoid disease, HIV infection, cancer, and immunosuppressant therapy.

Aetiology and pathogenesis

The most common organisms include *Staphylococcus aureus*, *Staphylococcus epidermidis* and coliforms. These pathogens are usually commensal organisms living on the host but can be transmitted by medical staff. Methicillin resistant *Staphylococcus aureus* infections (MRSA) are rare and are usually seen in patients with associated comorbidity who have had prolonged antibiotic therapy and long hospital admissions. In patients with sickle cell disease, other organisms such as *Salmonella* are seen. In HIV, the infections can be atypical and include fungi as well as bacteria.

Some bacteria produce a glycocalyx that acts as a biofilm. This biofilm helps the bacteria to adhere to the implant, inhibits the action of macrophages, and protects the bacteria from antibiotics. Glycocalyx-producing bacteria are harder to eradicate than conventional bacteria and almost always require two-stage revision surgery.

Classification

Broadly speaking infection can be classified as acute, chronic, or delayed acute (see Table 7.10.1). Acute infections present within the first postoperative month. Chronic infections probably occur at the time of surgery but present some months or years later. There may be little to find clinically. Delayed acute infections are those that arise via haematogenous spread some months or years after implantation of the THR and are best treated as acute infections.

**Prevention**

Measures that can be taken to avoid infection are subdivided into patient factors and hospital factors. Patients should be optimized prior to surgery. Diabetes should be well controlled, sites of potential infection should be screened, e.g. urine, and any pending dental treatment or ‘dirty’ surgery, e.g. prostatectomy, should be completed prior to THR. Hospital factors include using prophylactic antibiotics, laminar flow theatres, exhaust suits, minimizing the number of staff in theatre, careful soft tissue handling, antibiotic impregnated cement, wound lavage, and expert postoperative wound care.

**Clinical features**

Acute infections are normally associated with pyrexia, wound erythema, and purulent discharge. The presentation of chronic infections is more varied. Patients will often give a history of pain, particularly if the implants are loose. Clinically the picture ranges from a well healed, cool scar to a hot, erythematous thigh with draining sinuses.

**Investigation**

Standard investigations include plain radiographs, inflammatory markers (C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR)) and hip aspiration. Characteristics of infection seen on plain radiographs include loosening, endosteal scalloping, and periostitis (Figure 7.10.1). Technetium-99 bone scans are hot in the majority of cases of infection but can also be positive in aseptic loosening. White cell scans using indium-111 have higher specificity for infection. Often it is difficult to distinguish aseptic from septic loosening. If a THR is deeply infected it is important to attempt to identify the offending organisms and their sensitivities prior to any revision surgery so an antibiotic regimen can be planned in advance. It is also essential to obtain tissue samples sent at the time of revision surgery to confirm the suspected diagnosis of infection. These must be obtained prior to the administration of antibiotics perioperatively.

Fig. 7.10.1
Chronically infected THR with loosening of both components.

**Treatment**

The treatment strategy depends on the severity of symptoms, suitability of the patient for revision surgery and functional expectations of the patient. The goal in some patients is simply suppression of the infection and in others it is complete eradication of infection.

Patients who are not suitable for revision surgery, who have a solidly fixed prosthesis, and have a sensitive organism may simply be treated with long-term oral antibiotics.
Acutely infected THRs (including the acute delayed infections) can be salvaged with wound excision, aggressive debridement, extensive lavage, exchange of modular components, e.g. the head, acetabular liner, screws, hole eliminators, non-absorbable sutures, etc., and primary wound closure over a suction drain. Appropriate intravenous antibiotics should be started as soon as samples have been obtained for microbiology and continued until the inflammatory markers have returned to normal. The duration of treatment is usually 6–8 weeks. The reported success rate in eradicating infection using this treatment protocol is 80–90%.

Chronically infected THRs can be treated with either one- or two-stage revision. The gold standard in most hip revision centres is a two-stage revision. All of the implants and cement must be removed and a thorough ‘membranectomy’ performed. The femoral canal and acetabulum must be reamed until healthy bleeding bone is encountered and the whole surgical field subjected to extensive lavage. A temporary spacer is inserted and this is usually made from antibiotic impregnated cement. If the antibiotic sensitivities are known preoperatively, appropriate antibiotics can be incorporated into the spacer prior to insertion. The wound is closed over a suction drain and the patient mobilized. The same principles apply to the antibiotic regimen as for the acute infections discussed earlier. The reported success rate of two-stage revision in terms of eradicating infection is 90% in most series.

### Aseptic loosening

Aseptic loosening is by far the commonest cause of failure of THR and the commonest indication for revision THR. Approximately 3000 revision THRs are carried out each year in the United Kingdom for aseptic loosening. This accounts for 55% of the revision burden for hips.

#### Aetiology and pathogenesis

When a cobalt chrome femoral head articulates with a polyethylene cup wear particles with a diameter of 0.3–10 microns are produced. These particles activate macrophages that, in turn, release cytokines (interleukin (IL)-1\(\alpha\), IL-1\(\beta\), IL-6), prostaglandins (PGE-2) and tumour necrosis factor (TNF\(\alpha\)). These factors not only cause osteolysis but also activate osteoclasts that resorb bone. The result is loosening at the cement–bone interface. Typically a polyethylene acetabular component wears at the rate of 0.1mm per year. Larger head sizes generate greater volumes of wear particles and thin polyethylene components are also more susceptible to wear. It is recommended that the minimum thickness of polyethylene should be 8mm in order to minimize generation of wear particles. Recently, highly cross-linked polyethylene and polyethylene containing vitamin E have been introduced with potential improvements in wear characteristics.

Cementless components can also be subject to aseptic loosening. They normally have a porous coating or are plasma sprayed with hydroxyapatite (HA). The intention is for the component to osseointegrate within the first few months of implantation. In order for osseointegration to occur, the implant must be stable at the time of implantation. Stability is achieved by ‘press-fit’ of the component. Surgical technique must be accurate and it is essential that the correct sized implants are used and inserted in the correct orientation. If primary stability does not occur, the component will move and fibrous ingrowth, rather than osseointegration, will occur, resulting in early loosening of the component. This phenomenon is more common with femoral components than acetabular components and the incidence is around 2% based on the early failure rates quoted in the National Joint Registry.

#### Clinical features

Loosening may be asymptomatic. Symptomatic patients usually complain of thigh pain. Classically this is ‘start up’ pain experienced first thing in the morning or when getting out of a chair after a period of rest.

#### Investigation

Diagnosis is made from the history and plain radiographs in the majority of patients (Figure 7.10.2). It is important to distinguish aseptic from septic loosening, as important management decisions need to be made. In aseptic loosening the CRP and ESR should be normal.
Aseptic loosening of a THR. Using Harris criteria the cup is ‘definitely’ loose and the stem ‘possibly’ loose.

X-ray classification

Harris classified loosening into three groups: definitely loose, probably loose, and possibly loose, depending on the radiographic appearances (see Table 7.10.2). Furthermore, the zones of loosening around cemented femoral and acetabular components have been described by Gruen and DeLee (Figure 7.10.3).

Treatment

The treatment of choice for a non-infected, loose THR is a single-stage revision. The surgical procedure ranges from exchange of head and liner through to revision of both components. This is discussed in more detail in Chapter 7.11.

Dislocation (Figure 7.10.4)

The reported dislocation rate following THR is 1–3%. The causes of dislocation may be categorized as patient related, surgeon related and implant related. (See Table 7.10.3). The greatest risk of dislocation is within the first 3 months after surgery. Dislocations that occur after the first 6 weeks are more likely to become recurrent.

**Aetiology and pathogenesis**

**Patient factors**

It is reported that patients with hip dysplasia, rheumatoid arthritis, previous sepsis, those who have had previous hip surgery, and those who have previously suffered a fracture have higher dislocation rates after THR. Patients who lack full motor control of their hips are also at risk, e.g. alcoholics and those who have suffered a cerebrovascular accident. Poor compliance with postoperative rehabilitation and precautions may also result in dislocation.

**Surgical factors**

There are several factors that need to be considered including surgical approach, leg length, femoral offset, soft tissue tension, cup orientation, stem version, impingement, and soft tissue repair. Planning the THR in advance is mandatory. It is imperative that the choice of surgical approach and implants enables the restoration of normal anatomy and function. Traditionally the posterior approach had a higher dislocation rate than anterior or anterolateral approaches. With improvements in surgical technique and, in particular, repair of the posterior capsule the dislocation rates are now similar for all approaches.

Lewinnek described a ‘safe zone’ for the position of the acetabular component. Cups inserted at an inclination of 45 ± 10 degrees and with 15 ± 10 degrees anteversion have greater stability than cups inserted in positions outside this range. Dislocation is more common when cups are inserted more vertically and with incorrect version. When a trial reduction is performed with the definitive acetabular component correctly positioned, the femoral head should be congruently situated within the cup when the patient’s leg is in a neutral position.

**Fig. 7.10.4**

Plain radiograph illustrating an acutely dislocated THR.

It is important to put the hip through a range of motion, particularly internal rotation in flexion and external rotation in extension, to identify potential impingement. Frequently, rim osteophytes need to be trimmed and hypertrophic capsule excised in order to prevent impingement. Finally, the soft tissue tension needs to be considered. If an anterolateral approach is used it is essential that the tendons of gluteus medius and minimus are repaired accurately.
Implant factors

For a hip to stay ‘in joint’ the implants need have a satisfactory head:neck ratio. The smaller the ratio the greater the risk of dislocation and the greater the ratio the less the risk (Figure 7.10.5). There has been a trend in recent years to use larger head sizes in order to prevent this complication. There is a trade off, however, between head size and production of wear particles. With metal-on-polyethylene combinations, larger head sizes, e.g. 32mm or 36mm produce a greater volume of particles, especially with acetabular components less than 8mm thick, and this may lead to early loosening. The wear properties of smaller heads, e.g. 22.225mm as used on the original Charley stem, are better but the dislocation rate is higher. To counteract this problem hard-on-hard bearings (metal-on-metal or ceramic-on-ceramic) are becoming more popular. These allow large head sizes (36mm and above) with a favourable head:neck ratio while avoiding the risk of aseptic loosening.

Prevention

Key points in preventing dislocation include careful patient selection, thorough preoperative planning, use of appropriate implants, accurate implant positioning, protection of the soft tissues, meticulous wound closure, and well-supervised postoperative rehabilitation.

Clinical features and investigation

The usual clinical picture is of a patient who performed a movement at the extreme of range of motion, who felt a ‘clunk’ and then experienced severe pain. The dislocated limb is always short. Posterior dislocations are normally associated with flexion and internal rotation whilst anterior dislocations are usually extended and externally rotated. Plain radiographs confirm the dislocation.

Treatment

The treatment of choice for a first dislocation is a closed reduction. Ideally the procedure should be carried out in the operating theatre under general anaesthetic. The hip should be screened with the image intensifier to check the orientation of the implants and for impingement.

For recurrent instability, the cause of dislocation needs to be identified. This can be with plain radiographs, screening under image intensification or with computed tomography (CT). The causes of dislocation should be corrected and this almost always requires revision surgery. Sometimes the modular components can simply be exchanged and soft tissue balance improved. Occasionally, extra measures such as constrained cups are required.

Periprosthetic fracture (Figure 7.10.6)

The incidence of periprosthetic fracture after THR is rising. Nowadays, in the United Kingdom, the average age of patients undergoing THR is 73 years. Approximately 8% of patients undergoing THR are over 85 years old and about 500 hip revisions are carried out each year for periprosthetic fractures.

Aetiology and pathogenesis

These fractures can occur intraoperatively or postoperatively. During surgery fractures are more common when using cementless components. The acetabulum is at risk when it has been deliberately underreamed and the shell is impacted with force in order to achieve ‘press-fit’. The femur is at risk when inserting a ‘press-fit’, tapered implant. The type of fracture ranges from a simple, undisplaced crack in the calcar region to a grossly comminuted, displaced fracture. The femur is much more commonly fractured than the acetabulum and the calcar region should always be inspected after insertion of the femoral component.
Postoperatively, the fracture may follow significant trauma or may be a result of relatively minor trauma combined with a loose implant and/or osteoporosis.

**Clinical features and investigation**

The clinical features are those of an acute fracture of the proximal femur, namely, pain associated with shortening and external rotation of the leg. A thorough neurovascular assessment should be made with particular attention to the foot pulses and peripheral nerves. Plain radiographs should be obtained including an anteroposterior (AP) view of the pelvis and AP and lateral views of the whole femur.

**Classification**

Classification systems are described for intraoperative fractures but they are of limited use and do not guide patient management. The same can be said for postoperative acetabular fractures. In principle, acetabular fractures are classified as type 1 if the component is well fixed or type 2 if the component is unstable. As far as postoperative fractures of the femur are concerned, the Vancouver classification is the most widely used. This classification takes into consideration the location of the fracture, the stability of the implant and the quality of proximal femoral bone stock (see Table 7.10.4). Importantly, this classification system guides the management of the fracture.

</tr>
<tr>
<td>3 Femoral component loose and bone stock poor</td>
</tr>
</tbody>
</table>

**Prevention and treatment**

Ideally all intraoperative fractures are identified during surgery and fixed appropriately. Stable acetabular fractures may be treated conservatively with a period of protected weight bearing. Unstable fractures need to be reduced and internally fixed. It may be necessary to augment the acetabulum with a cage or support rings to accommodate the cup. Intraoperative femoral fractures are best treated by temporary removal of the implant, reduction of the fracture, fixation with cerclage wires and then reinsertion of the implant.

The management of periprosthetic fractures in the postoperative period is guided by the Vancouver classification and is described in more detail in Chapter 7.12.

Revision total hip replacement and complications in total hip replacement

DOI: 10.1093/med/9780198505064.003.007011

Summary points

- Revision hip replacement requires careful preoperative planning
- Accurate diagnosis is vital: particular attention must be paid to whether infection is present or not
- Extensive approaches are preferred
- Appropriate equipment is greatly helpful in explantation of the failed components
- Imaging, classification, and templating are useful in determining the best reconstruction techniques.

Introduction

Revision hip surgery is less commonly performed than primary procedures. The National Joint Register records that approaching 10% of operations are revisions or reoperations. However, this equates to 10 000 hip revisions in 2008 in England alone; the numbers are continuing to rise. In the United States, there were 43 000 revisions in 2002, accounting for 17.5% of hip replacements. Revision rates are 0.7% by 1 year and 1.3% at 3 years. Hip revision surgery accounts for disproportionately high costs to the health service: the operations are time consuming, require an extended hospital stay, and implant costs are higher. In addition, the rates of infection, dislocation, and mortality are all higher in revision surgery (Box 7.11.1).

Box 7.11.1 Factors associated with failure

- Implant factors:
  - Press-fit non-coated stem
  - Polyethylene irradiated in air
  - Metal-backed cemented cup
  - Screw-in cup
- Patient factors:
  - Inflammatory arthritis
  - Hip fracture
  - Avascular necrosis
  - Paediatric hip disorder
- Surgical factors:
  - Low-volume surgeon
  - Poor cementing technique
  - Failure to restore offset

The surgeon aims to answer a series of questions:

- Is the pain coming from the hip? Potential alternative diagnoses must be considered and may require further investigation to obtain an accurate diagnosis (Box 7.11.2).
- Is the patient as well as possible? Revision hip surgery is a major undertaking and the patient should be considered as a whole. In particular, the cardiovascular and respiratory systems should be assessed and any malfunction referred to a physician in case investigation and intervention are required. Common examples include lung function testing, cardiac angiography, and angioplasty.
- Is the hip replacement infected? Differentiation between aseptic loosening and a septic hip is vital and discussed further later in this chapter. Decisions as to whether the procedure should be performed in two separate phases are also influenced by this information. If the hip is infected, identification of the causative organism is very useful.
- What is the degree of bone loss? The magnitude and pattern of bone loss must be well understood for proper planning to take place. Consideration of modes of failure and sites of anatomical defect will determine whether one or other of the implants can be salvaged and determine the best reconstructive options available. The use of preoperative templating is then used to plan reconstruction of the bone loss.
Fig. 7.11.1
Femoral templating and osteotomy planning.

Are there other problems with the hip replacement? Common associated problems include leg-length discrepancy, recurrent dislocation, nerve injury and polyarthritis.

Box 7.11.2 Differential diagnosis of a painful total hip replacement

- Degenerative arthritis of the lumbar spine
- Sciatica
- Spinal stenosis
- Peripheral vascular disease
- Stress fractures
- Malignancy
- Neuroma, particularly traumatic neuroma caused at time of surgery.

The key to successful revision hip surgery is preoperative planning. It can shorten the learning curve, anticipate intraoperative challenges, identify the correct approach, allow ordering of necessary equipment and identify appropriate investigations (Box 7.11.3).

Box 7.11.3 Goals of surgery

- Restore centre of rotation
- Restore leg length
- Restore offset
- Restore anatomy and biomechanics
- Rigid fixation of implants.

Investigations of a painful total hip replacement

Accurate investigation allows for proper planning of revision hip surgery (Box 7.11.4). All hips should have anteroposterior and lateral views of the pelvis and proximal two-thirds of the femur.

Box 7.11.4 Preoperative investigations

- Blood tests:
  - Full blood count: baseline haemoglobin, white cell count rarely relevant
  - C-reactive protein: >20mg/L suggests infection
• Erythrocyte sedimentation rate: >30mm/h suggests infection

Microbiology and histopathology:
• Hip aspiration or biopsy
• Frozen section at time of revision

Radiology:
• Plain radiography-serial views can show migration as well as bone loss
• Judet views—column integrity
• CT scan
• 3D CT reconstruction.

Judet views are used to assess the integrity of the anterior and posterior acetabular columns in particular. The iliac oblique view demonstrates the anterior wall and posterior column, whilst the obturator oblique view demonstrates the posterior wall and anterior column.

Computed tomography (CT) is useful for analysis of component orientation as well as existing bone stock. Three-dimensional (3D) reconstruction can provide further evidence of bone loss.

If there is intra pelvic cement or the acetabular component has migrated through the medial wall, angiography can be needed to demonstrate the vessels.

Selection of the approach for revision surgery is even more critical than for primary surgery. There is no perfect solution through which all hips can be revised. Important considerations include the site of previous scars, the position and type of components to be removed, and the presence and extent of osseous defects. Adequate visualization is essential but must not be at the price of excessive damage to soft tissue or bone. Revision surgery is not always predictable and exposures should allow for flexibility when operative findings necessitate variance from the preoperative plan.

The posterior approach
The posterior approach is extensile and avoids damage to the abductor mechanism of the hip. It can be performed through extension of most previous lateral or posterior approach scars. More distal exposure of the femur can be achieved through release of the gluteus maximus and iliopsoas tendons. The exposure can continue with release of the vastus lateralis, allowing exposure of the entire length of the femur if necessary. The acetabulum is also extremely well visualized. Reports vary as to whether this approach is associated with a higher rate of dislocation at revision surgery but more recent work suggests that the rate can be as low as with other approaches.

The anterolateral approach
This extensile exposure allows excellent visualization of the proximal femur and good exposure of the acetabulum. The vastus lateralis can be reflected anteriorly to allow access to the proximal femur. The risk of gluteal nerve injury is higher in revision surgery, with a corresponding increase in Trendelenburg gait pattern after the procedure.

Trochanteric osteotomy
Trochanteric osteotomy can be carried out to improve visualization of the acetabulum where complex reconstruction is anticipated. A variety of methods have evolved. A simple osteotomy can be carried out at the base of the greater trochanter, as described by Charnley. Whilst this provides excellent exposure of both sides of the hip, there can be problems with vascularity of the trochanter, reattachment, and metalwork failure. These can be compounded by proximal bone loss, weakening the greater trochanteric cortices and giving rise to trochanteric escape in 15–20% of patients in most revision series. The use of ‘partial trochanteric osteotomy’ can reduce these problems. The trochanteric flip begins its osteotomy posteriorly and stops to leave a 1-cm bone bridge supporting the incision of the gluteal tendons and the vastus lateralis, thus reducing the damage to the vascularity of the trochanter. Partial anterior trochanteric osteotomy removes a small sliver of anterior bone with the insertions of gluteus medius and vastus lateralis attached but leaves the insertion of gluteus minimus intact, making reattachment easier and subsequent escape less likely. A trochanteric slide also preserves the attachment of gluteus medius and vastus lateralis on one segment of bone, increasing vascularity, improving the biomechanics (the proximal pull of the fragment by gluteus medius is countered by the distal pull of vastus lateralis) of the reattachment, and reducing non-union rates to 4%.

The extended trochanteric osteotomy is useful in removal of femoral components with solid distal fixation, typically fully porous-coated cementless stems, and stems in significant varus. It has a high rate of union, typically less than 2% have non-union or malunion. The osteotomy begins with a 5–10 cm osteotomy posterior and medial to the greater trochanter, running down the linea aspera. A transverse arm passes anteriorly then the anterior osteotomy is completed anterior and medial to the greater trochanter. It involves elevation of vastus lateralis off the linea aspera and can be a cause of muscle necrosis if a previous anterolateral or lateral approach has been used, in which case the vastus lateralis fibres should be left inserting into the osteotomized fragment. Following extended trochanteric osteotomy, a longer femoral revision prosthesis will be required in order to achieve stable fixation.
The transfemoral approach allows excellent visualization of the femoral canal through exposure of the implant and any cement mantle across its entire length. This is achieved at the price of weakening the available bone stock, so it is used in combination with a very long prosthesis achieving distal fixation (such as the Wagner stem).

**Component removal (Boxes 7.11.5 and 7.11.6)**

The explantation phase requires planning and can be made significantly easier by the use of appropriate specialist instruments but only if the surgeon has thought to have them available.

**Acetabular reconstruction**

Hemispherical uncemented cups will work well in the majority of cases. They require a minimum of 50% host bone contact in order to osseointegrate (NB host bone is intact pelvis—allograft is not included). Care must be taken to remove any pseudocapsule or membrane which may reduce the percentage of implant to host bone contact. If host bone contact is anticipated to be below 50%, further techniques will be required.

**Box 7.11.5 Removal of acetabular components**

**Cemented acetabular components**
- Curved chisels to disrupt cement mantle
- Divide cup into quadrants
- Drill a pilot hole and screw slap hammer into polyethylene.

**Uncemented acetabular components**
- Simple liner exchange
- Curved chisels to the implant-bone interface
- Explant (Zimmer)
- Cement polyethylene liner into well-fixed metal shell.

**Box 7.11.6 Removal of femoral components**

**Cemented femoral components**
- Remove overhanging bone, cement, soft tissue
- Looped extractor
- System specific removal tools
- Cement removal instruments e.g. Moreland instruments or ultrasonic tools
- Bone window over thick columns of cement.

**Uncemented femoral components**
- Cortical windows or extended trochanteric osteotomy
- High speed carbide disk cutters to transect stem
- Specialized trephines and flexible osteotomes
- Bone window over pedestal at tip of prosthesis.

</tr>
</tbody>
</table>

Type I defect (Table 7.11.1)

Segmental defects can be present in the anterior wall, posterior wall, medial wall, or superior margin of the acetabulum. Typically, these defects can be filled with augments or allograft. Augments can include the use of oblong cups or porous metal augments with screw fixation to bone. Impaction techniques of morcellized allograft work well in medial wall defects. Superior segmental defects can be treated with structural allograft and screw fixation to the ilium. Structural graft in particular is prone to resorption and collapse; thus one potential advantage of porous metal augments is avoidance of this complication.

Type II defect (Table 7.11.1 and Figure 7.11.2)

These cavitary defects have intact margins and floor of the acetabulum. They are often amenable to jumbo uncemented cup reconstruction, with or without morcellized allograft.

Type III defect (Table 7.11.1 and Figure 7.11.3)

These defects are a combination of segmental and cavitary bone loss. Their treatment, therefore, can require a combination of techniques. The use of antiprotrusio cages, with or without allograft, is more frequent. These gain superior fixation to the ilium via screws through a superior flange; inferior fixation is via an inferior hook in the obturator foramen.

Type IV defect (Table 7.11.1 and Figure 7.11.4)

In these cases, there is pelvic discontinuity and mechanical stability must be restored. Before the acetabulum is reconstructed, posterior reconstruction plating is performed to stop movement between the ilium and the ischium. Anterior plating is not necessary. Acetabular reconstruction cages are the mainstay of treatment; CAD/CAM components can be useful.

Femoral reconstruction (Box 7.11.1)

Cemented revision has advantages of immediate fixation, local delivery of antibiotics, and ability to flow into geometrically abnormal proximal femurs. It can, however, be difficult in severe bone loss and can be hard to re-revise. In addition, some series show high rates of early loosening because the internal femur is highly sclerotic, significantly reducing the microinterlock between cement and bone. If cement is used, meticulous cementing technique is vital. The use of impaction grafting is also successful in the femur, particularly in contained, proximal lesions.

Classification of femoral bone loss must be done after component removal to give an accurate evaluation of bone loss, as defects can be significantly larger after the explantation of the original stem.

If there is a cortical breach, the revision stem must bypass it by at least 5cm to reduce the chance of fracture.
If there is a completely intact cement mantle within healthy bone, a shorter stem can be cemented into the original cement mantle: a so-called cement-in-cement revision.

**Type 1 defect**

There is cancellous bone present, with minimal metaphyseal loss and an intact diaphysis. Proximal fixation is achieved with a porous coated, uncemented stem or use of a cemented prosthesis.

**Type 2 defect**

There is metaphyseal loss but the diaphysis is intact; this is a common finding at revision of cemented stems. An uncemented, proximally loaded, metaphyseal fitting stem can be used in less severe cases. If there is very poor proximal bone stock, an uncemented stem will require distal fixation and a fully porous coated stem is appropriate, with or without impaction bone grafting.

**Box 7.11.7 Principles of femoral reconstruction**

- Rotational and axial implant stability
- Rigid implant fixation
- Stability with range of movement
- Restore femoral integrity and continuity
- Prevent and/or augment bone loss
- Restore biomechanics.
Table 7.11.2 Paprosky classification of femoral abnormalities

<table>
<thead>
<tr>
<th>Type</th>
<th>Lesion</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>

</tr>
<tr>
<td>4</td>
<td>Extensive metadiaphyseal damage; cortical fixation at isthmus not reliable</td>
</tr>
</tbody>
</table>

**Type 3a defect**

The metaphysis is severely damaged and not supportive but there is at least 4cm of intact diaphyseal bone available for distal fixation. A fully porous coated stem can be used to achieve distal fixation, again with or without bone grafting.

**Type 3b defect**

The metaphysis is damaged and there is less than 4cm of intact diaphyseal bone distally. In this case a modular cementless stem with distal flutes is required in order to gain rotational stability.

**Type 4 defect**

There is extensive metaphyseal and diaphyseal bone loss, a widened femur and the isthmus is non-supportive. A conical, cementless stem will not achieve stable fixation. Options include extensive impaction grafting (if the proximal cortices are intact), use of a prosthesis allograft composite, or proximal femoral replacement.

**Infection**

See Chapter 7.13.

**Dislocation (Box 7.11.8)**

The options for revision will depend upon the cause and direction of the dislocation. Success is more likely if the cause of dislocation is accurately identified. For example, posterior dislocation can be prevented by replacing the socket in a more anteverted position or removal of excessive anterior acetabular bone upon which the femoral neck may impinge. It is not always necessary to remove all components. In modular implants, a longer femoral head or lateralized acetabular liner may be an appropriate method of increasing offset. A larger diameter femoral head and bearing or use of a lipped liner will also increase stability. If this is not possible, the use of trochanteric advancement increases tension in the hip abductors. In cases with a significant soft tissue component to the dislocation (typically multidirectional instability with severe shortening or neurological disorder), the use of a constrained acetabular liner can be necessary. This carries the disadvantage of reduced range of motion and higher rates of loosening. Revision to a bipolar femoral prosthesis alone can be used as a last resort in recurrent cases.

Fig. 7.11.5

Femoral defects by Paprosky classification: A) type 1; B) type 2; C) type 3a; D) type 4.

- Retractor injury
- Lengthening
- Dislocation
- Direct trauma/haemorrhage
- Thermal injury from cement
- Acetabular screws.

Periprosthetic fracture
See Chapter 7.12.

Nerve damage (Box 7.11.9)
The rate of nerve injury is 1–4% in primary hip replacement but rises to around 7% in revision surgery. Reconstruction of a dysplastic acetabulum also carries a higher risk of nerve injury.

The most commonly injured nerve is the posterior (peroneal) division of the sciatic nerve. The posterior division has a thinner perineurium than the anterior (tibial) branch and is more tethered at the fibula head, both of which are postulated to contribute to its increased rate of injury. Sciatic nerve injury is more common if the leg is lengthened at operation; lengthening less than 4cm tends to injure the posterior branch and lengthening over 4cm gives rise to complete sciatic palsy. Sciatic nerve injury is also caused by perineural haematoma, careless retractor positioning, and posterior capsular release, particularly in revision surgery. Dislocation can injure the sciatic nerve either peripherally or postoperatively.

The femoral nerve is less commonly injured. It passes anterior to the hip, overlying the iliopsoas tendon, and can be injured in anterior capsular release or through careless placement of anterior retractors during acetabular preparation.

Injury to the superior gluteal nerve is rarely recognized after hip surgery; its inferior branch in particular is at risk in anterolateral and lateral approaches to the hip and the hip injury can lead to abductor weakness and Trendelenburg gait pattern.

Obturator nerve injury is rare and may be associated with extrapelvic extrusion of cement or antiprotrusio cages.

Vascular injury
Vascular injury is rarer than neurological compromise, occurring in well under 0.5% of hip replacement. Again, the incidence is far higher in revision surgery; if the acetabular component is significantly protruded into the pelvis, preoperative angiography is recommended.

The femoral vessels run parallel to the femoral nerve and are protected in a similar fashion, i.e. careful placement of an anterior acetabular retractor lateral to the iliopsoas muscle.

Medial wall penetration can injure the iliac vessels, though this is rare. Acetabular screw fixation also risks injury to the iliac vessels posteriorly or the obturator vessels anteriorly.

If bleeding is massive and uncontrolled, exposure and temporary clamping of the iliac vessels may be needed, followed by emergency intervention by a vascular surgeon.

Management of total hip replacement periprosthetic fractures

DOI: 10.1093/med/9780199550647.003.007012

Summary points

- Periprosthetic fractures: intraoperative or postoperative femoral or acetabular fractures
- Third commonest reason for reoperation after THA
- Vancouver classification Type A, B, and C
- Three most important factors that determine treatment are:
  - Site of the fracture
  - Stability of the implant
  - Quality of the surrounding bone stock.

Introduction

Periprosthetic fracture of the femur after total hip arthroplasty (THA) surgery was first described in 1954 and the experience with periprosthetic femoral fractures was limited during this period. Nowadays, the reconstructive orthopaedic surgeon deals with periprosthetic fractures quite frequently. Periprosthetic femoral fracture is a devastating complication after THA that can result in poor clinical outcome. They are challenging to treat, as they require the skills of both a revision surgeon and a trauma specialist. In this review we summarize the epidemiology, aetiology, classification, and various modalities of management.

Epidemiology and aetiology

The Swedish Hip Registry data have shown that periprosthetic femoral fractures were the third commonest reason for reoperation (9.5%) after total hip replacement, after aseptic loosening (60.1%), and recurrent dislocation (13.1%). Periprosthetic femoral fractures can be classified as intraoperative and postoperative. The cumulative prevalence of periprosthetic femoral fractures is 1.0% in primary total hip replacements and 4% in revision total hip replacements (Mayo Clinic Joint Registry). The incidence of intraoperative fractures is 0.3% in primary cemented and up to 5.4% in uncemented THAs whereas in revision surgeries the incidence is 3.6% in cemented and 20.9% in uncemented revision THAs. There is an increasing incidence of late postoperative periprosthetic femoral fractures that is attributable to many factors, including an increasing number of elderly patients at risk for falls, increasing numbers of young patients with total hip replacements at risk for high-energy trauma events, and the increasing numbers of revision procedures using cementless press-fit fixation or bone impaction allograft techniques. Periprosthetic femoral fractures usually occur with low-energy events, either after falls or spontaneously during activities of daily living. Patients may present with insidious pain and fracture with no history of fall or trauma. It should be borne in mind that osteolytic lesions often occur in asymptomatic hips.

Continuous surveillance of THR patients, especially younger ones with higher activity levels, may help in timely intervention and reduce the incidence of osteolytic-related fractures. In primary and revision hip arthroplasty, femoral fractures can occur after dislocation of the existing prosthetic stem, cement removal, during femoral canal preparation, and during insertion of the prosthesis.

Acetabular fractures occur during component insertion or removal. Postoperative acetabular fractures are associated with uncemented acetabular component insertion because of bone loss in a failed THA. The first description of acetabular fractures around THA was in 1972. The reported incidence of intraoperative acetabular periprosthetic fracture is less than 0.2%. The prevalence of such fractures has increased since the introduction of uncemented components. The prevalence of periacetabular fracture with pelvic discontinuity at acetabular revision is 0.9%. These fractures are attributed to trauma, osteolysis, under-reaming and oversizing of the components, osteopenia, and Paget’s disease.

Classification

Various classification systems have been in and out of favour in the past based on site and pattern of fracture or implant instability. Some of the commonly used classification systems are given in Table 7.12.1. The Vancouver classification system for both intraoperative and postoperative femoral fractures has gained universal acceptance (Table 7.12.2). This is the only periprosthetic classification system that has been subjected to psychometric testing for its reliability and validity. The factors that determine treatment are fracture location, stability of the implant and fracture, quality of host bone stock, patient physiology and age, and surgeon experience. This classification consolidated the three most important factors, i.e. the site of the fracture, the stability of the implant, and the quality of the surrounding bone stock.

Periprosthetic femoral fractures are classified into:

- Type A fractures: proximal metaphyseal, not extending into the diaphysis
- Type B fractures: diaphyseal, not extending into the distal diaphysis and, therefore, not precluding diaphyseal long-stem fixation
- Type C fractures: distal fractures extending beyond the longest extent of the longest revision stem.

Intraoperative fractures are subclassified into:

- Subtype 1, representing a simple cortical perforation
- Subtype 2, representing an undisplaced linear crack
- Subtype 3, representing a displaced, or unstable fracture.

The postoperative fracture type A is subdivided into \(A_L\) (involves lesser trochanter) and \(A_G\) (greater trochanter). Type B is subdivided into B1, B2, and B3 based on implant stability and bone stock quality. B1 fractures have a solidly fixed implant. B2 fractures describe those in which there is an unstable implant and B3 fractures have an unstable implant and a compromised bone stock.

Figures 7.12.1 and 7.12.2 shows comprehensive treatment algorithms for periprosthetic femoral and acetabular fractures which were described in 2004.
Management

The conservative treatment of periprosthetic fractures has become obsolete. These methods are fraught with complications. For example, revision rates as a result of prosthesis loosening have been reported in the range of 19–100%; reports of pseudoarthrosis rates range from 25–42%, and abnormal varus positioning of the femur occurs at an average rate of 45%. Subsequent revision is fraught with difficulties due to malunion. We no longer recommend the use of non-operative methods such as traction or cast immobilization as they increase the risk of thrombosis, embolism, pneumonia, pressure ulceration, and knee joint contractures. The goals of treatment are: to achieve early union; anatomical alignment and length; a stable prosthesis; early mobilization; a return to premorbid function; and maintenance of bone stock.

Intraoperative fractures

In type A1, the cortical perforations are easily accessible and can be treated with simple bone grafting. In type A2, undisplaced linear cracks, the surgeon should assess the stability of the fracture and the stability of the implant and these fractures can be treated with cerclage wire or cable fixation. In type A3, displaced or unstable fracture of the proximal femur or greater trochanter, disruption of the integrity of the metaphyseal region of the proximal femur necessitates the use of a diaphyseal fitting uncemented femoral stem. Fracture of the greater trochanter can be fixed with wires, cables, or a trochanteric fixation claw and cables.

Type B1 (diaphyseal cortical perforation) most commonly occur during canal preparation and should be bypassed by two cortical diameters with a longer stem. Cerclage wiring of the bone at or below the perforation, before stem insertion, to prevent crack propagation is advisable. A combination of bone graft and cortical strut should be used to bypass the perforation if it is at the tip of the stem. Amplified hoop stresses created while inserting the prosthesis can cause undisplaced linear cracks (type B2). When recognized intraoperatively, they should be treated with cerclage wires or cables and the fracture should be bypassed. If unable to bypass the fracture with a longer stem, supplement with a cortical strut, or a plate and screws. Cortical onlay allograft struts increase cortical strength and are associated with good clinical results. Most of type B2 fractures are diagnosed only on the postoperative radiographs and they are treated with protected weight bearing for 6 weeks to 3 months until there are signs of healing. Type B3 (displaced fracture of the mid femur) occur during dislocation of the femur, broaching, femoral cement removal, canal preparation, and insertion of the prosthesis. The fracture should be adequately exposed, reduced, and fixed, with either cerclage wires or with one or two cortical struts. The continuity of femoral canal should be re-established and a femoral stem that bypasses the fracture by at least two cortical diameters should be inserted. For a stable implant, retain the stem augment with cables and cortical struts. Type C1 (cortical perforations) should be bone grafted and bypassed with a cortical strut. Type C2 (undisplaced linear crack extending just above the knee), if recognized intraoperatively and if fracture is potentially unstable,
cerclage wires with or without an onlay cortical strut allograft should be used. Whereas in type C3 (displaced fracture of the distal femur that cannot be bypassed by a femoral stem) should be treated with open reduction and internal fixation. For intraoperative acetabular fracture, the surgeon needs to assess for component stability, augment fixation with screws, buttress plating, or graft, and if loosening present, revision is inevitable.

The main aim of treatment is provision of bony columns to support an acetabular component. If the fracture pattern is more extensive with a transverse component or if there is displacement, the surgeon should stabilize the posterior column and fix anteriorly with lag screws and graft if required.

**Postoperative fractures (Box 7.12.2)**

Type A fractures are stable fractures treated with protected weight bearing up to 3 months and active abduction is avoided until union is achieved. Displacement greater than 2.5cm, trochanteric non-union, instability, or weakness of abduction are indications for internal fixation. When Type A fractures involve a large portion of the medial buttress, they may result in loss of implant stability and may warrant revision arthroplasty. These fractures are becoming more common with the increasing use of anatomical and tapered cementless stems.

The type B subgroup in the Vancouver system are probably the most crucial as they involve the bone in the vicinity of the femoral stem. They comprise more than 80% of late periprosthetic femoral fractures. There is a consensus that most fractures associated with a well-fixed stem (type B1 fractures) can be treated with open reduction and internal fixation whereas The mainstay of treatment for B2 type is revision of the femoral component using cemented or uncemented prostheses augmented with cerclage wires and strut grafts where indicated (Figures 7.12.3 and 7.12.4). Revision with a long-stem prosthesis permits stabilization of the fracture similar to that achieved when using an intramedullary nail, but the proximal femur may be a poor environment for recementing or proximal porous ongrowth if the index procedure was cemented. Uncemented prostheses help provide axial and rotational control in the diaphysis of the femur distal to the bone loss and comminution. In addition, they alleviate the potential concerns of cement inhibition or interposition on fracture healing. Fractures associated with a loose stem and extremely poor proximal bone quality (type B3 fractures), are treated with resection of the proximal femur and substitution with either a tumour prosthesis or an allograft prosthetic composite or a custom made implant (Figure 7.12.5). Every effort is made to preserve the abductor mechanism and reattach it to the implant or wrap the proximal femur around the implant.

**Box 7.12.1 Goals of treatment**

- Early union
- Anatomical alignment and length
- Maintenance of bone stock
- Stable prosthesis
- Bypass defects
- Adjuncts: cortical struts, circlage cables, plates
- Early mobilization.

Fig. 7.12.3
Type B2 fracture (A) and its revision with a long stem uncemented prosthesis augmented with cables (B).
Type C fractures are treated with open reduction and internal fixation.

The intramedullary blood supply is already compromised in periprosthetic fractures around THR. To add on to this the extraosseous blood supply is interfered due to dissection involved with open reduction and internal fixation (ORIF) with or without wiring. Bone grafting of all periprosthetic femoral shaft fractures treated with ORIF is recommended. Percutaneous fixation of periprosthetic fractures with dynamic compression plating (DCP) is a good alternative. In locking plates the screw locks onto the plate, providing additional angular stability; the plates are designed for minimally invasive insertion, allowing extraperiosteal application, preserving the periosseous blood supply and reducing soft tissue damage. The plates allow unicortical screw placement which makes it useful when dealing with periprosthetic fractures, as screws may be placed without damaging the cement mantle. However, some fracture configurations may affect the outcome of internal fixation even when the stem is stable; for example, transverse fractures at the tip of the stem are very difficult to treat with plates alone, and in these cases revision of the stem may be preferred. The other common implant systems used are the cable plate fixation devices. The third-generation systems allow cable retightening which is particularly useful.

Cortical onlay strut grafting, first described for the treatment of femoral periprosthetic fractures, is an attractive option because it combines fixation with the potential to restore the bone stock and increase cortical strength. Excellent union rates with this technique have been reported. Through union with the host bone, the allograft also may enhance the host bone stock and strength.

Impaction grafting with long cemented femoral protheses, bypassing the most distal fracture line, together with structural cortical grafts and/or plates, has also been attempted with encouraging results. An alternative of cement-in-cement revision to a longer stem is available for unfit patients providing the cement mantle is well preserved. This is particularly useful with tapered stems.

In acetabular fractures, the aim is to regain structural integrity of the columns and restoration of bone stock so that it allows stable fixation. All patients who are suspected of acetabular fractures after THAs should get standard and Judet views of the pelvis and a computed tomography scan to make an accurate diagnosis. These images are also used to define the anatomy. Patients with stable acetabular fractures are initially treated with 6–8 weeks of touch-toe weight bearing. In the presence of significant displacement revision surgery is necessary. Initial conservative treatment is justified to allow union and avoid stripping of the posterior column for late presenting fractures around cemented acetabular components with significant osteolysis and minimal displacement. If pelvic discontinuity is present at revision surgery they should be treated with tantalum sockets, cup cage constructs, or antiprotrusio cages (APC), with bone grafting and plating as necessary.
Periprosthetic fractures around endoprostheses with epiphyseal or metaphyseal fixation

Further classification of periprosthetic fractures around endoprostheses with epiphyseal or metaphyseal fixation has been proposed into EM-B and EM-C. EM-B fractures are found with surface replacement endoprostheses, which occur at the boundary of the cup endoprosthesis and the neck of the femur, or which occur in the metaphysis in the case of metaphyseal-fixed prostheses. The implant should be exchanged for a stem endoprosthesis in cases of EM-B fractures. The EM-C1 fractures are infrequent fractures that occur at some distance away from a stable cup endoprosthesis or below stable metaphyseal anchored prostheses. Internal fixation is the ideal treatment for these cases.

The indication of osteosynthesis should depend on the location of the fracture, quality of the osteosynthesis, and on whether polyethylene wear is radiologically detectable or not. If wear is present, these fractures should be managed like EM-C2 fractures and treated primarily by complete exchange of the prosthesis. The EM-C2 fractures are fractures that occur at some distance below a loosened implant and are treated by prosthetic exchange.

Interprosthetic fractures

Interprosthetic fracture is also proposed as an extension of the classification of periprosthetic fractures. Type IA are the fractures that occur between a stemmed endoprosthesis of the hip and surface replacement prosthesis of the knee joint, and type IB are those that occur between two stem prostheses (hip and knee). The type IA fractures are subclassified according to the implant stability: fractures with stable implant as type IA1 and loose implants as type IA2. Type IA1 fractures are treated with internal fixation techniques. Type IA2 require exchange of the implant at the same time with a prosthesis that bridges the fracture by at least two diaphysis diameters. Type IB fractures usually require a total femur prosthesis, whereby a stable stem implant can be integrated into a special prosthesis in the form of a pin prosthesis.

Conclusions

Surgical decision-making in this complex group is influenced by various factors such as the patient’s age, gender, femoral anatomy, bone stock quality, type and size of the prosthesis, surgical approaches, and techniques. The main strategies of management are: 1) identify the high-risk group, e.g. recurrent dislocation, loosening, subsidence and osteolysis; 2) perform revision arthroplasty before extensive bone loss results in periprosthetic femoral fracture; 3) in revision arthroplasties, it is prudent to obtain adequate surgical exposure, which may involve a trochanteric osteotomy, avoid eccentric or varus reaming, over-ream to avoid hoop stresses and fracture during the insertion of press fit stems, remove cement safely (by splitting it radially and at several levels or by ultrasound), and finally prevent propagation of fracture with the aid of prophylactic cerclage cables or wires.

Box 7.12.2 Management of postoperative periprosthetic femoral fractures

- Type A2:
  - Protected weight bearing up to 3 months
  - Active abduction is avoided until union is achieved
- Type A2 with displacement greater than 2.5cm, trochanteric non-union, instability, or weakness of abduction
  - Internal fixation
- Type B1 fractures: ORIF
- B2 type fractures:
  - Revision of the femoral component using cemented or uncemented prostheses
  - Augmented with cerclage wires and strut grafts
- Type B3 fractures:
  - Resection of the proximal femur
  - Substitution with either a tumour prosthesis, or an allograft prosthetic composite, or a custom-made implant
- Type C fractures: open reduction and internal fixation.

### Summary points

- Diagnosis of infected hip arthroplasty requires a multidisciplinary team approach
- Aims of treatment are to eradicate infection, alleviate pain, and restore function
- Treatment should be conducted in specialist centers.

### Introduction

Infection is a major complication of arthroplasty surgery with a reported incidence after primary operation of 0.2–1%. Its successful management depends on clear understanding of certain principles summarized in this chapter.

### Pathogenesis

All surgical wounds are contaminated by bacteria and it is surprising that relatively so few become clinically infected. Over 95% of prosthetic infections that occur during the first year after implantation are due to perioperative contamination. Infection can also occur through the bloodstream; such haematogenous infections tend to manifest later. Irrespective of the route, infection becomes established when the dose and virulence of bacteria overcome the host defences. The degree of virulence determines the speed of infection. In addition to surgical and environmental factors, patient factors play an important role, e.g. old age, chronic disease, immunosuppression, and a history of previous joint infection.

After implantation, body fluids immediately coat all surfaces of the prosthesis with a layer of serum proteins and platelets. Bacteria approach the surface of the prosthesis through an interaction of physical (van der Waals forces and hydrophobic interactions) and chemical forces (covalent and hydrogen ion bonds). There is then a race for colonization of the implant surface between the host’s cells and the bacteria. If this race is won by bacteria, adhesion progresses to aggregation on the surface of the prosthesis. In doing so, bacteria change from being planktonic to sessile: they become encased in a matrix of polysaccharides and proteins to form a slimy layer known as the biofilm. This has the following properties:

- Enhancing nutrition to the bacteria
- Preventing detachment of the bacteria in adequate numbers thereby making diagnosis by aspiration difficult
- Acting as a protective barrier inhibiting phagocytosis and preventing penetration by antibiotics.

Gram-positive cocci dominate the list of pathogens identified accounting for over 50% of infections within several units. The majority are coagulase-negative *Staphylococcus* and *Staph. aureus*. Aerobic Gram-negative bacteria cause 10–20% of all deep infections and anaerobic bacteria are responsible for another 10–15%.

### Classification

Infection can be superficial or deep.

- **Superficial**: superficial infections need to be treated with respect as they either represent a true superficial infection or an underlying deep infection presenting superficially.
- **Deep infection**: whilst several different classification systems have been described, that by Tsukayama and colleagues is most useful as it is a temporal classification with recommendations for treatment:
  - I: positive intraoperative cultures. Two or more specimens obtained intraoperatively have been cultured and found to be positive for the same organism
  - II: acute postoperative infection which is apparent within 1 month of implantation
  - III: chronic infection is of insidious onset occurring after the first month of implantation
  - IV: haematogenous infection occurs at any time after implantation from a distant source such as dental, urinary, or chest infection. The onset is often acute in a previously well-functioning hip.

As far as is known, haematogenous infection is relatively rare, many late infections being acquired from perioperative contamination.

### Diagnosis of deep infection

Sometimes diagnosis is obvious, but not always: there is no single investigation which can conclusively confirm or refute its presence; no single test is 100% sensitive or specific and multiple tests are required.
Preoperative considerations

History

Most patients following hip arthroplasty have a very good clinical result. Any deviation from this, particularly in the first 12–18 months should raise suspicion of infection. The nature of the pain should be ascertained; is it mechanical in nature or present at rest, is it associated with fever or night sweats, in fact, has the hip ever felt right? Did the wound heal quickly or did it require antibiotics and district nurse input?

Examination

Pain and reduced range of movement may be present in acute infection otherwise the joint may be only mildly irritable. Frank pus, abscess, or sinuses may present or sometimes more subtle changes like skin discolouration and induration. In the majority of cases there will be nothing specific to find on examination.

Investigations

Blood tests

It is normal practice to measure the ‘inflammatory markers’ in the blood: the white cell count (WCC), the erythrocyte sedimentation rate (ESR), and the C-reactive protein (CRP). Full blood count often shows a normal WCC but patients with long-standing infection can develop anaemia of chronic disease and a raised platelet count.

The ESR takes up to 1 year from the index operation to return to normal levels but a raised level of 30mm/h or greater raises the clinical suspicion of infection. Other causes for a raised ESR must be taken into consideration.

The CRP is acutely raised after the index operation for 48–72h then falls rapidly over the next 2–3 weeks in the absence of infection. However, it may remain elevated in patients with rheumatoid arthritis for up to 8 weeks. After this time a level of 10mg/L or greater raises the clinical suspicion of infection.

Gaston has shown that serial measurements of CRP and ESR are more helpful than isolated results. A single elevated CRP and ESR was in his series, associated with a 50% chance of infection. This rose to 80% for persistently elevated test results. Normal levels—both isolated and in series—had a stronger predictive value in ruling out infection (80% and 94% respectively).

Imaging

Plain radiographs in isolation may show radiolucent lines, osteolysis, scalloping, and periosteal reaction but these can also be present in aseptic loosening. Serial radiographs are more useful for assessing changes over time as infective loosening tends to be more rapid in its progression.

With increasing use of uncemented prostheses, radiographic changes may be more difficult to interpret. Provided a prosthesis is not becoming loose overall, relatively marked signs somewhere at the bone–cement interface may be pain free.

Radioisotope scans although expensive and time consuming, may be useful. Indium-111 (111In)-labelled white cell scans combined with technetium-99m (99mTc)-sulphur colloid marrow imaging have been found to be sensitive for loosening but not specific for infection. There is now interest in fluorodeoxyglucose positron emission tomography (PET scan) which may be more specific.

Aspiration and biopsy

Hip aspiration is regarded by many as the gold standard. In addition to diagnosing the bacteria responsible it also offers an antibiotic sensitivity profile. Bacteria spend most of their time in the sessile phase and so to optimize accuracy of the aspiration the following steps should be taken:

- Antibiotics should be stopped for a minimum of 2 weeks prior to aspiration
- Samples should be inoculated directly into enrichment media
- Prompt transfer to the laboratory should be ensured
- Prolonged culture for up to 14 days is necessary to ensure that slow-growing bacteria are identified
- Close liaison with a dedicated microbiologist is essential.

Numerous authors have found hip aspiration to be highly specific (see Table 7.13.1) and therefore making more invasive tissue biopsy unnecessary.

A simple WCC from the aspirate can be a useful adjunct. There is a reported sensitivity of 97% and specificity of 98% when there are $1.7 \times 10^8$ per microlitre white cells with a differential of 65% neutrophils.

Polymerase chain reaction

Polymerase chain reaction (PCR) allows detection of the bacteria in small numbers by amplification of microbial DNA but its usefulness is limited by a high rate of false positives.

**Perioperative considerations**

**Frozen section**

Although this investigation has been shown to be highly specific for the diagnosis of infection, it does not help with the preoperative diagnosis or yield antibiotic sensitivity profiles. It does, however, require an experienced pathologist. Whilst five polymorphs per high-power field is regarded as being consistent with a diagnosis of infection, the presence of ten polymorphs per high-power field gives an improved specificity of 99% without reducing sensitivity.

**Gram stain**

This simple test lacks any acceptable level of sensitivity and is not recommended for this purpose.

**Intraoperative samples**

Multiple intraoperative samples should be taken and sent for microbiological analysis. A fresh scalpel and forceps are used for each specimen and antibiotics withheld until the samples have been taken. It is imperative that these samples are sent directly to the laboratory. Three or more cultures growing a consistent micro-organism are thought to be diagnostic of infection.

The probability of diagnosing infection is increased with increasing number of positive results from all the investigations described here.

**Management protocols**

Eradication of the infection is the fundamental necessity taking precedence in the sequence of other curative measures, usually, but not always reimplantation. A stable implant will most usually be pain free.

The options are:

- Antibiotic therapy—rarely alone and usually accompanying surgery
- Surgical debridement with retention of prosthesis
- Single-stage revision
- Two-stage revision
- Excision arthroplasty
- Disarticulation.

**Antibiotics**

Surgery is not always the appropriate choice. In cases where the patient may not be fit for, or does not want surgery then long-term suppression with antibiotics can be an acceptable form of treatment. The prosthesis, however, must be soundly fixed and the infective organism sensitive to the antibiotic used. Nevertheless, it must be recognized that antibiotics alone will not eradicate the infection—only slow the infective process to some degree.
Surgical debridement with retention of prosthesis

Success rates of up to 84% have been reported with debridement and lavage with retention of the original prosthesis in cases of acute postoperative infection if performed within 2 weeks of the index procedure. After this time the chance of successful eradication of infection falls dramatically. A patient rarely presents during this time frame so making this treatment of later haematogenous infection much less successful.

Exchange arthroplasty

Exchange arthroplasty surgery offers the best way of eradicating infection along with restoration of function. This can be undertaken in a direct or staged manner. Results in the literature of each pathway are difficult to compare, but the key to success of both treatment modalities depends upon:

- Preoperative diagnosis of the infecting organism and its antibiotic sensitivity pattern
- Radical debridement
- Elution of antibiotic from bone cement.

Direct exchange

The major advantage of direct exchange surgery is that it is one operative procedure with benefits to both the patient and the healthcare system. It removes the morbidity of a temporary pseudarthrosis and lessens the cost of treatment.

The generally accepted criteria for performing direct exchange are:

- Cemented reconstruction
- Accurate preoperative bacteriological identification and an organism with an antibiogram appropriate to the antibiotics available
- Adequate bone stock and soft tissue support.

Direct exchange follows the principle that debridement removes all infected tissue and material, the dead space thus created is filled with the new implant which is fixed to the bone with cement acting as a depot for the release of local antibiotic. Recent published work has demonstrated the successful use of allograft bone as a delivery vehicle for antibiotics in single-stage surgery for infection using uncemented components. The combination of uncemented implants and an antibiotic bone compound used in a single-stage procedure has advantages and may improve long-term result.

It is generally accepted that direct exchange is less successful in eradicating infection than staged reconstruction. However, the difference is relatively small. The success of a one-stage procedure is highly dependent on the aggressiveness of the debridement, the experience of the surgeon, and close interaction with a microbiologist. Several European centres have reported excellent results treating all infections in this manner.

Although single-stage exchange has an obvious role we believe this should probably be restricted to the case of a single organism with known antibiotic sensitivities and reasonable bone stock.

Two-staged exchange

The only difference between direct and staged exchange is the interval phase. Radical debridement is essential to both. Antibiotics need to be administered either intravenously or to elute from bone cement (usually pellets or a spacer inserted during the interval phase as described later in this section) and after a period of weeks or even months the hip is reconstructed.

Following debridement, the extent of bone loss will be evident thereby allowing the surgeon to plan subsequent reconstruction. If bone graft is required, it can be safely used at the time of second stage without there being an increased risk of infection.

The interval phase allows for the administration of antibiotic. This can be given systemically or by elution from bone cement in the form of beads or a spacer. The advantage of cement elution is that it produces a much higher local concentration of antibiotic than could be safely given systemically. Local levels of gentamicin can be 10–100 times higher than the minimal inhibitory concentration of the causative bacteria whereas only 10% of the antibiotic available from the serum is found within bone when given systemically.

Any antibiotic can be added to the bone cement prior to polymerization as long as it is a sterile, dry powder which is heat stable and water soluble. It is usually mixed by hand in theatre at the time of surgery. The elution properties relate directly to the water uptake by the bone cement, antibiotic dissolves in the body fluid and elutes out. Generally no more than 4g of antibiotic should be added to each 40g packet of the polymethylmethacrylate (PMMA) polymer (10%) as above this level the biomechanical properties of the cement are affected.

Whilst the role of prophylactic antibiotics is established, is there a need for prolonged systemic therapy when the mainstay of treatment is surgical and such high concentrations can be delivered locally from the bone cement? Review of the literature is not particularly helpful when trying to evaluate the success of two-stage regimens. In Sheffield in the early nineties we took the decision to treat our infections in a two-stage manner on the principle of radical debridement, local elution of antibiotic without the need for prolonged adjunctive systemic therapy. Our results with respect to eradication of infection are comparable with other authors who have used prolonged courses of antibiotics, but have the advantage of reduced cost and no associated morbidity of prolonged therapy.

The timing of reimplantation is based upon the clinical progress of the patient as evidenced by the quality of soft tissues and falling...
ESR and CRP. The minimum period between stages is usually 6 weeks and there is no need for a prolonged interval before reimplantation according to the monitoring tests. If the soft tissues do not improve or inflammatory markers remain elevated it is preferable to explore and debride as opposed to delay.

The long-term results for successful eradication of infection with two-stage surgery range from 87–92% at 5- and 10-year follow-up. The results for successful eradication of infection following one stage exchange range from 86–91% at 3- and 10-year follow-up.

Excision arthroplasty

If, following debridement, hip reconstruction is not possible or the patient declines further surgery, then excision arthroplasty remains a viable option. Whilst the results for eradication of infection are good, lower limb function, particularly in the younger more active and the elderly frail patients, is poor.

Disarticulation

Disarticulation is the final option available to the surgeon and should be reserved for life-threatening sepsis or irreparable neurovascular damage.

Summary

Diagnosis and treatment of infected hip arthroplasty requires a multidisciplinary team approach to eradicate infection, alleviate pain, and restore function. Each patient must be treated on an individual basis. The spectrum ranges from conservative suppressive therapy to radical ablation. Most cases that present will be chronically infected so the mainstay of treatment is surgical debridement, which must be radical and complete. Antibiotics obviously have an important but secondary role.

The surgery necessary for these infected cases does not involve any special techniques but it is extensive with respect to excision, becoming on occasion alarming unless the surgeon has at their disposal a comprehensive shelf of instruments and implants, adequate bone graft material, and time for long operative procedures. These are the main reasons why treatment of the infected arthroplasty should be conducted in specialist centres.

Hip resurfacing

Summary points

- Hip resurfacing has emerged as an alternative method of hip arthroplasty for younger patients
- It is technically more demanding than total hip replacement
- The reported early and mid-term results are good with revision rates below 5% at 7 years
- Long term effect of raised levels of metal ions remains a major concern
- Long term clinical follow up and further research must continue.

Introduction

Hip resurfacing arthroplasty is an attractive concept, as it not only preserves proximal femoral bone stock at the time of surgery, but by optimizing stress transfer to the proximal femur it minimizes stress shielding in the medium to long term. The large diameter of the articulation offers inherent stability and optimal range of movement. Total hip replacement has a higher failure rate in younger patients, i.e. those under 55 years, compared to elderly patients. Hip resurfacing arthroplasty has emerged as an alternative to total hip replacement in younger patients (Box 7.14.1). In less than a decade, since its renaissance in the 1990s, resurfacing has become very popular with the number of implantations accounting for 8–10% of all primary hip replacements in countries such as the United Kingdom, Australia, and the Netherlands.

Box 7.14.1 Why hip resurfacing?

- Total hip replacement in younger patient has a higher failure rate
- Hip resurfacing has emerged as an alternative to total hip replacement in younger patients
- Bone preservation and better loading of proximal femur leading to less stress shielding
- Reduced risk of dislocation and leg-length discrepancy
- Low-wear bearing surface
- Hip resurfacing now accounts for 8–10% of all primary hip replacements.

History

The first hip resurfacing arthroplasty was performed by Smith-Petersen in 1923. He temporarily interposed a thin hemispherical shell between the femoral head and acetabulum in patients with arthritis and expected new cartilage to grow on the articular surfaces. Originally, the shells were made of glass, bakelite, or celluloid. In 1938, he first implanted metal shells made of vitallium (cobalt-chrome-molybdenum (Co-Cr-Mo) alloy). In the 1970s, the second generation of resurfacings were developed. They were total resurfacings with a metal-on-polyethylene bearing. The clinical results were disappointing. Their failures can be mainly attributed to osteolysis induced by wear particles from the thin-walled polyethylene acetabular component.

In the 1990s, recognizing this problem, the third generation of resurfacings with a metal-on-metal bearing was developed in Birmingham, United Kingdom, by McMinn and Treacy. After a few attempts of trial and error, they found that the best fixation was obtained with a cemented, stemmed femoral hemispherical Co-Cr-Mo cap and an uncemented hydroxyapatite (HA)-coated Co-Cr-Mo acetabular cup and in 1994, implantation of McMinn prosthesis was started. Now, at least 15 types of resurfacing prosthesis are available in the market. These prostheses differ in many details, such as shape, sizing, head coverage, clearance, metal alloy used, heat treatment, instrumentation, and so on. Just as with conventional hips, they exhibit differences in clinical outcome. The Swedish and Australian registries have listed a two- to threefold difference in revision rate between different makes.

Advantages and disadvantages

There are several theoretical advantages of hip resurfacing over conventional hip replacement but the lack of long-term data and emerging new modes of failure are the main disadvantages and cause for concern (Table 7.14.1).

**Indications and contraindications**

A man younger than 65 years with primary osteoarthritis with good bone quality and normal proximal femoral anatomy is the ideal candidate for hip resurfacing. Infection, osteoporosis, severe bone loss either of femoral head or acetabulum, and renal failure are the absolute contraindications for resurfacing. Patient selection for hip resurfacing is no less important than any other surgery. Important indications and contraindications are listed in Table 7.14.2.

DXA, dual energy X-ray absorptiometry.
The National Institute of Health and Clinical Excellence (NICE) recommend metal-on-metal hip resurfacing arthroplasty to be performed only by surgeons who have received training specifically in this technique. Resurfacing can be carried out through a posterior or a direct lateral approach. The lateral approach to the hip has been advocated as a way of preserving the deep branch of the medial femoral circumflex artery thus preserving blood supply to the anterosuperior quadrant of the femoral head but with the lateral approach there is significant risk of abductor dysfunction. Abductor dysfunction is very poorly tolerated in young patients who wish to regain an active lifestyle. The posterior approach is currently favoured by most surgeons. The approach is more extensile than traditional posterior approach. Circumferential capsulotomy and gluteus maximus tenotomy is required for good exposure of femoral head and creation of a superior pocket is required to accommodate the femoral head and neck while acetabulum is prepared.

Easy resurfacing arthroplasties do not exist; with a steep learning curve, it remains a difficult procedure even in experienced hands. In particular, component positioning and cementing technique are critical factors—and the main causes of failure in retrieval studies. The main reason for early revision is fracture of the neck arising from the edge of the implant, which can be initiated by uncovered reamed bone and notching. Early revisions are more common in older patients and females, and bone quality seems to be a critical factor. Late revisions are without fracture and most of them show signs of wear and rim loading, which can be related to malpositioning. Varus placement of the femoral component leads to higher levels of stress and increases the probability of failure. It is recommended that a surgeon should strive to achieve a relative valgus placement of 5–10 degrees while avoid to notch the superolateral cortex of the femoral neck.

Computer-assisted navigation systems have been used with success to avoid malpositioning of components, especially in early phase of learning curve.

### Results

Very good early and mid-term results have been reported from the centre of origin of Birmingham hip resurfacing prosthesis. They reported survival of 99.7% of 439 hips at a mean follow up of 3.3 years for patients under the age of 55 years, and 98% of 144 hips at a minimum follow up of 5 years for males under the age of 65 years and females under the age of 60 years. Their survival rates in multicentre studies have shown worse results. The National Joint Registry for England and Wales (2007) reported revision rates of 1.8% at 3 years; the Australian Orthopaedic Implant Register (2007) reported 3.7% at 5 years; and the Oswestry Hip Outcome Centre reported 4.6% at 7 years.

### Complications

The main reasons for revision of a metal-on-metal hip resurfacing are femoral neck fracture, aseptic loosening, and pain (Box 7.14.2).

#### Box 7.14.2 Surgical technique

- Hip resurfacing is a technically demanding procedure and needs specific training
- Lateral approach is advocated to preserve blood supply to femoral head but is associated with risk of abductor dysfunction
- Posterior approach currently favoured by most surgeons
- Circumferential capsulotomy and gluteus maximus tenotomy is required for good exposure
- Most failures can be attributed to technical errors, e.g. notching of superior neck, uncovering of reamed bone, varus femoral component, excessively open or anteverted acetabular component, or poor cementing technique.

#### Femoral neck fracture (Figure 7.14.1)

Femoral neck fracture is a unique complication of resurfacing occurring in 0–7%. The causes of fracture can be related to the patient, the surgical technique, or a combination of both. Patient-related factors include decreased bone mass, obesity, and inflammatory arthritis. Intraoperative characteristics that may lead to fracture if proceeding with resurfacing include cysts and/or exposed bone found in the femoral neck during preparation of femoral head. Surgical errors include notching of the femoral neck, preparing the femoral head and, therefore, tilting the prosthesis into excess varus (<130 degrees stem-shaft angle), and seating of the cup into retroversion.

#### Box 7.14.3 Complications of hip resurfacing

- Heterotopic ossification (28–68%)
- Neck narrowing (14–28%)
- Aseptic loosening (2%)
- Avascular necrosis (0.5–1%)
Undisplaced fracture can be successfully treated with a few weeks of toe-touch weight bearing. Displaced fractures or undisplaced fractures failing to unite with conservative treatment can be treated by conversion to standard total hip replacement. If the cup is in a good position and well fixed, the hip can be revised using a standard stem with a large modular femoral head to articulate with the cup, otherwise both components can be revised.

**Aseptic loosening**

Aseptic loosening of the femoral component has been reported in some series, occurring in up to 2% of cases. Large areas of cystic degeneration in the head leaving less surface area available for fixation and also a lower stem shaft angle are more frequently associated with aseptic loosening.
The approach for hip resurfacing is usually extensile and involves more tissue dissection and handling than conventional hip replacement. Heterotopic ossification has been seen in 28–60% of patients after hip resurfacing but only 7–8% develop Brooker grade 3 or 4. High-risk patients should have prophylactic treatment.

**Dislocation**

Hip resurfacing is inherently more stable than conventional hip replacement because of larger diametric clearance of femoral components. The reported incidence is less than 1% as opposed to 3–6% in conventional hip replacement.

**Narrowing of the neck (Figure 7.14.3)**

Some degree of narrowing of the femoral neck is seen in three-quarters of the patients who have had hip resurfacing but only 14–28% have more than 10% of narrowing. Female patients are 2.5 times more likely to develop neck narrowing and patients with higher (valgus) neck-shaft angle are also more at risk. Neck narrowing seems to stabilize with time with no adverse clinical or radiological features noted in cases followed-up for 6 years. No significant progression of narrowing was noted in these patients after 3 years.

Several other complications related to resurfacing arthroplasty have been reported including clicking, squeaking, soft tissue impingement, psoas tendinitis, nerve palsy, metallosis, osteolysis, raised metal ion levels, and aseptic lymphocytic vasculitis associated lesions (ALVAL) or pseudotumours (Figure 7.14.4).

The latter two have been investigated by many and remains focus of most research related to metal on metal bearing arthroplasty. The peak serum cobalt level and that of serum chromium level have been seen at 6 months and 9 months respectively. The serum levels of metal ions gradually decline as the bedding-in wear changes to steady-state wear but have remained higher than preoperative levels even at 2-year follow-up. Long-term impact of raised metal ion levels is unknown and remains a major concern against general acceptance of metal-on-metal hip resurfacing arthroplasty. The exact aetiology of aseptic periarthritis resides mass (pseudotumours) is unknown, but the two widely accepted explanations in the current period of time are T-lymphocyte-mediated delayed-type hypersensitivity reactions and/or direct toxic effect of a very high concentration of metal debris in the joint fluid. The individual biological response to the presence of wear debris seem to vary, and may be due to different toxic-effect threshold or immunological tolerance. They occur with an overall incidence of 1% in the first 5 years after implantation of metal-on-metal hip resurfacing and are commoner in females. Histological specimens harvested at the time of revision show inflammatory changes, vasculitis, and necrosis.

Periprosthetic osteolysis is a rare complication of metal-on-metal arthroplasty. The histological examination showing a perivascular accumulation of T-lymphocytes and immunohistochemical analysis showing elevated levels of bone-resorbing cytokines such as IL-1 and TNF-α produced by infiltrating lymphocytes and activated macrophages suggest that early osteolysis is associated with delayed-type hypersensitivity to metal.
Fig. 7.14.3
Anteroposterior radiographs. A) A few weeks postoperatively, the neck prosthesis ratio was 0.88 and B) at 2 years, the component was radiologically stable but the neck prosthesis ratio dropped down to 0.77. Neck was narrowed by 12.5%.

Speculation of future association of metal-on-metal bearing arthroplasty with malignancy or genotoxicity is based on the findings of research related to intracellular metabolism of chromium and cobalt, which has been found to release free radicals (reactive oxygen and nitrogen species). Free radicals are known to be involved in protein oxidation, leading to their degradation, lipid peroxidation, and DNA damage.

Conclusions
Lessons from the failure of previous generations of hip resurfacing have helped to select better materials, improve implant design and manufacture, and also upgrade instrumentation. Cementless acetabular components and cemented femoral components fixation provide better and more reliable results compared to alternative methods of fixation. Orientation of implants and surgical time improve with experience as surgical technique has a steep learning curve. Patient selection is of paramount importance and not all patients with osteoarthritis of hip under the age of 65 years are candidates for hip resurfacing. Female patients tend to have a higher incidence of complications and they must be carefully warned before offering hip resurfacing at any age. Recent studies demonstrating excellent short-term results of metal-on-metal resurfacing in active patients younger than 60 years of age have established it as an alternative to conventional hip replacement.

Box 7.14.4 Conclusions
♦ Survival rate above 95% at 7 years (reported from an independent centre)
♦ Female patients have higher incidence of complications at any age
♦ Long-term effect of raised levels of metal ions is unknown and remains a major concern against general acceptance
♦ Long-term clinical follow-up of patients and research into the pathogenesis of periprosthetic biological adverse reactions must continue.

The importance of long-term clinical follow-up of patients undergoing metal on metal hip resurfacing arthroplasty cannot be overstressed. The short-term success of resurfacing arthroplasty should not overwhelm and the research into the molecular and cellular mechanism involved in the pathogenesis of periprosthetic biological adverse reactions caused by metal wear particle must continue.

Further reading
Summary points

- The pelvis acts as a fulcrum for the forces transmitted between the lower limb and trunk especially on twisting and turning movements while running, and in the reverse direction when kicking. Sports injuries around the pelvis are therefore common in weight-bearing sports, such as running, football, rugby, and basketball.
- Injury can occur to the various structures around the pelvis. Bone stress injuries affect the symphysis pubis, pubic rami, femoral neck, and sacrum. Stress fractures are more common in women and may occur as part of the female athlete triad (Box 7.15.1) where there is hypo-oestrogenaemia and low bone density.
- Tendon injuries, including enthesopathies, most commonly affect the adductors, lower abdominals, glutei, and hamstrings. Hip injuries can occur as a result of labral tears and femoroacetabular impingement. Sacroiliac joint instability may also cause symptoms especially in the buttock region. Synovitis of either joint may suggest an inflammatory arthritis.
- Pain is the most common symptom. However, it may be referred from elsewhere, especially the lumbar spine. Pain may also originate from other systems including the reproductive organs and the gastrointestinal and urinary tracts.

Box 7.15.1 The female athlete triad

- Disordered eating—low energy intake
- Menstrual dysfunction—amenorrhoea
- Osteopenia—osteoporosis.

Introduction

Injuries around the pelvis usually cause pain, which tends to be in one of three regions:

- The anterior hip and groin
- The lateral hip
- The buttock.

There may be a degree of overlap of the site of the pain and sometimes, especially with primary hip joint pathology, the pain may be felt deeper within the pelvis. The diagnosis can usually be made following a detailed history and examination, which may include special tests. This can be confirmed by imaging, in particular magnetic resonance imaging (MRI) and ultrasound scanning.

Anterior hip and groin pain

Groin pain may be caused by local pathology but several systems can cause referred pain into the groin. There is, therefore, a large differential diagnosis (Table 7.15.1).

Acute symptoms are usually due to strains and minor tears which can be managed expectantly with a good outcome. However, chronic groin pain is often complicated by the fact that multiple pathologies may coexist. Furthermore, the aetiology of the so-called 'sports hernia', a diagnosis commonly made in athletes, is poorly understood. Therefore, the assessment and treatment of chronic groin pain can be difficult.
**Sports hernia and osteitis pubis (Box 7.15.2)**

These two injuries often coexist and although the description of osteitis pubis is well established, the diagnosis of sports hernia is poorly understood. This injury has been described by many terms, such as sportsman’s hernia, athletic pubalgia, and Gilmore’s groin. It is predominantly an injury of the male athlete. Both the aetiology and pathophysiology are controversial. The most common view is that it is due to a weakness or deficiency of the posterior inguinal wall. Findings at surgery include tears to the transversalis fascia or conjoint tendon and dilatation of the superficial inguinal ring.

The cause is thought to be the strong pull of overconditioned adductors against the relatively underconditioned lower abdominal muscles creating a shearing force across the front of the pelvis. This may also lead to instability of the symphysis, hence the association with osteitis pubis.

**Symptoms and signs**

The main symptom is a chronic, activity-related uni- (or bi-) lateral groin pain, which occurs in cutting and kicking sports, such as football, rugby and hockey. The onset is usually insidious initially with discomfort after a game. Gradually the pain comes on during a game, especially with cutting movements rather than running in a straight line. This then affects the ability of the athlete to train and perform. Examination findings are variable but can include tenderness over the pubic tubercle and around the superficial inguinal ring, which may be enlarged. There may be pain on testing the muscles groups attached around the symphysis, including the adductors and lower abdominals (tests include the adductor squeeze, double leg raise, and sit-up). Conventional hernia tests are negative.

**Box 7.15.2 Features of ‘sports hernia’/osteitis pubis**

- Caused by a weakness of posterior inguinal wall
- May result in uni- or bilateral groin pain
- Often tenderness over pubic tubercle and superficial inguinal ring
- MRI may show:
  - Osteitis pubis
  - Tears at rectus and adductor insertion
- Treatment:
  - Conservative: rest, NSAIDs, physiotherapy
  - Surgery in non-responders.

**Investigations**

Imaging may show changes around the symphysis with changes on x-ray and bone oedema on MRI, both suggestive of osteitis pubis. MRI may also show tears and tendinosis of the rectus insertion and adductors. In experienced hands, changes can sometimes be identified on ultrasound.

**Management**

Treatment should initially be conservative. This should include a period of relative rest from the provoking activities. Non-steroidal anti-inflammatory drugs (NSAIDs) may help to control the pain while the symptoms of osteitis pubis may respond to an intravenous bisphosphonate. Physiotherapy should include conditioning exercises involving the muscle groups around the front of the pelvis with core stability/strength training involving the lower abdominals. A progressive training ladder gradually working back to full sporting activity should then be followed. This process to full recovery can take about 4 months.

In those who don’t respond to this regimen or in those who want a quicker resolution of the injury (e.g. the professional athlete), surgery should be considered. The options are either an open or laparoscopic approach with exploration and repair of the abdominal wall, using a mesh or performing a modified Bassini repair. The success rate following surgery is extremely high with most studies reporting greater than 90% of the athletes back to full sporting activity within 4–8 weeks. Unfortunately there are no randomized, controlled trails comparing surgical with conservative interventions.

**Adductor muscle strains and tendinopathy**

These injuries are typically seen in footballers and ice hockey players. They usually occur acutely and can be graded from mild where minimal playing time is lost (grade I) to severe where there is almost complete loss of muscle function (grade III). The athlete complains of groin pain with tenderness over the adductor and/or at its insertion around the symphysis. There is pain on passive abduction and on active adduction. It is thought that without adequate rehabilitation there is a danger that an acute adductor strain may go on to a more chronic tendinopathy.

**Rectus abdominis strains**

These occur at the attachment to the superior pubic ramus as a result of excessive lifting or intensive ‘sit-up’ type exercises. There
is usually tenderness around the site of attachment and pain on active contraction of the lower abdominals. The injury responds to relative rest and physical therapy.

**Inguinal hernias**

These occasionally cause groin pain in the athlete. There may be an obvious swelling with a positive cough impulse. They respond to surgical treatment.

**Obturator neuropathy**

The diagnosis of obturator neuropathy is controversial. It is due to fascial entrapment leading to exercise-induced pain together with weakness of the adductors and numbness in the distal medial thigh immediately post-exercise. Electromyography (EMG) may show denervation in the adductor muscle. It often responds to conservative therapy but may require surgical release.

**Iliopsoas tendinopathy and bursitis**

The iliopsoas arises from the lumbar vertebrae and anterior surface of the ilium and inserts into the lesser trochanter of the hip. It is a powerful hip flexor and recurrent kicking actions can lead to an overuse injury. This is seen typically in dance but may also occur in football. The athlete complains of groin pain while examination findings include pain on iliopsoas stretch and on resisted hip flexion. Treatment consists of rest from kicking movements and reconditioning of the iliopsoas.

A bursa lies adjacent to the tendon insertion into the lesser trochanter. This can sometimes get inflamed and swollen. Symptoms and signs are similar to iliopsoas tendinopathy. Treatment includes image-guided aspiration and injection of the bursa.

**The ‘snapping hip’ syndrome**

The snapping hip syndrome is a condition commonly seen in ballet dancers. It can be associated with pain and is most commonly due to the iliopsoas tendon as it passes over the anterior aspect of the hip (anterior snap). A less common cause in dancers is from the iliotibial band (ITB) as it passes over the lateral aspect of the hip (lateral snap). The anterior snapping hip can be confirmed on ultrasound assessment and usually responds to stretching exercises.

**Femoroacetabular impingement/labral tear**

See Chapter 7.16.

**Synovitis of the hip**

Sero-negative arthropathy typically occurs in the young adult population and may present as an isolated monoarthritis of the hip. Alternatively, hip involvement may be part of a more generalized arthropathy involving several large joints including the sacroiliac joints. The athlete will present with unilateral groin pain with limitation of movement of the hip. X-rays are usually normal but MRI may show evidence of both synovitis and bone marrow oedema. Treatment involves NSAIDs and possibly second-line agents. An image-guided steroid injection can be very effective especially in an isolated monoarthritis.

**Stress fractures (Box 7.15.3)**

**Inferior pubic ramus**

This occurs in distance runners, more commonly in females. The athlete will complain of groin pain and have localized tenderness. Early diagnosis can be made either by bone scan or MRI as changes occur within 48h whereas the plain x-ray may remain normal. Treatment involves rest from weight-bearing sport and correction of relevant biomechanical factors. The injury usually heals within 6 –8 weeks.

**Femoral neck**

This injury is relatively uncommon, occurring in weight-bearing sports usually following a period of increased training. The diagnosis is often missed in the early stages as there is usually an insidious onset of exertional groin pain, a symptom that has a wide differential diagnosis. Furthermore, examination findings are often non-specific (with pain at end-of-range on hip examination) while plain x-ray is normal for several weeks. Diagnostic delay is therefore quite common and unfortunately this can lead to extension of the fracture with associated complications. Early diagnosis requires a high index of clinical suspicion supported by further imaging (either MRI or bone scan).

**Box 7.15.3 Types of stress fractures**

- Inferior pubic rami—common in female runners
- Neck of femur—pain on training, end-of-range discomfort, MRI to diagnose if x-rays normal:
  - Tension fracture, operative fixation
  - Compression fracture, non-weight bearing for 8 weeks.
There are two types of fracture:

- **Tension fractures** occur on the superior surface and are prone to extend to a full fracture. These require urgent treatment with either early surgical fixation or strict bed rest.
- **Compression fractures** occur on the inferior surface and are more stable. These usually respond to a period of non-weight bearing for 6–8 weeks, followed by a rehabilitation period gradually working back to full activity, which can take a further 6–8 weeks.

**Apophyseal disorder/avulsion fracture of the rectus femoris**

This injury occurs during adolescence, typically associated with sprinting and kicking. It occurs at the site of attachment of the rectus femoris to the anterior inferior iliac spine. It usually responds to conservative treatment but surgical re-attachment is occasionally necessary.

**Lateral hip pain (Box 7.15.5)**

Lateral hip pain typically occurs in long distance runners. It is commonly attributed to trochanteric bursitis. However, with improved availability of MRI and ultrasound scanning it is relatively uncommon to find a bursal swelling as the cause of lateral hip pain in an athlete. The trochanteric pain syndrome is a more useful description of this problem.

**Trochanteric pain syndrome**

The athlete complains of pain, which tends to radiate down the lateral aspect of the thigh. The aetiology is probably due to a tight ITB as it passes around the greater trochanter. Occasionally this can cause a snapping hip. With time this leads to an irritation of the ITB, the adjacent soft tissues, or the bursa, which is then responsible for the pain. Treatment consists of ITB stretches, gluteal conditioning exercises, and sometimes a local cortisone injection. In recalcitrant cases, surgery involving lengthening of the ITB can help.

**Box 7.15.4 Causes of anterior hip pain**

- Sports hernia/osteoitis pubis
- Adductor muscle strain and tendinopathy
- Rectus abdominis strain
- Inguinal hernia
- Obturator neuropathy
- Iliopsoas bursitis/tendinopathy
- Femoroacetabular impingement
- Synovitis
- Stress fracture
- Apophyseal disorder and avulsion fracture of rectus femoris.

**Box 7.15.5 Types of lateral hip pain**

- **Trochanteric pain syndrome:**
  - Thought to be due to a tight ITB which then irritates the surrounding tissues
  - Non-surgical treatment is the mainstay; occasionally ITB lengthening needed

- **Gluteus medius tendinopathy:**
  - Tenderness around the greater trochanter
  - Treatment is non-surgical.

**Gluteus medius tendinopathy**

This is an increasingly recognized cause of lateral hip pain and tenderness around the greater trochanter. There may also be pain on stretching the gluteus medius. Diagnosis can be confirmed on either ultrasound or MRI. Treatment involves reconditioning exercises for the gluteus medius and, occasionally, image-guided injections.

**Buttock pain (Box 7.15.6)**
Referred pain from the lower back or sacroiliac joint is the most common cause of buttock pain.

### Box 7.15.6 Types of buttock pain

- **Sacroiliac joint pain**
  - Can be due to instability or inflammation
  - Responds to physical therapy and addressing the cause
- **Sacral stress fracture**: uncommon, resolves in 8–12 weeks
- **Piriformis syndrome**:
  - Compression of sciatic nerve due to trauma or overuse
  - Responds to physical therapy and injections; rarely surgery needed
- **Proximal hamstring tendinopathy/enthesopathy**: usually insidious onset, responds to stretching and strengthening
- **Apophysial disorders of the ischial tuberosity**:
  - Occurs in the adolescent athlete, treated with rest
  - Avulsion fracture of ischial tuberosity can occur and if widely separated may need surgical reattachment.

### Sacroiliac joint pain

Sacroiliac joint pain can occur as a result of instability or due to inflammation. It causes unilateral buttock and possibly low back pain, which can radiate into the groin and the region of the symphysis pubis. It can also radiate into the thigh. Injury to the joint can occur as a result of intensive weight-bearing exercise especially in an athlete with a leg-length difference.

Treatment should consist of analgesia, correction of any biomechanical issues, and physical therapy techniques, including stability exercises. Therapeutic steroid injections may have a role to play. Surgical stabilization is rarely indicated.

### Sacral stress fracture

This uncommon injury does occur in distance runners and has been reported in other sports including tennis and hockey. Risk factors include biomechanical abnormalities, such as leg-length difference. The athlete complains of low back and buttock pain sometimes radiating down the thigh. Diagnosis can be made on MRI. The injury usually resolves with rest within 8–12 weeks.

### Piriformis syndrome

Piriformis muscle overuse or trauma can give rise to symptoms as a result of its close anatomical relationship with the sciatic nerve. The sciatic nerve may be compressed or otherwise irritated by the piriformis muscle causing pain, tingling, and numbness in the buttocks and along the path of the sciatic nerve. Treatment involves physical therapy, analgesia, and avoidance of contributory activities. Injections or surgical decompression are needed if symptoms do not resolve with conservative therapy.

Occasionally there may be a strain of the piriformis, which can cause buttock pain. Diagnosis can be made with clinical testing. The condition responds to conditioning exercises.

### Proximal hamstring tendinopathy/enthesopathy

This injury typically occurs in sprinters as either a tendinopathy or as an enthesial injury at the attachment to the ischial tuberosity. It causes deep buttock and posterior thigh pain. Although it can come on acutely, it more commonly has an insidious onset. It can usually be diagnosed on physical examination and then confirmed on imaging. Most cases respond to physical therapy including mobilizations, stretching and strengthening exercises. Occasionally steroid injections or surgical release is required.

### Apophysial disorders of the ischial tuberosity

These occur in the adolescent athlete and present with proximal posterior thigh pain and tenderness with pain on testing the hamstring. Therefore they can often be mistaken for a proximal hamstring injury and treated inappropriately.

Apophysitis of the ischial tuberosity usually occurs as an overuse injury in early adolescence. Diagnosis can sometimes be made on x-ray but more obvious findings occur on MRI where bone oedema may be seen. Treatment consists of relative rest and gradual reconditioning of tight hamstrings.

### Avulsion fracture of the ischial tuberosity

Usually occurs as an acute injury in late adolescence. The fragment of bone should be visible on x-ray. Usually this injury will respond to conservative treatment over a 6–12-week period. However, if there is a wide separation of a large fragment then surgical reattachment may be required.

Summary points

- Avascular Necrosis
- Paget’s disease
- Transient Osteoporosis of the Hip.

Introduction

The pelvis and hip can be affected by a number of medical conditions, and it is important that orthopaedic surgeons are aware of these when considering a differential diagnosis in patients presenting with problems at these skeletal sites. This chapter will review and discuss the management of avascular necrosis and Paget’s disease, which are two common conditions affecting the hip.

Avascular necrosis

Regional interruption of blood flow to the skeleton can cause ischaemic (aseptic or avascular) necrosis. Ischaemia, if sufficiently severe and prolonged, will kill osteoblasts and chondrocytes. Clinical problems arise if subsequent resorption of necrotic tissue during skeletal repair compromises bone strength enough to cause fracture with deformity of bone, and secondary damage to cartilage (Box 7.16.2).

Box 7.16.2 Avascular necrosis

- Often associated with other conditions, commonly secondary to trauma, steroids, and alcoholism
- Commonest site is the femoral head; presents with pain, exacerbated by weight bearing
- Graded from 0–6
- Treatment varies from non-weight bearing, prostacyclin, and bisphosphonates in the earlier stages to surgical decompression and joint replacement in later stages.

Epidemiology

There is little accurate data on the incidence of osteonecrosis, although it is estimated there are approximately 15,000 new cases per year in the United States. The disease appears to occur more frequently in males than in females, with the overall male to female ratio being 8:1. The age of onset is variable, although the majority of cases are less than 50 years of age. The average age of female cases is, on average, 10 years older than male cases.

Pathogenesis

Osteonecrosis is often seen in association with a variety of different conditions (Box 7.16.1). Trauma with fracture of the femoral neck interrupts the major part of the blood supply to the head and may lead to osteonecrosis. Glucocorticoids and alcoholism are two important factors known to predispose to osteonecrosis.

OMIN, Online Mendelian Inheritance in Man database

The occurrence of disease in twins and a clustering of cases in families suggest a genetic basis to idiopathic osteonecrosis of the femoral head. Increased incidence of osteonecrosis in specific animal models also provides further evidence of the existence of susceptibility genes. In sporadic cases of osteonecrosis of the femoral neck, a number of genetic association studies have been conducted, linking specific genes to the pathogenesis of disease. The majority of the studies have, to date, focused on gene polymorphisms affecting the coagulation and fibrinolytic system. Genetic mutations have recently been identified in three families with osteonecrosis and dominant inheritance. Mutations in the type II collagen (COL2A2) gene (mapped on chromosome 12q13) proved to be the genetic cause of the disease. Type II collagen is the major structural protein in the extracellular matrix of cartilage.

Clinical features

The clinical presentation depends on many factors, including the age of the patient, anatomical site of involvement, and the extent and severity of this involvement. The femoral head is the most common location for the development of osteonecrosis, although it may also occur at other sites including distal femur, humeral head, wrist, and foot. Patients may develop pain that can persist for weeks to months before radiographs show any change, although patients can be asymptomatic. Avascular necrosis at the hip classically will present with pain in the groin, although this can be referred to the buttock, thigh, or knee. The pain is exacerbated by weight bearing but can also be present at rest. Gait may be affected and patients can present with a limp. Once the femoral head has begun to collapse, range of hip movement will be reduced and leg shortening may develop.

In osteonecrosis of the hip, involvement of the contralateral hip is present in 30–70% of cases at the time of first examination. Within 3 years of diagnosis, more than 50% of cases will have progressed in the contralateral hip to such a stage where surgical intervention is required.

Radiological features

In the earliest stages of the disease, plain radiographs will be normal. Magnetic resonance imaging (MRI) is useful to detect early pathological changes. The most characteristic image is a margin of low signal on T1- and T2-weighted images, and is observed in 60–80% of cases. Radionuclide isotope bone scans and computed tomography (CT) can also be used in cases where MRI is either contraindicated or has been inconclusive. Osteonecrosis can be staged according to the sequence of the radiological changes. These are detailed in Table 7.16.1 and shown in Figure 7.16.1.

Fig. 7.16.1
Radiological changes in hip avascular necrosis. A) Area of subchondral hyperlucency (arrows)—the crescent sign. B) MRI showing an area of avascular necrosis present in the subarticular location of the left femoral head. There is artefact obscuring the right hemipelvis due to previous prosthetic replacement. C) AVN affecting the right hip with signs of previous decompression. A left Birmingham mid-head resurfacing arthroplasty has been performed for AVN on the left hip. D) Stage 4 AVN: radiolucent and sclerotic changes involve most of the femoral head, with flattening of the articular surface. E) Stage 5 AVN: sclerosis, lucency, flattening of the articular surface, and narrowing of the joint space right hip. F) Stage 6 AVN with joint destruction right hip.

Laboratory findings
In idiopathic osteonecrosis, laboratory investigations will generally be normal. Investigations may reveal potential contributory factors such as connective tissue disease, diabetes, hyperlipidaemia, and gout.

Histopathological examination of tissue from affected bone is consistent with the pathogenesis that is suggested from the radiographical examinations. It shows that these various processes of skeletal death and repair are focal, and may be occurring simultaneously.

Differential diagnosis
In stages 3 and 4 of the disease, the radiological features of the disease are specific. In the later stages 5 and 6, a differential diagnosis is not necessary as by this stage the bone and joint have been irreversibly damaged and the only treatment option would be joint replacement. In the earlier stages of the disease (1 and 2), other diseases of bone, cartilage, and synovial tissue should be considered in the differential diagnosis.

Treatment
Medical treatment includes non-weight bearing for osteonecrosis affecting load-bearing bones. This may be for 4–8 weeks. Vasoactive drugs such as prostacyclin may play a role in early stages of osteonecrosis. Bisphosphonates have also been shown to be effective in the treatment of osteonecrosis. Data has been observed for alendronate and more recently for zoledronate.

Surgical treatment for osteonecrosis involves core decompression. This reduces the intramedullary pressure within the ischaemic bone, and has been postulated to improve circulation. The outcome from core decompression at the femoral head, with regards to resolution of radiographic changes and improvement in symptoms, varies from 34–96% in the early stages of the disease. These results appear better than continuing with conservative measures such as non-weight bearing. In the later stages, joint replacement is often necessary. Box 7.16.2 summarizes the key points relating to osteonecrosis.

### Transient osteoporosis of the hip (Box 7.16.3)

This is a rare, self-limiting disorder. It can present idiopathically or may be seen in the third trimester of pregnancy. The cause is unknown, although it is thought to be related to local factors rather than a systemic cause.

Patients will present with unilateral or bilateral hip/groin pain. In some severe cases the condition can progress to hip fracture. In a small minority of cases the condition can migrate to affect either the contralateral hip or another skeletal site. There is evidence of radiological osteoporosis, assessed either with plain radiographs or dual energy x-ray absorptiometry (DXA). MRI demonstrates evidence of marrow oedema within the femoral head and/or neck (Figure 7.16.2). A joint effusion may also be present. The features may be similar to those for avascular necrosis.

**Box 7.16.3 Transient osteoporosis of the hip**

- Rare, self-limiting. Can be idiopathic or associated with third trimester of pregnancy
- Presents with hip/groin pain and occasionally may fracture
- Diagnosed with plain radiographs, bone scan, or MRI
- Non-surgical treatment with non-weight bearing or bisphosphonates

![Click to view larger](https://example.com/image.png)

**Fig. 7.16.2**

The symptoms and the radiological features will generally resolve within 6–9 months. Patients may be managed with non-weight bearing if there is thought to be risk of hip fracture. Bisphosphonates have been shown to accelerate recovery in some patients.

### Paget's disease

Paget's disease is the second most common metabolic bone disease in the United Kingdom. It was first described in 1877 by Sir James Paget (7.16.4).

**Epidemiology**

The disease rarely becomes clinically evident before the age of 40 years, and shows an exponential increase in prevalence with
age. Overall, the disease prevalence in the United Kingdom is estimated at 5% in those aged 55 years and over, rising to upwards of 10% in those aged 95 years. Recent epidemiological data suggest that over the last 20 years there has been a decline in both the incidence of the disease and its severity. The cause for this decline is not apparent, but suggests a possible environmental agent as an important activator in the disease process. Most studies have reported a slight sex bias, with men affected slightly more frequently than women, with ratios ranging from 7:6 to 2:1.

Pathogenesis

Paget's disease is a focal disorder of bone metabolism, primarily due to an increase in osteoclast-related bone resorption. The increased bone resorption is coupled with a vigorous osteoblastic response which causes abundant new formation of bone, in association with increased vascularity. The newly formed bone may be woven or lamellar in type (usually with abnormal spatial orientation), lacking the structural organization of the normal trabeculae and hence having greater flexibility and less resistance to deformation. Paget's disease is also usually associated with local enlargement of bone, suggesting that abnormal modelling is also involved in the disease process. The combination of structural and architectural bone abnormalities, in conjunction with biomechanical forces, accounts for the majority of the disease's clinical manifestations and complications.

The initial stimulus for increased bone turnover is unknown. Many studies have suggested a possible viral aetiology for Paget's disease, as pagetic osteoclasts have been found to contain paramyxoviral-like nuclear inclusions. The measles virus and the canine distemper virus have been implicated as the paramyxovirus present in pagetic osteoclasts and their precursors, although to date the viral material has not been isolated and their role in disease pathophysiology remains controversial.

Paget's disease has been demonstrated to have a familial tendency, suggesting a possible genetic cause for the disease. In patients with Paget's disease, 30–40% have been shown to have a first-degree relative similarly affected. In addition, several pedigrees have been identified where Paget's disease appears to be segregating as an autosomal dominant trait. To date, mutations or polymorphisms have been identified in four genes that cause classic Paget's disease or related syndromes. These genes include TNFRSF11A which encodes RANK, TNFRSF11B which encodes OPG, VCP which encodes p97, and SQSTM1 which encodes p62.

Clinical features

Paget's disease can have a wide spectrum of clinical presentations, ranging from asymptomatic to painful, disabling, and, very rarely, life threatening. In the majority of cases (greater than 80%), however, the disease is asymptomatic and is only diagnosed on the basis of an isolated increase in serum alkaline phosphatase or on classical radiological appearances following imaging. The clinical presentation of the disease is also dependent on the skeletal sites affected by pagetic lesions and their activity. Although any part of the skeleton may be affected, most commonly involved bones are the pelvis, femur, lumbar spine, skull, and tibia. The complications arising from Paget's disease can be attributable to local factors and to systemic factors. These are summarized in Table 7.16.2.

The most frequent symptom in patients with Paget’s disease is bone pain. It has been suggested that this symptom is due both to increased vascular supply and to periosteal stretching caused by local bone growth. Pagetic pain is classically described as insidious and boring in nature, not usually aggravated by movement, and only progresses slowly. Sometimes, the pain also coexists with bone deformity and enlargement. In some cases it is difficult, however, to differentiate between pain due to Paget’s disease and that due to secondary osteoarthritis and degenerative disease. Primary bone pain must also be differentiated from pain associated with certain complications of great clinical significance, i.e. fractures and sarcomatous change.

Painful fissure fracture (or pseudofracture) and complete pathological fracture occur in areas of high mechanical stress, particularly in the weight-bearing bones of the lower limbs. Fractures in pagetic bone usually follow very minimal trauma. The great majority of these are located in the subtrochanteric region or shaft of the femur, and, less often, in the upper third of the tibia. Occasionally they are also seen at other sites such as the forearm, humerus or pelvic brim. Prolonged immobilization should be avoided following fractures in patients with Paget’s disease as it can accelerate bone loss (leading to osteoporosis and an increased fracture risk) and can provoke hypercalciuria and hypercalcaemia.

Sarcoma arising in pagetic bone is the most serious complication of the disease, although is a rare event affecting fewer than 1% of Paget’s patients. Sarcomatous change should be suspected when severe pain of sudden onset arises in bone known to have been previously affected by the disease. Such pain is usually unresponsive both to analgesics and medical therapy aimed to suppress pagetic disease activity. Other clues pointing towards a possible sarcoma include swelling at the site of the tumour, which may enlarge rapidly, and a significant rise in the serum total alkaline phosphatase. At present, the prognosis for patients with Paget’s disease who develop sarcoma is poor with neither chemotherapy nor radical surgery having any significant effect on long-term survival.

Radiological features (Figure 7.16.3)

Plain radiographs are normally sufficient to make a diagnosis of Paget’s disease. Additional investigations that may be required include isotope bone scan, CT, and MRI.

Laboratory findings
The main biochemical abnormality in Paget’s disease is an increase in the serum total and bone-specific alkaline phosphatase (ALP). The extent of the increase in the ALP is proportionate to the number of skeletal sites involved, and in some patients with mild disease where there is little skeletal involvement the ALP may be normal.

In cases where the diagnosis is not clear, bone biopsy is indicated.

**Differential diagnosis**

The differential diagnosis includes osteomalacia, osteitis fibrosa, fibrous dysplasia, fibrogenesis imperfecta ossium, and metastatic bone disease.

**Management**

Historically medical treatment for Paget’s disease has been reserved for the symptomatic management of pain in patients with active disease, or as an adjunct to surgery in those with serious complications (i.e. spinal cord compression). There are now a number of available therapies which have been successfully used to suppress abnormal osteoclast activity and control bone turnover. The treatment of choice would now be a bisphosphonate. With the advent of these agents, there is now a move to treat the disease earlier in either patients whose disease is only mildly active or in those who are asymptomatic. It remains unclear, however, whether this aggressive treatment of Paget’s disease to normalize disease activity (as assessed by serum alkaline phosphatase or radionuclide imaging) will result in fewer long-term complications.

**Surgical management**

Surgery may be necessary for patients with severe complications, as highlighted earlier. The more common indication for surgery is in patients with secondary osteoarthritis who have pain that is not adequately controlled with conventional medical therapies. In these circumstances, total joint arthroplasty at both the hip and knee has been shown to be effective and safe in patients with Paget’s disease. There has been concern that the operative procedures may be more difficult with surgery involving pagetic bone, and although not evidence based, many patients receive bisphosphonates treatment preoperatively in an attempt to suppress disease activity and reduce local complications. This area of practice requires further evaluation. In addition, although there has been long-term (between 5–10-year) follow-up of Paget’s patients undergoing total hip arthroplasty, only limited data is available for those with total knee arthroplasty and again research is needed in this area. Most of the reported studies regarding surgical outcome have also focused on specialist centres, and it remains to be determined if outcomes are equivalent at other less specialized orthopaedic units.

---

**Fig. 7.16.3**

Radiographic features of Paget’s disease: sclerosis, coarse trabeculae, and remodelled cortices. A) Involving the pelvis and proximal femora; features of osteopetrosis also noted and pathological right femoral shaft fracture (internally fixed). B) Tibia with typical Paget’s deformity. C) Tibia with residual Paget’s proximally and below-knee amputation following sarcomatous change.

**Box 7.16.4 Paget’s disease**

- Paget’s is a focal disorder of bone metabolism
- Primarily due to an increase in osteoclast-related bone resorption, coupled with a vigorous osteoblastic response causing abundant new bone formation in association with increased vascularity. Abnormal remodelling is also involved, leading to a combination of structural and architectural bone abnormalities
- Often asymptomatic and found incidentally. Common sites are the pelvis, femur, lumbar spine, skull, and tibia. Commonest symptom is pain
- Diagnosed radiographically often, and with raised ALP
Treated with bisphosphonates; surgery directed towards the complications of Paget’s.

Hip pain in the radiologically normal hip

Summary points

- Patients who present with hip pain can have multiple origins of pathology—this may be intra- or extra-articular in origin
- In the majority, a definable diagnosis can be obtained through a detailed history, examination, and subsequent radiological evaluation
- However, there remains a group of patients who have intractable hip pain without a definitive diagnosis despite extensive non-invasive radiological investigation.

History

A detailed history is vital in the assessment of hip pain. Any history of trauma and the mechanism of injury should be noted. Overuse of the hip or an abrupt change in the level of activity may point towards a musculotendinous injury. Previous muscle strains or other injury should be documented.

The site, nature of the pain, location, duration, frequency, pattern, or radiation of pain should be recorded. The onset may be acute or insidious. There may be positions or activities which exacerbate the pain. There may be loss of function with inability to participate in certain activities or pain with sitting for prolonged periods.

The site of the pain can be an important indicator of its source. It aids in differentiating intra-articular pain from extra-articular pain (Table 7.17.1).

Mechanical symptoms may be present. This also helps in not only differentiating intra-articular and extra-articular pathology but also inflammatory conditions which tend to have pain at rest and multiple joint involvement. The snapping hip is discussed in the “Coxa saltans” section. Pinching or clicking may indicate a labral tear. A pop may be heard with an acute tendon injury. A change in sensibility or weakness in the leg may indicate pressure from an intervertebral disc. Relevant occupational and recreational history is important. Certain sports such as football, marathon running, gymnastics, and rugby have been associated with an increased incidence of degenerative hip disease.

A drug history should include amount of alcohol consumption and use of corticosteroids. Past medical history should enquire about the presence of any connective tissue and chronic inflammatory conditions as well as any history of carcinoma. Red flag symptoms include weight loss, fatigue, fever, or loss of appetite. Sepeis must be excluded. Abdominal and pelvic pathology such as appendicitis, prostatitis, and gynaecological conditions may masquerade as hip pain and should be considered.
Examination

Thorough examination of the hip should include examination of the lumbar spine and ipsilateral knee to rule out referred pain. Perform a full neurological examination of the lower extremities with assessment of sensation and motor power. Pain on resisted range of movement suggests a muscular or tendinous injury. Muscle weakness and altered sensation may be identified with nerve root compression. Straight leg raise and the sciatic stretch test may exclude referred radicular pain.

Investigation

**Blood tests**

Primary investigation of hip pain includes blood tests, including inflammatory markers.

**Plain radiographs**

A plain x-ray (anteroposterior and lateral) will exclude in the majority osteoarthritis, fracture, or avascular necrosis. The frog lateral radiograph is extremely useful in diagnosing and assessing the extent of avascular necrosis. Plain radiographs are unreliable in the diagnosis of un-mineralized loose bodies, labral tears, or chondral lesion. The signs of femoroacetabular impingement (FAI) are subtle and may also be missed.

**Ultrasound**

An ultrasound scan can be used to detect fluid within the joint, thickened or torn tendons, or fluid-filled bursae. Dynamic ultrasound can be used to find the source of a snapping hip, particularly a snapping iliopsoas tendon.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) will demonstrate tendon thickening. Labral tears can be seen with the injection of contrast and are most reliably seen on the axial slices. In the presence of inflammation (iliopsoas and/or trochanteric bursitis or gluteus tendon tears) or fluid, there may be high signal intensity on T2 scans. Both ultrasound and MRI can be used to help guide injections. MRI of the lumbar spine may exclude radicular causes of pain.

MRI and bone scans are indicated for suspicion of stress fractures in athletes and can aid the diagnosis of degenerative conditions and tumours.

**Examination under anaesthesia**

If still in doubt, examine under anaesthesia, assessing range of movement. A dynamic arthrogram is useful to assess congruency and stability. Intra-articular injection of local anaesthetic may help differentiate between intra-articular and extra-articular hip pain. Local anaesthetic and steroid injections into the trochanteric and iliopsoas bursa are useful diagnostic tests and potentially therapeutic benefit.

Electromyogram studies may be useful in the assessment of extra pelvic compression of sciatic nerve.

Differential diagnosis

**Labral tears**

The diagnosis of a labral tear can be made on a clinical basis. Symptoms of a labral tear are analogous to those who present with meniscal tear.

The history may be of an acute traumatic event or related to overuse, especially in athletes. The pain may be positional or induced with activity that fails to relieve with rest. There may be an associated feeling of instability. Patients describe catching and painful clicking of the hip with restricted range of movement. Clicking can often be misdiagnosed as a snapping iliobibial or hypermobile psoas tendon.

FAI may predispose to labral tears. It is a common cause of hip pain in young adults. Morphological abnormalities of the hip result in abnormal loading and impingement. X-rays may appear normal at first, or there may be the presence of an acetabular subchondral cyst. The impingement test (flexion, adduction and internal rotation—FADIR test) is almost always positive. However, a negative FADIR test does not exclude a labral tear. A dynamic arthrogram will demonstrate impingement and labral tears in the majority. A magnetic resonance arthrogram (MRA) will also demonstrate a labral tear in the majority of cases.

**Coxa saltans**

Coxa saltans is described as external, internal, or intra-articular. The external type is the commonest. Outside of the hip joint a tight iliobibial band (or the anterior border of gluteus maximus) can cause an audible or palpable snap as it translates forward over the greater trochanter in flexion or adduction of the hip. A tight iliobibial band can also be demonstrated with the Ober test: with the patient lying on the unaffected side, passively abduct the upper leg and flex the knee to 90 degrees. Slightly extend the hip, and observe if the hip drops into the adducted position. Decreased adduction is a sign of tightness in the tensor fasciae latae and/or the iliobibial band.
Internal causes of coxa saltans are less common. The psoas tendon is felt to snap as it moves over structures located behind it. These include the iliopsoas muscle, the anterior inferior iliac spine, and, in some cases, the femoral head or prominent acetabular components following total hip replacement surgery.

Intra-articular causes of the snapping hip include loose bodies and labral tears or synovial chondromatosis.

The snapping hip can be voluntary and painless but may be painful especially with repetitive movement such as dancing or sport. There is an audible, palpable, and sometimes visible snap, usually as a muscle or tendon moves over a bony prominence. It is more common in the young athlete and women are more commonly affected than men. Athletes whose sport involves repetitive twisting about the hip have been identified as being particularly prone to develop a clicking hip.

**Bursitis**

The bursae are fluid-filled sacs lined with a membrane similar to synovium. They may be normal, in areas where soft tissues are found to move over bony prominences, or they may develop as a result of repeated trauma. They serve to protect tissues from friction or pressure. Independently they are susceptible to acute or chronic inflammation and infection but may also commonly be involved in inflammatory conditions of an underlying joint.

Inflammation of the trochanteric bursae, separating the gluteal muscles from the greater trochanter, is a common cause of lateral hip pain. There may be visible swelling and tenderness over the prominent greater trochanter.

The iliopsoas bursa lies posterior to the iliopsoas muscle. It is the largest bursa of the hip. Inflammation may result in anterior hip pain with resistance to extension. There may be a palpable mass. Mild bursitis can cause a snapping hip syndrome (see earlier).

On T₂-weighted MRI scans, high signal may be seen in the presence of fluid within the trochanteric or iliopsoas bursae.

**Tendonitis and muscle strains**

Injuries to musculotendinous units usually occur with overuse (repetitive activity) or overload (sudden increase in activity). Symptoms can vary depending on the severity of strain or inflammation present.

Predisposing factors include abrupt change in level of activity, poor warm up, or a history of previous strains. These injuries can become chronic if not treated early and are significant causes of disability for athletic individuals.

A strain of the rectus muscle usually occurs in its middle third. There is pain and swelling over the anterior thigh with tenderness but little functional loss. Ecchymosis may be seen.

Gluteus medius syndrome is often seen in women who start vigorous walking or a new exercise programme. There will be tenderness over the insertion of gluteus medius and in severe cases a Trendelenburg gait. Gluteal tendinitis can be difficult to differentiate from a trochanteric bursitis. Resisted abduction will elicit pain in the gluteus medius tendon and, if still in doubt, an ultrasound or MRI scan can exclude fluid in the bursal sac.

Adductor strains are commonly seen in athletes. Following rapid deceleration or strong eccentric contractions of the muscle during activities such as kicking, a pop is heard and there is immediate pain and disability. Adductor longus is commonly affected. Pain is felt on palpation of muscle belly or over its insertion and on resisted contraction. Strains of the hamstring muscles occur with acceleration injuries, seen with sprinting or court sports.

Avulsion fractures around the pelvis occur in prepubertal athletes as a result of an actively contracting muscle encountering abrupt resistance such as a misstep, rapid acceleration, or eccentric movements.

**Piriformis syndrome**

Piriformis syndrome is usually a diagnosis of exclusion. It is a rare cause of posterior hip pain and it can be confused with sciatica. It often presents with intolerance to sitting and numbness and tenderness over the sciatic notch. Pain may be reproduced by bringing the hip into maximum flexion and internal rotation.

Blunt trauma is thought to result in haematoma formation and scarring between the muscle and the closely-related sciatic nerve. Branches of the nerve may in some cases pass through piriformis muscle resulting in further compression of the nerve on internal rotation.

There are six classical findings: trauma to the sacroiliac and gluteal region; pain in the region of the sacroiliac joint, greater sciatic notch, and piriformis that extends down the leg; exacerbation of pain with stooping or lifting; a palpable sausage-shape mass over piriformis muscle; positive straight leg raise; and gluteal atrophy depending on the duration of symptoms.

**Management**

Labral tears are increasingly managed by hip arthroscopy. The tears can either be debrided or repaired. Similarly, loose bodies can be removed arthroscopically in the majority. In the presence of FAI, debridement of either the acetabular rim and or the head-neck junction can be undertaken arthroscopically or, less commonly, via a mini open approach.

Snapping hip is usually painless and this can be managed by providing an explanation reassurance to the patient. In cases where the patient complains of pain, most respond to behaviour modification, physiotherapy with stretching exercises, and non-steroidal anti-inflammatory drugs (NSAIDs). In individuals who fail to respond to this treatment, a combination of local anaesthetic and
steroid injection into the underlying trochanteric or iliopsoas bursa may be helpful. If symptoms are recurrent and painful, surgery can be undertaken either arthroscopically or via open surgery.

The management of bursitis includes rest, alteration in activity, and NSAIDs. There is often good response to aspiration and injection of steroids. In chronic cases, excision of the thickened bursa may be necessary. This can be undertaken either arthroscopically or via open surgery.

Tendonitis caused by overuse or overload injuries usually respond well to relative rest, ice, and anti-inflammatory medications. Use of orthotics may be beneficial where there are mechanical abnormalities, such as leg-length inequality or foot abnormalities. Muscle imbalance should be treated with appropriate flexibility and strengthening exercise programmes. Increasing joint flexibility and muscle strengthening exercises will prevent the risk of future injury.

The treatment of smaller avulsion fractures is similar to the treatment of strains of the muscle–tendon unit. Large avulsion fractures may need to be internally fixed.

Initial management of piriformis syndrome should again be conservative with stretching, physiotherapy, and NSAIDs. Some may respond to transrectal massage or electrical stimulation. Surgery in non-responsive cases involves release of the tendon and lysis of adhesions surrounding the nerve.

Summary points

Learning objectives:
• Understand hip arthroscopic anatomy
• Awareness of indications and contraindications for hip arthroscopy
• Understand what femoroacetabular impingement (FAI) is, and how to investigate and treat this condition

Assessment: FADIR and FABER tests

Investigations: plain x-ray, magnetic resonance imaging/arthroscopy, computed tomography scan in Pritchard O’Donnell (POD) position

Interventions: central and peripheral compartments, periarticular space, lateral compartment, FAI correction—cam, pincer, or combined.

Introduction

The development of arthroscopic surgery to the hip joint has been slow for two reasons. Firstly, the hip is relatively difficult to access. Secondly, unlike the knee, shoulder, and abdomen, open procedures were not routinely undertaken on the hip so there was nothing to be superseded by arthroscopic techniques.

Arthroscopic examination of cadaveric hips was first described by Burman in 1931. Until 2003, hip arthroscopy was a procedure undertaken by enthusiasts to diagnose synovial pathologies, to remove intra-articular loose bodies, to resect damaged labral tissue, to debride damaged ligamentum teres ligaments, and to debride joints with early to moderate degenerative disease. Since the publication of Ganz’s work on femoroacetabular impingement (FAI), orthopaedic surgeons have developed both open and arthroscopic strategies to address the damage caused by these mechanisms. With growing recognition of the efficacy and benefits of these interventions it has also become apparent that arthroscopic interventions achieve comparable outcomes, with less morbidity. In consequence, the orthopaedic community is gaining interest in learning and undertaking arthroscopic hip surgery.

As with all developing technologies, subdivision is inevitable. In the case of the hip, three distinct areas of intervention have evolved. These are:

1) The hip joint (central and peripheral compartments)
2) The periarticular space (ilio psoas tendon and periarticular structures)
3) The lateral compartment (trochanteric regions).

Arthroscopic anatomy

From the hip arthroscopist’s perspective, the hip joint comprises central and peripheral compartments which are separated by the acetabular labrum (Figure 7.18.1). The central compartment can only be visualized when the bearing surfaces are separated through application of traction and fluid insufflation. While much of the peripheral compartment can be visualized while the hip is distracted, it is only after removal of traction and re-erlocation of the femoral head that joint movement can be visualized, FAI verified, and confirmation obtained that interventions have been effective.

The lateral compartment is deep to the tensor fascia lata. Arthroscopic access to this space allows visualization and interventions to the trochanteric bursa and gluteus medius and minimus tendons.

Indications, surgical techniques, and instrumentation for arthroscopic hip surgery are evolving and improving rapidly. To date, the majority of articles on hip arthroscopy provide anecdotal information, case reports, or results of short-term outcome studies. As yet, relatively few medium- and long-term outcome studies are available.
Indications for hip arthroscopy

Current indications for hip arthroscopy include: the presence of symptomatic acetabular labral tears; FAI; chondral lesions; osteochondritis dissecans; ligamentum teres injuries; snapping hip syndrome; iliopsoas bursitis; unexplained symptoms post-hip replacement; and removal of loose bodies.

Less common indications include: management of osteonecrosis of the femoral head; synovial abnormalities; crystalline hip arthropathy (gout and pseudogout); infection and post-traumatic haematomas; and intra-articular debris.

Some hip arthroscopists have noted that the symptoms of mild-to-moderate hip osteoarthritis can be temporized, particularly when peripheral osteophytes are causing mechanical symptoms. The benefit and duration of improvement are variable and these interventions require further evaluation.

Contraindications to hip arthroscopy

Conditions that limit the potential for hip distraction may preclude arthroscopy. These include: advanced osteoarthritis; osteonecrosis with femoral head collapse; significant protrusion; grade III or IV heterotopic bone; and joint ankylosis.

Types of impingement

Two distinctive types of FAI are recognized. 'Pincer impingement' occurs as a result of anterior overcoverage of the acetabulum or acetabular retroversion. 'Cam impingement' occurs when a non-spherical femoral head abuts against the anterior acetabulum, usually with the hip in flexion. In practice, it is common to see a mixed cam and pincer pathology, occurring along the anterior femoral neck and the anterior–superior acetabular rim.

Clinical presentation

Patients with hip impingement typically present with pain deep to the anterior portion of the tensor fascia lata muscle. In cases where cam impingement predominates, symptoms are often precipitated by prolonged upright sitting and internal rotation movement in flexion. Where pincer-type impingement predominates, abduction and external rotation movements may be more troublesome. A significant proportion of female patients with impingement will report exacerbation of their symptoms during sexual intercourse. Athletes, sportspeople, and dancers typically describe pain on training and early fatigue. These symptoms will improve with rest but always recur on resumption of exercise.

Clinical examination findings

A standard examination of the hip joint will often reveal asymmetric ranges of movement and evidence of irriatability. Cases of cam impingement typically show reduced internal rotation of the hip in flexion. This may be bilateral. In cases of pincer-type impingement, ranges of movement may appear normal but with pain towards the extremes of movement.

Specific tests for impingement are:

- **FADIR test** With the hip in high flexion, adduction, and internal rotation (FADIR), abutment and impingement of the labrum and cartilage occurs. The reproducibility of this examination technique has been reported with a kappa value of 0.58 (95% CI: 0.29–0.87).
- **FABER test** With the hip in flexion, abduction, and external rotation (FABER), abutment of the abutment of the labrum and cartilage also can occur. The reproducibility of this examination technique has been reported with a kappa value of 0.63 (95% CI: 0.43–0.83).

Investigations

Plain radiographs

The first imaging study that should be requested is for plain x-rays of the hips. These should comprise an AP standing view of both hips, a standard lateral of the affected hip, and a cross-table true lateral of the affected hip. The AP view should be assessed both for degenerative changes and also evidence of the cam type deformity shown in Figure 7.18.1A and the profunda socket shown in Figure 7.18.1B, as well as the cross-over sign, indicating a prominent anterior acetabular wall, or acetabular retroversion.

The standard lateral view will reveal subchondral sclerosis and early subchondral cyst formation of the anterior acetabular rim and the cross-table true lateral will profile cam deformity or lack of concavity of the anterior head neck junction (Figure 7.18.1C).

Magnetic resonance arthrography

Where labral pathology is suspected, magnetic resonance (MR) arthrography is the preferred investigation. While these scans will show articular cartilage thinning, the contrast will seldom penetrate beneath delaminating articular cartilage and the extent of peripheral articular cartilage instability may be underestimated.
Alpha angles

Notzli and colleagues compared MR images obtained in 39 patients with FAI with MR images obtained in 35 asymptomatic control subjects. They measured the non-spherical shape of the femoral head–neck junction by measuring the alpha angle (see Figure 7.18.1) at the anterior position. The average alpha angle was 74 degrees in patients with FAI and 42 degrees in control subjects (P=0.001). A cut-off angle of 55 degrees was proposed to diagnose FAI.

Pritchard and O’Donnell computed tomography scan

Where the shape of the femoral head–neck junction needs to be assessed for the presence of a cam deformity, computed tomography (CT) three-dimensional surface reconstructions allow the lesion to be visualized and surgical resection planned (Figure 7.18.2A).

![Fig. 7.18.2](image)

A preoperative plan showing the marking out the bone for resection.

A new CT view has been developed by Pritchard and O’Donnell (the POD view) to demonstrate FAI lesions. Figure 7.18.3A shows an axial CT scan through the hip of a patient with a typical cam deformity. A fibrocystic impingement lesion of the anterior head–neck junction is seen but no evidence of joint space compromise. In Figure 7.18.3B, the same hip has been scanned in the POD position (patient supine with the hip flexed, adducted, and internally rotated). The scan reveals the impingement lesions and also confirms articular cartilage loss at the point of impingement.

![Fig. 7.18.3](image)

Treatment

Hip arthroscopy

Hip arthroscopy can be undertaken either in the supine or lateral decubitus position. Either the central or the peripheral compartment may be visualized first, and the use of an image intensifier may be used to facilitate portal placement.

To enter the central compartment the limb is placed in traction with the leg in abduction and slight forward flexion. To achieve
separation of the joint surface, traction must be applied in the direction of the femoral neck. This is achieved by combining a lateral force through the peroneal post in conjunction with a longitudinal force through the traction boot.

The force necessary for distraction is reduced by injection of saline into the joint. Most arthroscopy procedures can be completed via a viewing portal located just above the apex of the greater trochanter and an instrumentation portal 3–4cm more anteriorly. Additional portals can be created as required. An arthroscopic pump is used throughout to maintain constant distension of the joint with saline solution. A 70-degree arthroscope is used most commonly for central and peripheral compartment hip arthroscopy. A 30-degree arthroscope is useful for the lateral compartment and visualization of the distal iliosposas tendon.

**Femoroacetabular impingement surgery**

Arthroscopic recontouring of the non-spherical femoral heads seeks to eliminate trauma to the anterior acetabular margin and slow or prevent the development of osteoarthritis. Anterior acetabular wall overcoverage can be corrected by labral elevation, rim trimming, and labral repair. The arthroscopic approach minimizes postoperative morbidity and facilitates more rapid return to high-functioning lifestyles.

**Labral surgery**

Arthroscopic labral debridement has been reported as providing good or excellent results for two-thirds of patients with labral damage. Where reconstruction is viable, there is growing evidence that better outcomes are achieved with this treatment. However, if the underlying cause for labral damage is not addressed, any labral intervention will be followed by recurrence and progression of symptoms.

**Arthroscopy of the soft tissues around the joint**

**Iliopsoas tendinopathy and anterior soft tissue fibrosis after total hip replacement**

A minority of patients complain of persistent anterior hip pain after total hip replacement. Arthroscopic assessment and intracapsular release of the iliosposas can be helpful in such cases.

**Iliopsoas release at level of lesser trochanter if no periarticular tethering**

Snapping iliosposas tendon that is painful with no evidence of periarticular tethering can be treated by performing extra-articular arthroscopic psoas tenotomy at the level of the lesser trochanter.

**Arthroscopy in the lateral compartment trochanteric regions**

In the lateral compartment, tight or snapping iliotibial band, inflamed bursa, and gluteus medius and minimus tendinosis can all be treated arthroscopically. Gluteus medius sprains can be treated with coagulation and tears can be repaired with anchor sutures.

Trochanteric bursitis can be treated with arthroscopic bursectomy combined with fascia lata releases.

**Conclusion**

Hip arthroscopy has become established over the past 10 years. Recognition of FAI has been the principal driver for the development of this field of hip surgery. While these interventions can provide excellent symptomatic relief of symptoms, it remains to be seen whether the natural history of premature hip degeneration will be modified.

# Indications for hip replacement

**Summary points**

- Hip replacement is commonly performed as treatment of a multitude of degenerative hip disorders.
- Pain, stiffness, and loss of function remain the primary indicators of the need for hip surgery.
- As implant designs and surgical techniques have improved, the range of indications has expanded.
- Contraindications and risks must always be counterbalanced with the potential benefits.

## Introduction

Total hip replacement is one of the most successful of all elective operations in terms of symptomatic relief (Box 7.1.1). It provides long-term success: currently 90–95% implant survivorship is achieved to 10 years and 85% to 20 years. There are significant improvements in both joint-specific score measurements (such as the Oxford Hip Score) and more general measures of wellbeing (such as health-related quality of life, HRQOL). Improvements in movement and pain relief translate to improved activity levels and well-being. Younger patients demonstrate the most marked improvement in joint-specific and general health scores postoperatively but all groups show a significant improvement in physical and social function.

**Box 7.1.1 Epidemiology of total hip replacement**

- 1 million hip replacements worldwide in 2008
- 71 000 hip replacements in the UK in 2008
- 5% of individuals over 65 have hip osteoarthritis
- Women more commonly affected than men.

## Aetiology

Primary osteoarthritis remains the most common indication for hip arthroplasty (Table 7.1.1). Its use following fracture is becoming increasingly prevalent, either as an acute procedure at the time of a displaced subcapital fracture or as an elective procedure for secondary osteoarthritis. Inflammatory arthropathies and sequelae of childhood conditions expose a younger age group to hip replacement. Ankylosing spondylitis frequently presents with hip pain and should be considered in young male patients (Figure 7.1.1).

Johnstone and colleagues described the six most specific features of hip pathology which should be addressed by hip replacement; these are detailed in Box 7.1.2. The symptoms which are important to the patient are not always the same as the surgeon would imagine: leisure activities, sexual activities, and limb-length discrepancies are more important to the individual than surgeons recognizes (Box 7.1.3). See Box 7.1.4 for a summary of the indications for surgery.

**Box 7.1.2 The important aims of hip replacement**

- Pain relief
- Ability to work
- Increased level of activity
- Further walking capacity
- Satisfaction of the patient
- Physical examination parameters improved.

**Box 7.1.3 Surgeons’ rating of symptoms**

- Rest pain
- Night pain
- Pain with activity
- Functional impairment
- Decreased range of motion
- Osteoarthritis x-ray changes
- Impaired social contact.

**Box 7.1.4 Indications and contraindications for hip surgery**

- **Indications:**
  - Pain
  - Loss of function
  - Stiffness
  - Gait abnormalities

- **Contraindications:**
  - Sepsis (local or distant)
  - Neuropathic hip
  - Systemic comorbidity
  - Inadequate vascularity
  - Psychiatric illness.
Pain

This is usually the most prominent symptom of hip arthritis and the most significant indication for hip replacement. It begins with an intermittent ache which is related to activity and relieved by rest. The most common sites of pain are the groin, the anterior and lateral thigh, the buttock, and the knee. As the degeneration progresses, it tends to constancy, including pain at rest and pain waking the patient at night. Both surgeons and referring physicians agree that rest pain, night pain, and pain affecting activity are the most significant indications that a hip should be replaced.

Examination of an early osteoarthritic hip reveals pain on flexion and internal rotation, with reduced range of motion and pain on abduction following with further degeneration.

There is no valid point at which pain can be defined as necessitating hip replacement: the balance of benefits against risks is determined, on an individual basis, between surgeon and patient.

Loss of function

Functional deterioration is usually closely linked to pain. Even moderate hip degeneration can lead to difficulties with pedicure and putting on footwear. Advanced arthropathy frequently affects the ability to climb stairs, access public transport, or rise from a chair. Loss of function can lead to loss of work, reduction in social well-being, and, eventually, dependence upon higher levels of support without intervention. Hip arthroplasty produces functional improvement in all areas, whatever the hip pathology.

Stiffness

The extreme rigidity associated with ankylosing spondylitis is frequently relatively pain-free, even in complete ankylosis. The typical flexion hip deformities are extremely disabling and significant improvement is offered by hip arthroplasty.

A previous hip fusion, even when successful, often produces low back pain, contralateral hip arthritis, and ipsilateral knee arthritis. Hip replacement is successful, whether the arkylosis is surgical or spontaneous (usually as a result of infection). Most patients achieve relief of pain in adjacent joints and an improvement in walking ability, although the latter is dependent on the persistence of gluteal function in the operated hip.

Gait abnormalities

Limp is a common symptom and can be due to limb-length discrepancy, capsular contractions, muscle weakness, and pain. The use of walking aids is usually well tolerated but the majority of patients walk unsupported after primary hip replacement.

Radiographic changes

Joint destruction and clinical deterioration of hip function tend to go hand in hand. X-ray appearances alone are not used as indication for arthroplasty without clinical need. It is also possible that severe symptoms can coexist with mild radiological signs of wear. In these cases, the injection of local anaesthetic into the hip joint can be used diagnostically; it is safe and reliable. Temporary relief of symptoms predicts successful hip replacement, but failure of relief suggests an alternative diagnosis should be sought.

Contraindications to surgery (Box 7.1.4)

Absolute contraindications

The presence of joint sepsis is an inescapable contraindication to surgery. Presence of distant infection with systemic upset (hyperthermia or raised inflammatory markers) or active cutaneous infection overlying the affected limb also precludes surgery. Chronic infective processes should be dampened as much as is possible before surgery.

Relative contraindications

Extremes of age are frequently cited as relative contraindications to surgery. Hip replacement has expanded to both ends of the age range as it has proven successful. It is now undertaken from teenagers to centurions with success. Its potential benefits in youth must be weighed up against the likelihood of multiple revisions. However, it is now the operation of choice in patients with arthritis above closed physes, having displaced fusion and excision due to their inferior results. Similarly, improved anaesthetic techniques have improved survivorship amongst the elderly. In a population of patients operated on at over 85 years of age, survivorship to 5 years after surgery is over 50% and to 10 years is over 35%.

Obesity is no longer an absolute contraindication to hip replacement as several papers have shown equivalent results in patients with a body mass index (BMI) above 30 to those with a BMI below 30. In morbid obesity, BMI above 40, the surgery is lengthy and more difficult but results remain satisfactory.

Neuropathic arthropathy, usually secondary to diabetes, syphilis, or syringomyelia, is a very rare cause of hip pathology and has previously been seen as an absolute contraindication to hip replacement. Although associated with high rates of complications, it is amenable to hip replacement in cases of severe joint destruction associated with significant symptoms. Similarly, sequelae of cerebral palsy can be treated with hip replacement but are associated with high rates of loosening or dislocation. It is best reserved for ambulatory patients with unilateral hip involvement; non-ambulatory patients may achieve pain relief with arthrodesis.
Manual labour in younger patients is now possible after hip replacement. Return to work has been shown to be multifactorial, not just related to the type of work. Other factors include level of education, underlying illness, and the balance of social security benefits against work pay.

Significant medical comorbidity can be a relative contraindication: particularly poorly controlled diabetes, cardiac insufficiency, and respiratory failure. Cooperation between the patient, surgeon, physician, and anaesthetist is required to reach an informed decision. Similarly, local factors such as poor vascularity or soft tissue compromise can require input from vascular and plastic surgeons respectively in order to reach an informed decision as to whether hip replacement is advised.

Psychiatric disease, including dementia, should be evaluated to ascertain if the individual will be able to benefit from improved function and comply with basic postoperative requirements.

Further reading

Summary points

- History and examination of the knee are linked and specific examination is determined by the likely diagnosis indicated by the history.
- The 5 diagnostics groups are: Anterior knee pain; Traumatic injury to knee ligaments, meniscus, or other structures; Degenerative osteoarthritis; Inflammatory joint problem; and other problems.
- General examination of the knee is still required with the patient, walking, standing, sitting, and lying supine.
- Specific examination is targeted to 4 areas: The patello-femoral joint and extensor mechanism; Meniscal pathology; Ligament stability; and Arthritis. The pattern of signs elicited should lead to definitive diagnosis.

Introduction

Traditionally, examination of a joint involves the principle ‘look, feel, move’, but for the knee the order and sequence of examination changes, depending on the likely diagnosis suggested by the history. The history is key in detecting the characteristic patterns of symptoms that will direct examination. Specific direct questions may be needed to aid this process. This is not asking ‘leading questions’ but is rather ‘direct questioning’ and this helps focus the patient’s mind onto the specific symptoms and the examiner onto specific possible diagnoses.

In addition, the level of disability caused by the symptoms as well as patient expectations need to to be carefully elicited as this will have a significant bearing on the management plan.

This chapter on history and examination of the knee breaks down the process into three parts: history, general knee examination, and targeted knee examination.

History

Clinical presentation

The three key features when addressing a patient with a knee problem are:

- **The main symptom or symptoms**: pain, swelling, locking, or giving way.
- **Age of the patient**: younger age is more likely to be associated with a traumatic injury or anterior knee pain whereas older age usually indicates a degenerative arthritic process.
- **Mechanism of onset of problem**: onset associated with trauma indicates specific injury to the anatomical structures in the knee whereas gradual onset over time indicates a degenerative process.

Main symptoms

Pain

In principle, the site, nature, character, and severity of pain are determined by specific questions.

General questions

- **Location** (vague widespread suggesting patellofemoral source or more localized to medial or lateral joint line).
- **Nature** (sharp, burning, dull ache, etc.).
- **Exacerbating features** (activity related or at rest).
- **Pain radiation**.
- **Progress over time** (getting worse or better).

Specific scenarios

- **Pain on medial aspect of knee on deep squatting**: indicates a meniscal tear.
- **Joint pain radiating down leg**: indicates arthritic aching process.
- **Pain at rest**: usually indicates severe arthritis.

Principles of history taking
Examination of knee directed by the history
Accurate history taking will lead to five diagnostic groups:
• Anterior knee pain
• Traumatic injury to knee ligaments, meniscus, or other structures
• Degenerative osteoarthritis
• Inflammatory joint problem
• Other problem.

- Pain at night: indicates inflammatory cause
- Pain worse on sitting for prolonged periods or on climbing/descending stairs: indicates patellofemoral problems
- Pain in multiple sites: indicates either a generalized problem or may indicate inappropriate pain response.

Swelling
Swelling usually indicates that there is a significant problem in the knee.
General questions
• Relation to onset of symptoms (early or late)
• Exacerbating features
• Relieving features.
Specific scenarios
• Swelling occurring within four hours from pivoting injury: usually indicates torn anterior cruciate ligament
• Swelling occurring greater than 4h after twisting injury: usually indicates a meniscal tear
• Swelling with activity: usually indicates a degenerative process
• Localized hard swelling on lateral joint line after activity: indicates lateral meniscal cyst from tear
• Extra-articular swelling: indicates a bursa
• Non-specific onset: indicates an inflammatory problem
• A very tense and painful swelling following injury: usually means haemarthrosis and a more significant injury.

Locking
This means the transient inability of the knee to go out straight rather than difficulty in flexing the knee. It is important to distinguish this from pseudo locking from the patellofemoral joint or following medial collateral injury where extension is limited by pain.
General questions
• Exacerbating factors (squatting, twisting, etc.)
• Relieving factors
• Exact description of locking (asking the patient what they mean by locking)
• Permanently blocked or intermittent
• True meniscal locking or false patella catching.
Specific scenarios
• Intermittent locking of the knee relieved by shaking the leg or a trick manoeuvre: indicates a loose body
• Inability to fully straighten the leg at any time following trauma: indicates a meniscal tear, osteochondral fragment, or anterior cruciate ligament (ACL) stump blocking full extension
• Transient locking on standing: may indicate catching of the worn arthritic surfaces.

Giving way
Giving way can also be described as buckling, not trusting the knee or giving out.
General questions
• Movements associated with the giving way (pivot movements, straight line activities, or descending stairs)
• Description of giving way sensation (twisting knuckles sign or patella giving way)
• Relation to pain (twisting knuckles sign or patella giving way).
Specific scenarios
Rotational giving way mimicked by twisted knuckles: indicates ACL deficiency
Knee giving way on pivoting to one side and feeling of patella jumping: indicates patella dislocation
Knee giving way on squatting associated with medial pain: indicates meniscal tear
Knee giving way on stairs with falling over: indicates patella dislocation. With ACL type giving way the patient is usually able to catch themselves
Giving way after pain: usually due to quads inhibition associated with pain from the catching of worn surfaces.

Additional clinical features to elicit

Other specific detail is required to lead to an action plan and these include:

- Noises and sensations in the joint:
  - A feeling of something moving around indicates a loose body
  - A painful grating sensation indicates crepitus and possible damage to the joint surface
  - A thudding clunk usually indicates a meniscal tear catching in the joint.

- Severity of the symptoms in relation to lifestyle:
  - For the active individual this means sporting aims and desired activity levels
  - For the arthritic assessment this means walking distance, ability to climb stairs, pain at night, and interference with quality of life.

Conclusion of history (Box 8.1.1)

After taking the history then there should be a fairly good idea of the diagnosis or, if not likely diagnoses, then the main category of problem.

Essentially the patient will be in one of five categories:

- Anterior knee pain
- Traumatic injury to knee ligaments, meniscus, or other structures
- Degenerative osteoarthritis
- Inflammatory joint problem
- Other problem.

Examination

Examination starts with a general examination of the knee followed by specific examination to confirm a specific diagnosis that has been indicated by the history. The history and examination should lead to a management plan that may involve further targeted investigation or the initial stage of treatment.

General examination includes assessing the patient standing, walking, and lying supine, and includes active, passive, and provocative tests or movements. This should allow specific examination to concentrate on one of four areas (Box 8.1.2):

- The patellofemoral joint and extensor mechanism
- Meniscal pathology
- Ligament stability
- Arthritis.

Box 8.1.2 Principles of knee examination

- General examination:
  - Standing
  - Walking
  - Supine.

- Specific examination:
  - The patellofemoral joint and extensor mechanism
  - Meniscal pathology
  - Ligament stability
  - Arthritis.
General examination

Standing and walking

This includes general habitus, leg alignment, posture, change in alignment on walking, the presence of an antalgic hip gait, and muscle wasting. Looking at the leg starts as the patient walks into the clinic and takes into account their general demeanour, appearance, manner of walking, and mobility around the examination area. All these factors add information to the diagnostic equation.

Normal alignment, varus (bow-legged), or valgus (knock-kneed) alignment is noted and the presence of increasing deformity as a lateral or medial thrust on walking is also elicited (Figure 8.1.1).

[Image: Fig. 8.1.1 Lateral thrust of the knee on walking, indicating malalignment.]

Malalignment may also be rotational. Squinting patellae occur when the feet point forward but the knees squint towards each other representing abnormal femoral and tibial torsion. Isolated external tibial torsion may be noted if the patella points forward but the feet point outwards more than 10–15 degrees. There is clearly a wide range of what is normal and physiological varus or hyperextension, for example, may be a variant of normal.

Supine

Examination supine involves a combination of look, feel and move. In order to look properly we need to feel the knee aiming to detect and confirm specific appearances and problems.

- General inspection: this takes into account evaluating alignment, position of the knee, skin problems, scars, muscle wasting, bruising for site of trauma, and the manner in which the knee is held
- Presence of effusion: there may be obvious fullness of the knee or it is detected by the bulge test (milking fluid from the medial side via the suprapatella pouch into the lateral gutter and then stroking the lateral gutter with the back of the hand eliciting a bulge on the medial side) or the patella tap sign (squeezing the suprapatella pouch with one hand and balloting the patella [Figure 8.1.2])
- Fixed flexion deformity: the patient may hold the knee in a flexed posture indicating true locking or pseudo locking due to pain. The knee can be gently straightened to full hyperextension looking for any loss compared to the other side
- Range of movement (ROM): this will elicit how painful the knee is and therefore guide the remainder of the examination. In the obviously arthritic knee, ROM is the most important sign and palpation of tender points less so. By convention ROM is expressed by three numbers: passive hyperextension or recurvatum, active extension, and flexion, e.g. 5/0/135.
Specific examination

The patellofemoral joint and extensor mechanism

Inspection of the patellofemoral joint is initially best performed with the patient sitting with the leg flexed over the edge of the couch, noting the following features or signs:

- Position of the patellae: the patella normally faces forward and slightly up—higher indicates patella alta, lower indicates patella baja
- Position of the tibial tubercle: this should be directly inferior to the centre of the patella. Inspection gives a guide to the tibial tubercle trochlea groove (TT-TG) offset that is more formally quantified by computed tomography or magnetic resonance imaging scanning
- Patella tracking: on active extension the patella should track centrally toward the groin. Tracking laterally in extension as an inverted J-sign indicates lateral subluxation in extension and potential or real patellar instability
- Feeling the articulation: holding the hand gently over the patella detects crepitus.

With the patient lying supine the following tests can be performed:

- Detection of effusion: as previously described
- Palpation for tender points:
  - Tibial tubercle for Osgood–Schlatter’s
  - Lower pole patella for patella tendinopathy (jumper’s knee) or Sinding–Larsen Johansson syndrome in the adolescent. The patella is tilted from superior while pushing into the lower pole with the thumb
  - Superior pole of the patella for quads tendinopathy
  - Tenderness on the medial or lateral border of patella
  - Any specific trigger points looking for neuroma or tender nodules
  - Medial retinaculum for tenderness over the medial plica, felt as a chord on rolling the finger against the condyle (with the knee in extension)
  - Excessive patella tilt by holding the axis of the patella between finger and thumb
- Movements of the patella:
  - Patella glide is quantified as the proportion of patella width that it can move medially or laterally in either full extension or at 30 degrees of flexion (Figure 8.1.3)
  - Apprehension sign. Detected by gently trying to dislocate the patella laterally, eliciting an obvious sense of apprehension by the patient
  - Patellofemoral compression. Examined by compressing the patella into the groove and rocking the knee into flexion and extension, eliciting pain, catching, crepitus, or bare-bone grinding
  - Patella tendon movements. Tethering of the patella to the anterior tibia will reduce medial/lateral movement of the patella tendon.
Assessment of patella mobility by medial and lateral glide, expressed as a proportion of patella width that the patella moves.

With the knee flexed at 90 degrees, the knee is further examined

- Palpation for trigger points:
  - Fat pad tenderness either side of the patella tendon
  - Lateral iliobial band syndrome. Deep tenderness 2cm proximal to the lateral joint line over the lateral epicondyle. Capsular irritation over a prominent osteophytic edge of the articular surface may be noted
  - Tender nodules or points representing a neuroma or painful scar.

Examination of the menisci

This is best performed with the knee flexed at 90 degrees.

- Palpation

  - Meniscal tenderness: this is particularly deep and therefore may take a fair amount of force to elicit the pain:
    - Medial meniscal tenderness is classically on the posteromedial part of the joint line (Figure 8.1.4)
    - Lateral meniscal tear tenderness is on the midlateral aspect (Figure 8.1.5)
    - Anterior joint line tenderness may indicate a bucket handle tear, especially if associated with a block to full extension

  - Swelling: an associated fullness or obvious swelling may be sensed due to either an associated cyst (usually lateral) or sometimes the flap of a meniscus (typically medial).

Pain on movement

- Meniscal pain on full flexion: pressure on the meniscus is increased in full flexion and may be resisted by the patient
- McMurray’s test: in this test rotation in forced flexion with compression over the medial joint line is positive if it elicits a clunk from a torn meniscus as the test was originally described. It is less reliable if used with simple detection of pain. (Figure 8.1.6)
- Squat or duck walking (mimics McMurray’s manoeuvre): the patient is asked to squat and walk or waddle a few steps, eliciting their characteristic pain. This can be a very useful confirmatory test
- Apley’s grind test: this is less commonly used but the patient is positioned prone, the knee flexed to 90 degrees and the tibia
ground into the femur looking for pain from a meniscal tear.

Fig. 8.1.6
McMurray test performed holding the knee to achieve full flexion and by applying rotational movements by grasping the heel.

Examination for ligament instability

The following ligaments or ligament complexes can be examined individually or in combination and the pattern of instability determined:

- Collateral ligaments
- Anterior cruciate ligament
- Posterior cruciate ligament
- Posterolateral corner
- Posteromedial corner.

Collateral ligament examination

Tenderness following acute injury is examined for with the knee at 90 degrees, applying deep palpation over the epicondyles and, for the medial collateral ligament, over the tibial attachment. Laxity and pain on stressing the collateral ligaments is detected at full hyperextension, 0 degrees extension and at 20–30 degrees with the purpose of detecting a difference with the other side. The patient should be asked whether the movement feels the same.

For detection of movement the knee is cupped by one hand using the fingers and the palm alternately as a fulcrum against the epicondyles, and the leg is levered to the side by firmly grasping the heel (Figure 8.1.7). Flexion beyond 20–30 degrees will result in rotation at the hip rather than opening of the knee.

Fig. 8.1.7
Assessment of the collateral ligaments, achieved by cupping the knee and then applying medial and lateral movements of the leg by grasping the heel. The fingers and the palm are used as a fulcrum.

Integrity of the lateral collateral ligament can be checked by palpation in the ‘figure four’ position, feeling the chord-like structure running from fibula head to femur.

Anterior cruciate ligament examination
To detect laxity of the ACL the patient needs to be relaxed to avoid involuntary contraction of the hamstrings. With appropriate techniques it is usually possible to reliably detect laxity in the awake patient.

**Lachman test**

This detects increased AP movement in the knee at 10–15 degrees flexion (Figure 8.1.8). Firm AP force is applied, pushing back with the thigh hand and pulling forward with the tibial hand.

![Click to view larger](Fig. 8.1.8)

Lachman test: the thumb and fingers of each hand, placed as near to the midline as possible—grip the leg in order to achieve direct anterior and posterior movement. A difference between the two sides in terms of endpoint or excursion is all that is required to indicate ACL injury.

Two differences are sought:

- Increased anterior movement—it doesn't matter how much, just that it is different to the other knee
- Quality of the endpoint: hard endpoint, indicating some fibres may be intact, or soft endpoint.

**Pivot shift test**

The pivot shift test is pathognomonic of ACL deficiency and reproduces the giving way instability sensation felt by the patient.

The test has a reputation as painful and difficult to perform but with adequate support of the leg it is painless and easily reproducible. The principle is to detect a jumping, or familiar buckling sensation, as the lateral tibia slides from its normal position articulating with the lateral femoral condyle into an abnormal anterior subluxed position, and vice versa, at around 20 degrees flexion on bending and straightening the knee.

Figure 8.1.9 shows how the tibia is supported, between the examiner’s side and over the examiner’s forearm. The hand is then interlocked over the wrist of the other hand, which is applied against the lateral aspect of the proximal tibia and fibula. This is an active test involving participation of the patient. Initially their confidence is obtained by asking them to flex their knee from extension without the examiner applying any force on the leg.

![Click to view larger](Fig. 8.1.9)

Pivot shift test.

The examiner then flexes the knee passively by lifting from the patient’s posterior calf, exerting an anterior force on the tibia. In a positive test the tibia is felt to slide or jump posteriorly back into place as the knee bends. Conversely as the knee is straightened the tibia is felt to sublux anteriorly. This can be an obvious clunk or a subtle glide. To emphasize the test, looking for reproduction of the patient’s distrust of their knee, increasing load is applied, both in valgus and by inline compression, loading the lateral
compartment to exaggerate the sliding of the femur over the dome of the lateral tibial plateau. When it is difficult for the patient to relax, the patient is asked to straighten their knee, thereby relaxing the hamstrings and allowing the pivot shift slide or clunk to be felt.

**Anterior draw test**

This test, in which the tibia is pulled anteriorly with the knee at 90 degrees (Figure 8.1.10), is much less reliable in the detection of ACL insufficiency. Paradoxically, it is very useful in detecting posterior sag and the step-off sign for posterior cruciate ligament insufficiency. The examiner sits against the foot and the palms grip the sides of the tibia exerting a strong anterior pull. The index fingers of both hands are used to ‘knock out’ posterior pull by the hamstrings.

![Anterior draw test](image)

**Fig. 8.1.10**

Anterior draw test. The examiner sits just against the foot and exerts anterior pull on the tibia, holding the hamstrings out of the way with the index fingers while gripping the tibia with the palm of the hands.

**Posterior cruciate ligament examination**

The posterior cruciate ligament acts to resist posterior translation of the tibia. Laxity is best examined with the knee at 90 degrees.

**Posterior sag**

When both knees are viewed from the side, any sagging back of the tibial tubercle and upper tibia is noted as posterior sag. A straight edge such as an x-ray packet (if available) may be useful to demonstrate subtle sag (Figure 8.1.11).

![X-ray packet sign](image)

**Fig. 8.1.11**

X-ray packet sign showing normal gap between the edge and the patella (B) and the loss of gap (C) in posterior cruciate ligament insufficiency.

**Posterior draw test**

With the knee at 80–90 degrees the tibia is pushed posteriorly to detect any increased posterior translation.

**The step-off sign**

This is perhaps the most useful sign in detecting posterior cruciate ligament laxity as it also helps to determine treatment. Figure 8.1.12 shows the three grades based on the stepping down from the tibia on to the femur. Grade II means the tibia is flush with the femur and when grade III is detected (tibia posterior to femur) there is likely to be injury to the posterolateral corner.
The step-off sign classification in determining the amount of loss of the normal anterior position of the tibia in relation to the femur: a) Normal step-off, b) Grade 1: reduced step-off, c) Grade 2: tibia flush with femur, d) Grade 4: tibia posterior to femur.

**Posterior Lachman test**

Increased posterior sag can also be detected at 15–20 degrees flexion when the tibia is pushed posteriorly in relation to the femur.

**Posterolateral corner examination**

Injuries to structures of the posterolateral corner result in increased external rotation of the tibia on the femur.

**Dial test at 30 and 90 degrees**

The patient can be supine or prone (Figure 8.1.13), but prone is probably more accurate. The examiner externally rotates the supported feet while an assistant keeps the knees together to eliminate femoral rotation. Greater than 15 degrees 'dialled' external rotation indicates injury.

Increased external rotation at 30 degrees suggests an isolated posterolateral corner injury whilst increased external rotation at 30 and 90 degrees suggests injuries to both the posterolateral corner and posterior cruciate ligament.

**Lateral hypermobility at 90 degrees**

With the knee at 90 degrees the knee is rotated by gripping the proximal tibiofibular joint and pushing it posteriorly in order to detect an increase in posterolateral mobility compared to the other side (Figure 8.1.14). Alternatively, with the patient sitting, the examiner spins out the tibia while the patient keeps their knees together (spin test). Increased posterolateral rotation can be noted by feeling and looking at the superior tibiofibular joint.
Spin test: testing increased rotation externally of the tibia by rotating the tibia and noting the position of the tibial tubercle and the fibula head.

External rotation recurvatum test

When the legs are picked up by the big toe or forefoot then the knees fall into external rotation as the knee goes into hyperextension (Figure 8.1.15) when the posterolateral corner is stretched out.

Reverse pivot shift test

This test detects the opposite of the pivot shift phenomenon. The knee is supported in flexion with the foot externally rotated and the knee in compression and valgus. On moving into extension the lateral compartment reduces under the femur with a clunk. This is a difficult test to perform reliably.

Posteromedial corner

Injury to the posterior oblique ligament of the posteromedial corner is present when instability to valgus stress is present with the knee in full extension. In this situation injury to one or both cruciate ligaments should be suspected.

Examination for arthritis or joint surface damage

The hallmark signs when examining for joint surface damage are signs associated with catching of worn articular cartilage surfaces. Fine crepitus on joint movement can be heard but it usually needs to be felt. Active movement loads the joint and the examiner places a hand over the moving part, either feeling with the fingers or the flat of the palm. Popping, snapping, or clunking may also be felt on movement under load and if painless are considered ‘safe’.
Bare bone crepitus

When two bare bone surfaces are forcibly compressed together then there is very high friction and the surfaces momentarily stick together before sliding in a juddering fashion. This sign has been described as the pepper mill sign for obvious reasons and can be felt in the medial and lateral compartments by carefully forcing the knee into varus or valgus and slowly moving the joint under compressive load. With pausing, the thin synovial fluid is being compressed out of the articulation removing any lubrication benefit.

Range of movement

Loss of flexion and or extension is an early sign of joint degeneration. For consistency and accuracy, flexion is best measured with the patient reclined nearly supine, keeping the quadriceps at maximum length.

Palpation of articular surfaces

When the knee is at 90 degrees the distal articular surface of the medial femoral condyle is facing distally and is not covered by the patella. Deep tenderness on palpation of this surface is consistent with articular surface damage.

Popliteal cysts

Cysts and fullness in the popliteal fossa are best seen and palpated with the knee in extension and when standing.

Conclusion

History and examination are linked and specific examination is substantially determined by the likely diagnosis or group of diagnoses indicated by the history (Box 8.1.3). It is, however, important to undertake general examination of the knee with the patient, walking, standing, sitting and lying supine. Specific examination will then create a pattern of signs which should lead to definitive diagnosis (Table 8.1.1).

Box 8.1.3 Specific knee diagnostic scenarios

Groups of symptoms and signs can predict likely diagnoses:

- History of non-contact rotational injury, and feeling of not trusting knee Rotational giving way mimicked by twisted knuckles: indicates ACL deficiency
- Description of knee ‘dislocating’ and persistent feeling of patella jumping out of joint on twisting movements: indicates patella dislocation
- History of twisting injury, knee effusion, and posteromedial joint line tenderness: indicates meniscal tear
- Knee giving way on stairs with falling over: indicates patella dislocation. With ACL type giving way the patient is usually able to catch themselves

Summary points

- Articular cartilage has a poor capacity to heal by itself
- Left alone, large areas are likely to progress into osteoarthritis
- The goal of cartilage repair is both short term improvement in function and long term durability
- There are several available strategies including non-surgical options, and these are formulated into an algorithm
- Cartilage repair is an advancing field and the future lies in bioengineering and high quality comparative clinical analysis.

Introduction

The treatment of articular cartilage injuries in the young knee poses a difficult management problem, because articular cartilage has a very poor capacity to heal. Repair occurs with poor quality fibrocartilage which does not have the endurance and function of normal hyaline articular cartilage and is unlikely to allow the patient to return to full function. Metal and plastic are final alternatives for the older more sedentary patient but the younger, more active patient poses a challenge.

This chapter outlines the structure of articular cartilage, explaining why it does not heal and outlines the treatment options available both now and in the near future with tissue engineering. The aim of articular cartilage repair techniques is the prevention or delay of later osteoarthritis, and so inevitably good evidence for the ideal treatment option is lacking due to the long follow-up periods required.

Cartilage injury—the beauty and the problem of hyaline cartilage

The behaviour of articular cartilage is determined very much by its biomechanical, biochemical, and morphological properties. Articular cartilage consists of distinct structural zones and the specific arrangement of the components and the fibres determines the characteristic properties of cartilage—namely to withstand high load with almost no friction. The coefficient of friction of the articular surface is less than that of ice on ice and, when damaged, friction increases so that much more effort is required to move the joint, resulting in acceleration of mechanical wear.

Articular cartilage has a very poor ability to regenerate itself following injury. This is because of its structure and lack of a neurovascular supply. Structure is important because the chondrocytes are trapped within the matrix and cannot migrate after injury to lay down new matrix of type II collagen and proteoglycans.

Full-thickness cartilage injuries that penetrate subchondral bone connect with the subchondral marrow elements resulting in migration of mesenchymal stem cells and fibroblasts which lay down repair tissue. This tissue is generally a fibrocartilage type of repair, heavy in type I collagen rather than the normal specialized type II collagen found in hyaline cartilage. Fibrocartilage does not have the same wear and endurance characteristics of type II collagen, hence the poor durability.

Natural history of articular cartilage injury (Box 8.2.1)

The natural history of chondral injury is unclear but it is generally accepted that a significant area of chondral damage is likely to lead to the development of degenerative change through enzymatic degradation and mechanical wear with the subsequent development of symptoms. Untreated lesions are likely to progress to osteoarthritis in the long term.

In degenerative joint disease, loss of articular cartilage is caused by a failure of the catabolic and anabolic ratio. This results in generalized destruction of the tissue under load and affects a large area of the chondral surface. This differs from traumatic cartilage lesions where a more isolated area of damage disrupts chondrocyte biosynthetic function, and this affects the structure and composition of the cartilage matrix. Cartilage defects are classified by the depth and size of the lesion (Figure 8.2.1).

Box 8.2.1 Natural history of cartilage injury

- Articular cartilage has poor capacity to heal
- Any natural healing results in fibrocartilage repair with poor durability
- Current technologies aim to reproduce hyaline-like articular cartilage
- Future technologies aim to reduce healing time by development of scaffolds containing engineered tissue.

Box 8.2.2 Articular cartilage repair
Patient factors to consider for correction:
- Alignment
- Meniscus deficiency
- Ligament insufficiency

Lesion factors:
- Size of lesion
- Primary or secondary repair.

Articular cartilage repair (Box 8.2.2)

The goal of articular cartilage repair surgery is to improve patient symptoms and function and to achieve a durable surface which will alter the natural progression towards osteoarthritis. Repair with hyaline or hyaline-like cartilage instead of fibrocartilage has produced better clinical and mechanical results.

Treatment options (Box 8.2.3)

Non-surgical options

Non-surgical options for treating articular cartilage damage include reducing activity level, physiotherapy, taking simple analgesics, and non-steroidal anti-inflammatory drugs. Viscosupplementation injections and oral chondroprotective nutraceuticals such as glucosamine have also been tried but evidence for long-term benefit is lacking. Reducing load on the joint surface by changing activity level and by decreasing weight as appropriate may well decrease symptoms in the knee.

Arthroscopic debridement and thermal chondroplasty

Arthroscopic debridement techniques include mechanically smoothing (shaving) the roughened articular surface by removing unstable edges of articular surface and areas of fibrillation, washing out debris, and treating any torn menisci. In addition to mechanical shaving, energy can be applied using radiofrequency (RF) probes to produce ablate damaged tissue and seal fibrillation of articular cartilage. Heat applied to the proteoglycan protein results in shrinking and contraction of the surface producing a smooth and aesthetically appealing surface. Initial generations of RF probes, however, produced significant heat damage to unpredictable depths and iatrogenic damage of surrounding articular cartilage with cell apoptosis and avascular necrosis of underlying bone were reported in early series. Current generations of RF probes, using plasma technology, produce a very controlled depth of heat penetration and careful use has resulted in few reported side effects.

Box 8.2.3 Options for surgical treatment

- Arthroscopic debridement provides short-term benefit relieving mechanical irritation to the joint
- Microfracture: stimulates repair from marrow cells and results in fibrocartilage repair tissue which may not have sufficient...
durability

♦ ACI techniques: expensive with long recovery time. Poorly assessed in comparative trials but hold the hope of long term durability
♦ Osteochondral grafting: transplanting healthy articular cartilage but limited by donor site morbidity.

Microfracture and marrow stimulation techniques

Background

Microfracture and other similar procedures are based on the principle that healing of articular cartilage is better if the bone marrow connects to the joint surface.

Surgical technique

Following cartilage debridement multiple small holes are made through the subchondral plate using specially designed sharp angled picks. The calcified layer of cartilage must be removed, usually by using a sharp curette, to provide a platform for the cells to attach to. Subchondral bone penetration occurs to a depth of 3–4mm and holes are spaced approximately 3–4mm apart. Ideally, a contained defect with sharp sided walls is prepared allowing the bone marrow blood in the defect to form a ‘super clot’. Later differentiation into fibrocartilage then occurs.

Postoperative rehabilitation with a strict period of non-weight bearing is essential to allow the new tissue appropriate time to fill the lesion without being exposed to load. Rehabilitation, involving continuous passive motion therapy (CPM), is considered to be essential in postoperative management. Patients need to be aware of the requirement to use the CPM for 6h per day for 6 weeks or to perform at least 500 revolutions three times a day on a static bike without load.

Results of microfracture

Clinical results depend on the age of the patient, the size of the lesion, and the amount of fill that is achieved, as visualized on a magnetic resonance imaging scan. Younger (age <40 years) and active patients with smaller isolated traumatic lesions on the femoral condyles have the best long-term results. Results deteriorate with time, usually beginning after 18 months, particularly in older patients with defects in the patellofemoral and tibial joint surfaces. The inferior quality of the repair tissue, with incomplete defect filling and the appearance of new bone formation in the defect area are thought to be the cause of failure in these cases.

Indications

Microfracture is indicated for smaller (<2cm²) contained lesions, not extending beyond underlying subchondral bone.

Autologous chondrocyte implantation (ACI)

Background

In this procedure, chondrocytes are harvested from a normal area in the knee prior to culturing in a laboratory and later reimplantation into the damaged area of the knee. Animal studies commenced in the 1960s and the first studies on humans were published in 1994.

Technique (Figure 8.2.2)

The first stage is arthroscopic, with inspection of the articular surface and confirmation of suitability for ACI treatment (full thickness chondral defect, area greater than 2cm², opposing surface with less than grade II changes, and patient able to comply with the rehabilitation protocol). A small (100–200mg) biopsy of articular cartilage is harvested from either the notch or the superomedial aspect of the trochlea using a curette. In the laboratory, individual chondrocytes are then released from the biopsy by enzymatic breakdown followed by cell culture in autologous serum.

Four to six weeks later an open arthrotomy is performed and the lesion curetted down to the subchondral bone plate. A flap of periosteum or a synthetic collagen membrane is prepared to the exact size using a paper or foil template and sutured over the prepared articular cartilage defect using fine 6/0 absorbable sutures to create a watertight space. Cells are then implanted by injection into the space with the recommendation of a minimum of 1 million cells per square cm of defect area.

In more recent developments of the ACI technique, cultured cells are seeded directly on to a synthetic membrane such as MACI (Genzyme UK) or into a three-dimensional matrix such as hyaluronic acid (Hyalograft-C, Fidia, Italy). Application of the patch in smaller contained defects arthroscopically has also been described.
Rehabilitation

Strict postoperative protocols are required, reducing load on the repaired area to allow healing. For tibiofemoral surface repairs 20kg of weight bearing is recommended whilst for patellofemoral surface repairs full weight bearing is allowed with limitations placed on stair climbing. Full rehabilitation is a lengthy process and tissue maturation continues for up to 3 years to create a resilient articular surface. Running or impact sports are not recommended for 9 months after surgery.

Histology and clinical results

Results are available with up to 16 years follow-up, and improvements have been demonstrated in more than 80% of the patients with relatively few complications. To date, six randomized trials have been published in addition to many case series. The short- to medium-term results from these early studies indicate no clear advantage of ACI over other surgical interventions but a more recent study comparing ACI with microfracture showed better histology and clinical results following ACI using characterized chondrocytes.

Returning to sports is an important goal of cartilage repair. In follow-up studies of ACI, clinical activity scores showed that return to sports including professional impact sports like football (soccer), ice hockey, and team handball, was possible in isolated femoral lesions and osteochondritis dissecans in eight to nine out of ten patients. In one study examining return to soccer in 45 patients, 92% had a good or excellent result on isolated femoral condyle lesions. Eighty-three per cent of high-skill level players returned to pre-injury level, with the highest chance in those who underwent surgery within 12 months of injury.

In another study of 35 young adolescent athletes undergoing ACI, 17 had previously had a failed microfracture procedure. All patients had a clinical improvement and returned to pre-injury level of sports. No failures were observed. The authors concluded that return to a high level of sports after ACI is possible, even if it takes 15 months to return to high-impact sports such as soccer.

Indications

ACI is primarily indicated for International Cartilage Repair Society (ICRS) grade III–IV contained lesions on one side of the joint or osteochondritis dissecans of the femoral condyle, trochlea, or patella. Salvage indications include uncontained lesions and those involving both sides of the joint (bipolar lesions).

Contraindications include rheumatoid arthritis and other systemic inflammatory joint diseases, as well as generalized osteoarthritis. Relative contraindications include obesity and smoking.

Osteochondral autograft transplantation

Background

This procedure involves transplanting healthy articular surface from one part of the knee to the damaged area as a functional osteochondral unit.

Technique

Healthy articular cartilage is normally harvested from the superolateral edge of the lateral trochlea or from around the intercondylar notch using harvesting coring devices of varying diameters. These cores of healthy tissue are then transplanted in to the damaged area as close to a perpendicular orientation as possible. The procedure can either be performed arthroscopically or using an open arthrotomy. Developments in instrumentation have allowed for this to become a reproducible, though demanding, arthroscopic procedure.

Results

Areas surrounding the grafted circles of tissue heal with fibrocartilage. It is recognized that harvesting itself damages the articular surface and approximately 25% of the grafted cartilage surface becomes non-viable after harvest. Initial outcome series reported good results for smaller lesions in 91% but there are few long-term studies or good comparative studies.
Indications

This technique is limited to full-thickness chondral and osteochondral defects in the knee with a maximum size up to 4cm² and less than 10mm in depth. For larger areas, donor site morbidity becomes unacceptable.

Realignment surgery

Any cartilage repair surgery will be compromised if the affected compartment is overloaded and it is essential to consider reducing the deforming force that may have initiated the damage process. A high tibial osteotomy can be performed to unload the medial compartment and a distal femoral osteotomy can be performed for lateral compartment overload. Anteromedialization of the tibial tubercle may be needed for trochlea or patella surface treatment with or without proximal soft tissue realignment.

Algorithm and factors for treatment

An algorithm for the treatment of articular cartilage defects affecting the femoral condyle or trochlea is given in Figure 8.2.3.

![Click to view larger](Fig. 8.2.3)

Algorithm of treatment for chondral lesions.

The natural history of a cartilage lesion is not fully understood, but lesions less than 1cm usually do not progress. In addition, some lesions do not cause symptoms it is important to tailor the treatment to various patient factors—it is not just one treatment for all patients. The three primary determining factors are the size of the lesion, patient demands or functional expectations, and whether treatment is primary or secondary with persistent symptoms following previous surgery. General patient factors include the age and gender of the patient, leg alignment, meniscal integrity, and ligament stability. However, overall factors including the financial cost of the procedure, experience of the surgeon, the implication of rehabilitation time for the patient, and the risk of complications also influence the decision.

Lesions up to 1cm diameter with unstable edges causing synovial irritation can be treated with simple mechanical debridement or radiofrequency treatment. For lesions 1–2cm found at arthroscopy and considered to be causing symptoms, treatment depends on the patient’s demands and simple debridement may be all that is necessary. Certainly procedures such as microfracture and grafting with synthetic or osteochondral plugs, which are indicated for the higher demand patient, should not be performed without ensuring the patient is aware of the commitment to rehabilitation.

For lesions over 2cm the choice is more difficult. Up to 4cm in the lower demand patient under age 40 then the fibrocartilage repair induced by microfracture may be sufficient to protect the joint and relieve symptoms. In the higher demand patient, however, this is unlikely and ACI is indicated, taking into account the financial cost and the prolonged rehabilitation time.

Management of the larger lesions above 4cm is more challenging and the prognosis is more guarded. Use of ACI in very large lesions is considered salvage surgery and alternatives such as massive allografts or prosthetic replacement need to be considered.

In revision cases, treatment is often determined by the first procedure and use of ACI is more likely to be indicated.

Future

The results of ongoing clinical studies are eagerly anticipated to answer remaining questions on the long-term results of articular cartilage repair surgery. Without treatment, articular cartilage injury is likely to result in post-traumatic osteoarthritis by degradation as the body lacks intrinsic repair capacity. Unfortunately, in the early stages of cartilage repair surgery, strict randomized trials were not performed and long-term data are therefore not available. Studies analysing the quality of the repaired surface indicates that only filling of the defect is required for early stage function but that the generation of hyaline articular cartilage is important for long-term durability.

It is clear that the goal of cartilage repair is to regenerate mature hyaline cartilage and to achieve this aim, regulation of chondrogenesis is required, involving either recruitment of host cells or differentiation of transplanted cells. In the advancing field of tissue bioengineering, scaffolds or matrices are being developed on which the cellular part of developing articular cartilage can grow. Much current research is focused on stimulation of this cellular growth with growth factors or genes.

It may be that development of in situ scaffolds that will capture the mesenchymal stem cells, such as the new bilayer scaffold.
made from poly(D,L-lactide-co-glycolide), PGA fibres, calcium sulphate, and surfactant (TruFit plugs, Smith and Nephew, USA) will provide a sufficient hyaline-like articular surface without the expense of culturing cells. Alternatively, the future may lie with cells held in synthetic scaffolds, including hyaluronic acid fleeces, collagen membranes, and hydrogels.

Demands for focal cartilage lesion treatment with cell therapy are likely to increase in the future and cartilage repair will continue to be one of the most rapidly advancing fields in knee surgery.

**Further reading**

Magnetic resonance imaging (MRI) has revolutionized the investigation and treatment of the painful knee. It is non-invasive and avoids patient exposure to ionizing radiation. MRI has the advantage of establishing diagnoses in a painful knee without the morbidity of surgical intervention. It is now widely available and has moved from a simple diagnostic adjunct into a key planning tool. It offers improved management of theatre resources and it allows for more accurate planning of postoperative rehabilitation.

The role of MRI in management of the injured knee is determined by its cost-effectiveness and its ability to augment the diagnostic accuracy of clinical examination. Accuracy of clinical examination by specialist orthopaedic surgeons is comparable to MRI when interpreted by specialist radiologists (Table 8.3.1). Increasingly, MRI has been shown to be cost neutral. Whilst costs are high, diagnostic information reduces the need for unnecessary surgery.

Protocols

MRI protocols will differ slightly between units (Box 8.3.1). MRI T1-weighted sequences are used to define local anatomy and can be used to identify trabecular microfracture. T2-weighted sequences (with fat suppression) are most commonly employed to demonstrate oedema of both soft tissues and bone marrow. Proton density and T2 gradient echo sequences are utilized to highlight meniscal pathology. Viewing images on a workstation is now preferred to hardcopy films with enhancement of brightness, contrast, and magnification with linking of orthogonal views. Comparison with plain radiographs complements interpretation of calcific lesions and assists identification of small avulsion injuries.

Box 8.3.1 MRI protocols

- **T1-weighted:**
  - Local anatomy
  - Trabecular microfracture
- **T2-weighted:**
Oedema in soft tissue and bone marrow

Meniscal pathology.

**Bone bruising**

Bone bruises are occult bony injuries and represent the local sequelae of chondral and microtrabecular trauma (Figure 8.3.1). Patterns of bone bruising can be pathognomonic for specific ligamentous injuries. Bone bruises have been described as reticular (oedema not extending to the subarticular cortical bone), or geographic (oedema which is continuous with the subarticular cortical bone). The long-term significance of these lesions has yet to be determined. However, histopathological studies of geographic bone bruises have demonstrated local chondrocyte and osteocyte death and have suggested that severe bone bruising may represent a precursor of early degenerative change. This could explain why degenerative changes develop despite successful anterior cruciate ligament (ACL) reconstruction and may provide justification for less aggressive rehabilitation programmes in patients with large subcortical lesions.

**Cruciate ligament rupture**

MRI is useful in the diagnosis of ACL rupture (Figure 8.3.1) and associated meniscal or chondral lesions. ACL rupture can be inferred from absence, discontinuity, or oedematous replacement of the normal ligamentous band that parallels Blumensaat’s line. Less accurate indirect radiological signs such as buckling of either the posterior cruciate ligament (PCL) or patella tendons are evidence of anterior tibial translation (usually more than 5–7mm referenced from posterior margins of the tibia and femoral condyles). Difficulty arises from evaluation of partial tears, which should be correlated with clinical findings to determine appropriate management. Transient subluxation and impaction of the femur into the tibia at time of injury can lead to a ‘kissing contusion’ au. This ‘traumatic pivot shift’ is also responsible for the associated chondral, capsuloligamentous, and meniscal injuries.

**Meniscal pathology**

Clinical assessment of meniscal injuries (Table 8.3.1) is difficult and a combination of history and positive provocation tests are required for accurate diagnosis. In a systematic review of 32 papers, Ryzewicz and colleagues found that routine MRI was not indicated, as clinical assessment in experienced hands was of equal or higher reliability. However, MRI is able to assess the type of meniscal injury, aids surgical planning, and assists diagnosis with concomitant ligamentous injury where clinical examination becomes less reliable.

Detection of meniscal pathology involves identification of abnormal meniscal morphology and signal. Care should be taken as many asymptomatic individuals will have areas of high intrameniscal signal which is generally considered to be a normal consequence of aging. Abnormal signal, extending to the free edge of the meniscus, is accepted as representing a tear. However, a degenerative tear may not always represent the problematic pathology, and MRI review should not cease once a tear is identified. Meniscal fragments can become displaced into the intercondylar notch or settle into synovial recesses. It should also be noted that aberrant meniscal anatomy may mask injury. Remnants of a torn discoid meniscus can appear misleadingly normal.

**Posterolateral corner injury**

Posterolateral corner (PLC) injuries pose a difficult clinical problem. They often occur in conjunction with other ligamentous injuries and physical examination may be impossible in the acute setting. MRI allows evaluation of the PLC and can influence surgical management. Injuries to the PLC structures can be assessed with a variety of coronal, sagittal, and oblique views. Oblique coronal slices through the fibular head can more accurately demonstrate the popliteofibular ligament and inclusion of the fibular head in all sequences assists in diagnosis. Soft tissue oedema in the posterolateral aspect of the knee should always be viewed with suspicion. Oseous injuries such as occult arcuate fracture, Segond fracture, medial femoral condyle bone bruising, anterior rim tibial plateau fracture, and avulsion of Gerdy’s tubercle should all be assessed. Each component should be reviewed and evidence of thickening, oedema, tear, disruption, or avulsion should be sought. However, the anatomical definition and individual variation of the PLC mean that defining all structures can be difficult. The popliteus, popliteofibular ligament, arcuate ligament, and lateral collateral ligament are primary structures considered for repair and thus their evaluation will provide the most useful information for surgical decision making.
Postoperative imaging

Postoperative MRI is more difficult to interpret, although it is useful for the assessment of graft integrity, tunnel position, and tunnel widening following cruciate reconstruction, monitoring osteochondral defects or for missed meniscal pathology following arthroscopy. MR arthrography using gadolinium has been employed to assess the postoperative meniscus and reconstructive grafts. Although this technique is invasive, it provides joint distension which facilitates imbibition of fluid into latent tears, potentially improving accuracy. However, at this time there are no convincing results to justify its routine use. Artefacts from modern metallic implants can now be minimized by various MRI techniques and do not preclude evaluation.

Miscellaneous pathology

MRI should be considered in the evaluation of other lesions in the knee joint. It can be used to provide prognostic data to patients with spontaneous osteonecrosis of the knee (SONK), examine the extent of spread of bony and soft tissue tumours (e.g. pigmented villonodular synovitis, PVNS), and evaluate postoperative cartilage repair after procedures such as chondrocyte implantation or marrow stimulating techniques.

Dramatic improvements in the quality of images produced by MRI over the past decade have provided clinicians with invaluable data that has undoubtedly saved patients from unnecessary surgery. It has also improved our understanding of pathology and the postoperative healing processes. As new technology improves resolution, and experimental techniques such as real-time MRI become more accessible, our understanding of individual patients' pathokinematics will improve. The increasing quality of MRI will continue to augment clinical orthopaedic practice, and should ultimately result in improved outcomes for patients.

Osteotomies around the knee

Summary points

- Osteotomy about the knee can correct deformity and alter the alignment of the knee in different planes.
- Osteotomy of the knee is indicated for correction of alignment and offloading of affected compartment in osteoarthritis, instability, post cartilage repair and meniscectomy.
- Pre-operative planning for osteotomy of the knee involves patient selection, clinical and radiological assessment to achieve the desired knee alignment.
- Depending of the type of knee deformity, distal femoral or proximal osteotomy is indicated of the correction of the deformity.
- Osteotomy of the knee has been shown to provide pain relief and improve function in majority of patient.

Introduction

Osteotomy of the proximal tibia or distal femur can alter the alignment of the knee in three planes—coronal, sagittal, or rotational axes.

The aims of osteotomy are to correct deformity due to fracture, growth plate arrest, or metabolic disease; to unload a compartment damaged by osteoarthritis or cartilage injury; or to improve stability (Box 8.4.1).

Box 8.4.1 Aims of osteotomy

- Correct deformity
- Unload a damaged compartment
- Balance soft tissue.

The ideal patient will be active, young or middle aged, and have healthy bones and a mobile knee. The pathology will be either a unicompartmental problem or involve instability with deformity.

The principles of osteotomy involve creating the osteotomy as close to the site of deformity as possible, preferably through cancellous bone with stable internal fixation (Box 8.4.2).

Box 8.4.2 Principles of osteotomy

- As close to the site of deformity as possible
- Through cancellous bone
- In a mobile knee joint
- With stable internal fixation.

Principles of osteotomy

Osteotomy for osteoarthritis

The principle of osteotomy to unload a damaged compartment is based on the mechanical pathogenesis of osteoarthritis.

The mechanical axis (hip/knee/ankle alignment) of the leg is 0 degrees although the anatomical axis (femoro–tibial angle) is 5 degrees of valgus. This results from the distal femur being 8 degrees of valgus and the proximal tibia being 3 degrees of varus. With this alignment, 70% of the weight-bearing load passes through the medial compartment.

There are a number of factors which may increase this load, such as obesity. With an intact medial meniscus the surface contact area between medial femoral condyle and medial tibial condyle is 6cm². Total meniscectomy reduces this to 2cm² and hence a three times increase in load per unit area.

Articular cartilage is designed to withstand loads of 25kg/cm²—if the load exceeds 35kg/cm² then matrix breakdown begins.

Cadaver studies have shown that in normal joints, very small changes in the relative alignment of the femur and the tibia produced marked changes in the amount of weight borne by the medial and lateral compartments of the knee. Osteotomy for osteoarthritis is
based on this unloading effect on the damaged compartment.

**Osteotomy for instability**

Soft tissue surgery for correction of collateral instability is unlikely to be successful in the presence of malalignment with tension forces stretching the ligament repair or reconstruction. For example, lateral ligament instability will be aggravated in a varus knee. Corrective valgus osteotomy will relieve stress on the lateral soft tissues.

In a study relating gait analysis to results of valgus high tibial osteotomy (HTO), a low adduction moment gave uniformly good results whilst patients having a high adduction moment (varus thrust on walking) had only 64% good results.

With collateral ligament instabilities, balance of the knee is improved by osteotomy which moves the mechanical axis to the convex side. This relieves the tension stresses on the side of laxity although soft tissue repair or reconstruction is often also required to achieve stability (Figure 8.4.1).

![Click to view larger](Fig. 8.4.1)

Lateral collateral ligament laxity postosteotomy.

The normal posterior slope of the medial tibial condyle is 6.7 degrees and the lateral tibial condyle 3 degrees. Any increase in slope will contribute to anterior translation of the tibia (and aggravate anterior cruciate ligament [ACL] instability) whilst a decrease slope will contribute to posterior translation (Figure 8.4.2). Any osteotomy that alters tibial slope may therefore influence cruciate stability.

![Click to view larger](Fig. 8.4.2)

Chronic ACL insufficiency with increased posterior tibial slope.

Opening wedge HTO tends to result in increased tibial slope and thus increased anterior tibial translation. This is an advantage in posterior cruciate ligament instability resulting in symptomatic improvement. The converse is true of closing wedge HTO where tibial slope tends to decrease, favouring its use in the ACL deficient knee.

Opening wedge HTO increasing the posterior tibial slope is also indicated in situations of hyperextension caused by premature closure of the anterior tibial growth plate or in some cases of soft tissue instability.
With varus plus ACL instability there is debate as to whether ACL reconstruction alone is sufficient to control symptoms or whether combined HTO and ACL reconstruction is more reliable. ACL graft forces are high in varus and internal rotation and most surgeons favour combined surgery (Figures 8.4.3–8.4.5).

Fig. 8.4.4
Combined closing wedge HTO and ACL reconstruction.

Fig. 8.4.3
ACL deficiency with genu varus.

Fig. 8.4.5
Combined closing wedge HTO and ACL reconstruction.
Osteotomy for cartilage repair and postmeniscectomy

In the young patient with osteochondritis dissecans or post-traumatic full thickness articular cartilage loss on weight-bearing aspects of the femoral condyles consideration may be given to cartilage repair procedures such as microfracture, autologous chondrocyte implantation, or osteochondral grafting (Figure 8.4.6). Mechanical axis alignment becomes important as such procedures are unlikely to succeed if subject to excessive load. Hence osteotomy may be considered to unload a medial femoral condyle lesion in a varus knee or lateral lesion in a valgus knee. However, to reduce pressure on articular cartilage soft tissue release may also be required.

Fig. 8.4.6
Full thickness medial femoral condyle cartilage lesion.

Meniscectomy

Meniscectomy predisposes to the premature onset of osteoarthritis, especially in association with malalignment (Figure 8.4.7). A long-term follow-up of arthroscopic lateral meniscectomy has shown a very high incidence of osteoarthritis.

Fig. 8.4.7
Development of secondary osteoarthritis postmeniscectomy.

When assessing the patient with postmeniscectomy pain, alignment is important. Magnetic resonance imaging or bone scan may confirm excessive stress in subchondral bone with thinning of articular cartilage and osteotomy may be appropriate to unload the damaged compartment.

Osteotomy versus replacement arthroplasty

Replacement arthroplasty of the knee involves a polished metal on ultra-high-molecular-weight polyethylene articulation. Polyethylene has a load to failure of 25MPa and this is exceeded in all high-impact activities which result in subsurface cracks, delamination, and fragmentation. Activities such as hiking and jogging also exceed polyethylene yield points.

As a result, the young, heavy, and active patient with osteoarthritis may be best managed with osteotomy whilst the older, lighter, and less active patient might be better managed with an arthroplasty. Comparative studies between tibial osteotomy and medial unicompartmental replacement have tended to favour arthroplasty, underlying the importance of patient selection for the appropriate procedure.
Preoperative planning

Osteotomy may be considered a four-dimensional procedure involving:

1) Positioning of the mechanical axis to a desired point
2) Manipulation of the tibial slope to influence anteroposterior stability
3) Consideration of rotation in cruciate, rotary, or patellar instability
4) Awareness of soft tissue balance with lax or contracted collateral and capsular ligaments.

Clinical examination

Active and passive range of movement is assessed noting fixed flexion or fixed angular deformity. The stability of the soft tissues and the mechanical axis alignment when weight bearing is recorded. The gait pattern is observed, especially noting any adduction moment or varus thrust.

X-ray evaluation

Standard anteroposterior, lateral, intercondylar, and skyline views are obtained for basic assessment.

A full-length standing hip/knee/ankle anteroposterior x-ray is required to assess the mechanical axis (Figure 8.4.8). Single leg standing x-rays will show greater deformity if a varus thrust is present on walking.

Fig. 8.4.8
Full-length standing hip/knee/ankle anteroposterior radiograph for assessment of the mechanical axis.

On occasion, varus valgus stress views are of value to assess soft tissue tension and determine whether soft tissue release is necessary for decompression or correction of alignment.

A bone scan may be helpful to demonstrate increased uptake in over loaded bones.

Determination of the desired position of the mechanical axis is critical to allow templating with measurement of the required angle of correction. In the varus osteoarthritic knee this is commonly at Fujisawa’s point at 35% across the lateral tibial condyle. The degree of correction may also vary depending on the degree of joint damage with more correction required for greater degree of cartilage loss (Figure 8.4.9).

Fig. 8.4.9

Operative technique

The amount of correction required to place the mechanical axis in the desired position and the tibial slope correction is measured using x-ray templates (Figure 8.4.10).

Fig. 8.4.10
X-ray template to guide the extent of correction.

Intraoperative instrumented jigs allow measurement of the angular correction during surgery.

Computer assisted surgery

If the accuracy of computer navigation in osteotomy can be confirmed then it holds great promise for more accurate correction of deformity which should lead to improved results. The essential advantage of computer assisted surgery is accurate localization of the femoral head during surgery which should improve the accuracy of assessment of the mechanical axis.

Varus knee

Most commonly bone loss is on the tibial side and proximal tibial osteotomy is appropriate. This may be opening wedge from the medial side or closing wedge from the lateral side.

Closing wedge

A lateral approach involves reflection of tibialis anterior to expose the lateral surface of the tibia. A laterally-based wedge of bone immediately proximal to the tibial tubercle is excised. To allow closure of the osteotomy, release of the fibula is required and this may be performed at different levels. Release through the superior tibiofibular joint is safest and most popular; osteotomy of the fibular head or neck places the common peroneal nerve at risk; through the proximal third of the fibula threatens the nerve to extensor hallucis longus; and through the distal third of the fibula has a high incidence of non-union.

For stability of the osteotomy it is important to protect the medial tibial cortex and maintain correction with internal fixation.

The advantage of closing wedge HTO is bone-to-bone apposition which allows for early weight bearing and bone union. It is therefore favoured in older patients with osteoarthritis, large corrections of more than 12 degrees, and with associated ACL instability to reduce the posterior slope of the tibia.

Opening wedge

A medial approach releasing part of the superficial medial collateral ligament is performed and the osteotomy is directed proximal to the tibial tubercle towards the superior tibiofibular joint. Again the opposite cortex is preserved intact for stability. Gradual opening to the desired correction and stable fixation is required. For larger corrections bone graft is recommended—this can be autograft, allograft, or synthetic bone graft substitute. Major risks are fracture into the knee joint and non-union.

The advantages are that the fibula is not disturbed and there is less distortion of proximal tibial morphology which may be important should total knee replacement be required at a later date.

Opening wedge osteotomy is therefore recommended in younger patients, for corrections of less than 12 degrees or for posterior cruciate ligament instability or hyperextension because of the increased posterior slope of the tibia.

Valgus knees

In valgus knees the bone loss contributing to the deformity is most commonly on the femoral side (Figure 8.4.11). Hence a distal...
femoral osteotomy is recommended. As with the tibia this can be opening wedge or closing wedge but risk of non-union has led to closing wedge being more reliable. Again accurate intraoperative correction is required; protection of the opposite cortex and stable internal fixation to maintain correction, promote bone union, and allow early motion.

In some circumstances, e.g. previous lateral meniscectomy or fractured lateral tibial condyle, more minor valgus deformities may be corrected by a varus closing wedge HTO. However the correction should not exceed 8 degrees because of risks of creating an oblique joint line.

Recurvatum knee

Hyperextension or recurvatum deformity may follow premature closure of the anterior tibial growth plate, soft tissue instability, or fracture malunion (Figure 8.4.12).

Anterior opening wedge HTO and bone grafting will correct the deformity (Figure 8.4.13). If proximal to the tibial tubercle there is risk of increased patellofemoral pressure.
Opening wedge versus closing wedge

There is a place for both opening wedge and closing wedge HTO but on the femoral side closing wedge is favoured because of the high incidence of delayed union and non-union with opening wedge distal femoral osteotomy (Table 8.4.1, Figures 8.4.14 and 8.4.15).

Risks and complications

The risks of HTO are summarized in Box 8.4.3.

Box 8.4.3 Risks and complications of osteotomy

- Loss of correction
- Delayed union/non-union
- Common peroneal nerve injury
- Intra-articular fracture
- Vascular injury
- Compartment syndrome
- Patella infera.

Evidence in favour of osteotomy

- Long-term survival correlates with maintenance of correction. The greater the valgus correction, the slower the progress of medial joint arthrosis
- If correction of deformity is maintained there is a lower incidence of subsequent revision to replacement arthroplasty. Using arthroplasty as the endpoint, it has been shown that survival at 10 years was 90% when the radiographic valgus angle at 1 year was between 8 and 16 degrees
- With bone scans performed before and after surgery there is a resolution of the preoperative increased uptake indicating unloading of the damaged compartment
- High articular cartilage and subchondral bone stresses are relieved by correction of malalignment
- High impact forces exceed the yield point of polyethylene and hence young, heavy, active patients are best considered for osteotomy
- Anteroposterior stability is altered by adjustments to the posterior tibial slope
- Fibrocartilage will heal across eburnated subchondral bone with restoration of joint space if adequate correction is obtained.
Long-term results of osteotomy

In general, osteotomy has been shown to improve function and provide pain relief for the majority of patients. A 10- to 21-year follow-up study on tibial osteotomy for varus osteoarthritis demonstrated that osteotomy allowed 10 to 15 years of pain relief, good range of motion and function in a large number of patients. However, results tend to deteriorate with time.

The 10-year survival rate of HTO varies from 51% to 90% in different studies.

In a Cochrane review (2007) based on 13 studies, most studies showed less pain and improvement in function scores after osteotomy, but no study compared osteotomy with conservative treatment.

Function can be improved with low-impact activities such as walking and stair climbing but improvement in true activity levels as measured on the Tegner scale has not been demonstrated.

Total knee arthroplasty after osteotomy

Inadequate symptomatic relief with persisting pain and limited function often associated with recurrent varus deformity or complications may require revision to total replacement arthroplasty.

A number of studies have reported poorer results in the osteotomy group with reduced flexion and higher reoperation rate with many concluding that total knee arthroplasty (TKA) after HTO is a technically more challenging procedure than primary TKA. The functional outcomes at a mean follow-up of 5 years after TKA in patients with a previous HTO tend to be inferior.
Others have reported a high rate of radiographic evidence of loosening with 8% of knees revised at 5.9 years postarthroplasty. Male gender, increased weight, young age at the time of TKA, coronal laxity, and preoperative limb malalignment have been identified as risk factors for early failure.

In contrast, a comparative study of patients who had bilateral total knee replacement following unilateral HTO reported that while patients with a previous HTO have important differences preoperatively, including valgus alignment, patella infera, and decreased bone stock in the proximal part of the tibia, results of arthroplasty in knees with and without a previous HTO are not substantially different.

Perceived difficulties are listed in Box 8.4.4.

**Box 8.4.4**

- Non-union or malunion
- Previous scarring with difficult access
- Extra exposure required
- Patella infera
- Soft tissue imbalance
- Oblique joint line
- Alterations to tibial slope
- Adherent neurovascular structures
- Removal of metal fixation devices.

The principles for revision of osteotomy to arthroplasty involve:

- A two-stage procedure with the first stage being removal of metal and arthroscopy in order to avoid added trauma and exposure
- Templating for the possible need of an offset fixation stem
- Choosing the exposure which least disturbs the extensor mechanism
- Resurfacing the patella because of altered height and tilt
- Dividing and substituting for the posterior cruciate ligament because it is contracted by changes in tibial slope
- Anticipating difficulty with soft tissue balance because of an oblique joint line and high fibula
- Cementing the tibial component because of abnormal proximal tibial bone.

In conclusion, most authors agree that it is technically more demanding to perform a total knee arthroplasty after an HTO.

**Conclusion**

Osteotomy about the knee is an effective method of unloading a damaged compartment and improving stability. Surgery for ligament reconstruction or cartilage repair will fail in the presence of malalignment. However, the aims and principles of osteotomy must be adhered to, together with careful preoperative preparation and surgical technique.

Maintenance of correction of the osteotomy correlates with long-term successful outcome.

Arthrodesis of the knee

Summary points

- Rare operation in developed countries
- Most often used for post infection damage in developing countries
- Still used as a last resort for failed knee replacements.

Introduction

Arthrodesis of the knee is a rare operation in the developed world—being largely a salvage procedure for a failed knee replacement—particularly following infection. In the developing world, it still has a place after primary joint infections, in particular tuberculosis and in post-traumatic osteoarthritis. Individual circumstances are paramount. A rigid straight knee might be a very disabling problem for a Western business man needing to travel by automobile or airplane. The same pain-free knee might be life saving in a subsistence farmer struggling to feed a family.

Indications

Arthrodesis of the knee should be considered in a painful and unstable knee joint which is not suitable for knee replacement. Stiffness of the joint would also favour arthrodesis. Suitability for knee replacement is addressed in a later chapter. Arthrodesis may be appropriate in paralytic conditions such as poliomyelitis but a locking caliper allowing the knee to flex for sitting is preferable in the majority of cases. The need to squat for toilet purposes is a relative but not complete contraindication for knee arthrodesis. Temporary preoperative immobilization of the knee in a cast is strongly recommended to allow the patient to assess the social and practical limitations of a permanently stiff knee. The ipsilateral hip and ankle joint should, ideally, be mobile and pain free. Bilateral knee arthrodeses make life extremely awkward and should be avoided if at all possible.

Without doubt the most common indication for a knee arthrodesis in the developed world is failure of a total knee replacement, particularly following infection. The presence of infection and lack of bone stock with poor blood supply makes this a particularly challenging problem best addressed by experienced knee surgeons with adequate facilities. Any infection should be treated energetically prior to an attempt at fusion. This should be by drainage and debridement supplemented with appropriate antibiotics. A two-stage procedure with initial implantation of antibiotic-impregnated beads may be necessary. In rare cases, where low-grade infection persists, arthrodesis may still be undertaken. Stabilization of the bone and soft tissues may, in some cases, enhance resolution of the infection.

Arthrodesis may also be appropriate following tumour resection around the knee where a knee replacement is not technically feasible.

Technique

While arthrodesis of a stable post-tubercular joint has a very high success rate and can be achieved with simple techniques, arthrodesis of an infected failed knee replacement with poor soft tissue cover and scanty residual bone is extremely challenging and will require very sophisticated techniques. The greatest advance in recent years has been the use of circular frames such as the Ilizarov system. Large blocks of well profused cancellous bone are straightforward to fuse—thinned out, devitalized cortical shells may be impossible.

Biological factors such as bone vitality, the state of the soft tissue envelope, and the virulence of the infection are paramount in decision making. Some form of rigid fixation is advocated in achieving knee arthrodesis. Techniques are summarized in Table 8.5.1.

Long intramedullary nails (Figure 8.5.1A) produce the highest success rate of all techniques. Intramedullary nails require accurate preoperative planning and measurement of both the medullary diameter and leg length. They are probably best supplied with a gentle anterior curve to simulate slight flexion at the arthrodesis. Although a curved nail may break more easily than a straight one, a curved nail is better at controlling rotation. Active infection, gross deformity, previous fractures causing obliteration of the medullary canal, as well as an ipsilateral hip replacement may be contraindications to the use of a long intramedullary nail. Shorter locking nails with a locking device at the knee are a possible alternative.

Double compression plating is an option (Figure 8.5.1B) but may have significant problems with skin closure if scarring, infection, and other soft tissue problems exist. With intramedullary nailing, the femur and tibia will be in a straight line, whilst with plating the normal mechanical axis can be maintained. There is no evidence, however, that technical difference significantly affects the outcome. External fixators are particularly appropriate in infected cases. Two-plane fixation or double-ended pins provide superior fixation to single-plane, one-sided fixators. Three to six pins above and below the knee confer a rigidity completely lacking in old-fashioned devices such as the Charnley clamp, aiding prompt union.

Ring fixators such as the Ilizarov device have achieved success where other techniques have failed at the expense of prolonged immobilization and a very awkward and bulky device for the patient’s daily activities. The advantages of ring fixators are the ability to fully weight bear early, particularly in patients with poor bone quality.

Resection arthrodesis for tumour surgery may require the interposition of allografts or autografts—preferably vascularized autografts. In this situation, greater stress will be applied to the fixation device for a longer time. Such cases should be confined to surgeons and centres with sufficient experience and expertise.

Summary points

- Modern total knee replacement is a safe, effective, durable, and reproducible solution to address symptomatic degenerative joint disease of the knee.

Introduction

The era of modern total knee arthroplasty (TKA) has undergone numerous design changes over the last three decades. It is an effective procedure that reduces pain and improves function. Despite multiple advances, surgical management and successful clinical outcomes continue to rely on the basic principles of accurate soft tissue balancing, well positioned components, and a neutrally aligned mechanical axis.

Indications

A complete history and physical examination are important in localizing pain and disability in the degenerative knee. Initial management may include non-steroidal anti-inflammatory drugs (NSAIDs), intra-articular injections, and possibly surgical arthroscopy. Other important modalities often overlooked in early management include an exercise programme and weight loss, both of which have been shown to be of benefit to patients with symptomatic arthritis.

Cemented TKA remains the gold standard for surgical management of symptomatic unicompartmental, bicompartmental, and tricompartmental arthritis of the knee that fails non-operative management. Predictable and durable results have been achieved in older and younger patient populations. Gender differences in preoperative functional decline and pre-existing quadriceps weakness suggest that a more aggressive approach and earlier intervention may be indicated when addressing females with progressive knee arthritis.

Athletic activity and high demand following TKA is a growing area of interest as little is known about the impact of these activities on long-term survivorship. Surgeon surveys have demonstrated that for the most part, moderate non-impact activities were recommended, although whether these guidelines are followed by younger, healthy, more active individuals is unknown. Implantable monitors may provide further insight into the forces in a total knee replacement following surgery, allowing surgeons to develop more scientific basis for these recommendations.

Design considerations

Fixation

Concern arose in total hip fixation when the well-designed cemented total hip system popularized by Charnley was applied to younger patients. Multiple centres reported higher rates of failures in this younger cohort which prompted the development of uncemented surfaces. Forces at the cement bone interface in the hip include a combination of shear, tension, and compression. This is distinctly different from the total knee setting, where the interface is primarily subjected to compressive forces, for which a cement interface is much better suited.

Long-term comparative studies of cemented versus uncemented total knees have shown superior survivorship in the cemented group with some designs. Other studies have demonstrated equivalent results. No studies have demonstrated superior survivorship with uncemented designs.

We continue to use a cemented, posterior stabilized design and have had excellent results in both our large outcome series, survivorship study, and in those selected patients less than 50 years old (Figure 8.6.1). A similar result, with greater than 95% survivorship at 10 years has also been noted elsewhere in younger patients.
Antibiotic cement

There are currently a number of commercially available, pre-mixed antibiotic cements for prophylactic use in total joint arthroplasty. Results from the Norwegian Arthroplasty Registry revealed a 1.8 times higher rate of infection when only systemic antibiotic therapy was used in cemented total hip arthroplasty. One randomized study in cemented primary total knees, demonstrated no infections with antibiotic cement, versus a 3.1% rate in total knees with standard cement. All infections occurred in patients with diabetes mellitus. These results provide evidence for the use of antibiotics in high-risk groups and have created debate as to the benefit of routine use of low-dose antibiotic cement in primary TKA.

Posterior cruciate ligament management

Excellent clinical results have been reported with both modern posterior cruciate ligament-retaining and posterior stabilized designs. A meta-analysis of eight randomized trials comparing the two techniques failed to demonstrate a difference in outcomes. Some studies have shown superior outcomes with posterior stabilized components in specific subsets of patients. Rheumatoid knees have been shown to have a higher failure rate with one posterior cruciate-retaining design, though more recent studies have presented more favourable results with other posterior cruciate ligament-retaining designs. Patients with a planovalgus foot deformity are also at increased risk of failure when a posterior cruciate ligament-retaining component is used.

Fixed versus mobile bearing

Multiple studies have examined the clinical outcomes of mobile versus fixed bearing designs and have failed to demonstrate a benefit to the mobile bearing design. Bearing dislocation remains a risk with this design if the knee is not appropriately balanced. One of the strongest arguments for mobile bearings is that they are more forgiving of component malrotation, and thus decrease patellar based complications, but again this has not been shown clinically. A second theoretical benefit of mobile bearings is decreased wear. An early retrieval study has demonstrated increased polyethylene wear with this type of bearing, but this has not yet been confirmed in clinical outcome studies.

Articular conformity

We currently employ a conforming, high flexion design, with highly cross-linked polyethylene, for the vast majority of our primary TKAs. Our early outcome studies with this new design have been promising, as have in vivo biomechanical studies, but long-term follow-up does not yet exist.

Designs with flat-on-round articulations created point and edge loading resulting in increased failure rates. The current high flexion fixed bearing designs employed today involve a conforming articular tibial geometry. The tibial component allows a higher degree of flexion without posterior edge loading, and also has an anterior recess for the patellar component as the knee goes into deep flexion.

Patellar resurfacing

Improvements in implant design have resulted in a significant decrease in patellar component-related modes of failure in TKA. Modifications include more anatomical trochlear geometry, tibial polyethylene recession, and the redesign of metal-backed patellae. It must be emphasized that although metal backing has been associated with high rates of failure with some designs, this is not always the case and is likely to be design specific.

A number of randomized clinical trials exist comparing patellar resurfacing versus non-resurfacing in modern designs with no significant difference in outcomes shown. The two longest demonstrate no clinical difference at a minimum of 10-year follow-up.

Modularity

Tibial modularity was introduced for a number of reasons: biomechanical studies showed improved stress distribution with a metal-
backed design; lower rates of loosening were observed in some early metal-backed designs versus a similar monoblock polyethylene component; and the option for isolated liner exchange existed if symmetric laxity or polyethylene wear occurred. However, recent long-term follow-up results have begun to question the benefit of modularity, as clinical results have demonstrated significant wear rates with some modular implants, although this is likely design, preparation (sterilization), and technique specific as other modular designs have not demonstrated increased wear.

Recent reconsideration of the monoblock design has been prompted by a number of long-term studies demonstrating excellent survivorship. A 98% survival at 14 years in patients over 75 years of age and no failures in a younger active population with monoblock designs were reported in recent studies. Other authors have not only noted excellent survival, but also a significant cost savings of over 700 USD per case.

A new design consisting of compression-moulded polyethylene on a porous tantalum base plate has introduced the possibility for long-term biological fixation into the porous metal surface. Basic science research involving porous metal has shown a number of benefits including its bone ingrowth qualities, the low modulus of elasticity, and initial friction fit. Early clinical results have been presented, but no long-term follow-up studies have been published.

Gender-specific designs

Review of the National Joint Registry for England and Wales demonstrated a lower level of satisfaction in females following TKA. Other authors have confirmed this observation with increased rates of pain and stiffness in radiographically well fixed and well aligned components. Anatomical studies as far back as 1996 have demonstrated important size and alignment discrepancies between male and female knees. The combined results of these anatomical and clinical studies have lead to gender-specific femoral component designs (Figure 8.6.2). Our early surgical results were reviewed, and demonstrated a statistically significant reduction in lateral patellar release rates in women with a modified femoral design. Clinical results following the introduction of these modifications are not yet available.

Surgical technique

Approach

A significant body of literature has recently been published regarding less invasive surgical techniques in TKA. Advances in perioperative management associated with these new protocols include preoperative education, multimodal pain management, rapid mobilization, and less invasive surgical techniques. Most studies have shown a steep learning curve, with limited early, or no benefits and more complications with mini-approaches. We favour a mini medial parapatellar approach as it is familiar to surgeons, can be gradually introduced, and can be extended to a formal medial parapatellar approach if necessary.

Ligament balancing

When alignment is not sufficiently corrected, due to poor bony cuts, or ligament imbalance, the components will be unequally loaded and subjected to excessive stress, resulting in eventual loosening of the prosthesis. Despite significant advances in component design and instrumentation, TKA remains a soft tissue balancing procedure. When a fixed angular deformity exists, the ligament on the concave side is contracted, and the other on the convex side is stretched. It is very rare for complete incompetence to exist. The principle of balancing of the collateral ligaments is to release the contracted side to the length of the stretched side.

Varus knees may require release of contracted medial structures including the superficial medial collateral ligament and the pes anserinus. Following standard bone cuts including a conservatively liberal cut, a titrated subperiosteal release is performed until gap balancing is achieved. When a varus–valgus imbalance exists, it is important to achieve soft tissue balancing prior to recutting bone.

Valgus knees are addressed by similarly releasing the contracted lateral structures. In this case our preferred technique is to ‘pie crust’ lateral structures, again in a titrated manner. Structures released include the arcuate ligament, lateral collateral ligament, and the iliotibial band. The popliteus tendon is preserved. Care must be taken when performing this procedure in the posterolateral
region of the knee due to the proximity of the peroneal nerve. Good clinical success has been demonstrated with this technique in a number of studies. In selected elderly patients with low physical demands, a constrained condylar knee prosthesis without ligamentous release is another option with no failures reported at an average 7.8-year follow-up.

Rotation

Rotational malalignment in TKA is associated with an increased rate of pain, wear, and patellar instability together resulting in mechanical failure. The most reliable reference for femoral component rotation is the epicondylar axis, which averages three degrees of external rotation with respect to the posterior condylar axis. Special consideration must be taken when simply referencing the posterior condylar axis when a hypoplastic lateral femoral condyle, or varus joint line obliquity exists.

On the tibial side, two popularly used techniques exist for establishing rotation. The first is to apply the tibial template and then flex and extend the knee allowing the tibial component to find the appropriate rotation, and then fix it in that position. The second method employs external landmarks including the medial third of the tubercle, the shaft of the tibia, and the second metatarsal. We employ the latter technique, and its superiority has been demonstrated in a recent comparison study.

Navigation

Significant advances have been achieved in surgical navigational tools. Studies have shown improvements in femoral component alignment alone; both tibial and femoral component alignment; and component rotation. Though this improved accuracy should be reflected in improved outcomes, this has not been demonstrated clinically. The benefit of computer-aided techniques in decreasing outliers (excess alignment errors) is particularly useful with unusual bony deformities; periarthritis hardware precluding intramedullary femoral guidance; and in combination with minimally invasive techniques, where exposure and landmark recognition may be compromised.

In future, computer-aided guidance may also provide a benefit in surgical education and for the low-volume orthopaedic surgeon. Despite these benefits, the cost, increased surgical time, learning curve, and unfamiliar new technique, have been barriers to widespread adoption of computer navigation into total joint surgery.

Pain management

Current trends in pain management include a multimodal approach from the preoperative period through the outpatient rehabilitation phase. This includes NSAIDs, long acting narcotics, local infiltration, peripheral nerve blocks, and epidural pain management. In fact this may be the most important advance in patient care management as a result of the introduction of minimally invasive and rapid rehabilitation protocols. Early mobilization in turn, decreases associated postoperative morbidity including rates of deep vein thrombosis.

Outcomes

The success of cemented total knee replacement supports its continued use. Early posterior ligament-retaining designs, such as the Kinematic Total Knee Prosthesis (Howmedica, Rutherford, NJ) have had long-term success. In a 10–14-year follow-up study of this prosthetic design, the investigators reported a 6.5% revision rate. Results with a modular fixed-bearing posterior cruciate design at a minimum 15 years demonstrated a 92.6% survival rate. Of 139 patients there were five reoperations, four due to polyethylene wear, and one due to a loose cemented femoral component. Similarly, in the subset of patients under the age of 55, a 95% survivorship at 12 year follow-up has been published.

Results with the total condylar prosthesis, which sacrificed the posterior cruciate ligament, were excellent, supporting the belief that cemented knee replacement is a durable and predictable procedure. Despite this success, the posterior stabilized prosthesis was introduced. The intent was to design a prosthesis that improved stair-climbing ability, increased range of motion, and prevented tibial subluxation. The 9–12-year results with the posterior stabilized prosthesis and an all polyethylene tibial component demonstrated 87% good to excellent results. An analysis of failures revealed a 3% rate of tibial loosening. This prompted a modification to a metal-backed tibial component. In a subsequent 10–12-year follow-up study on this design, a 96% good to excellent result was reported. Despite the occurrence of two loose femoral components, there were no loose tibial components. Further modifications of patellar geometry, posterior femoral condylar offset, tibial shape, and conformity have resulted in the modern modular, cemented, third-generation posterior-stabilized prosthesis. Long-term studies do not yet exist for this design, but at a mean 48 months, no cases of aseptic loosening, no patellar complications, no evidence of osteolysis or wear, and an average Knee Society Knee Score of 96 were noted.

Speculating that the level of activity would influence the longevity of cemented TKA, the long-term results and functional outcome in patients who were 55 years or younger at the time of index procedure have been evaluated. All patients were rated good to excellent at an average follow-up of 8 years. The 18-year cumulative survivorship was 94%. This represented an active group of patients who regularly participated in exercises which placed high stresses on the cement interface. Although there was one case of polyethylene wear, there were no cases of component loosening.

Registry data

Registry data can provide some insight into both demographic as well as survivorship figures in large groups of patients followed over many years. Survivorship method analysis was performed on 2629 consecutive cemented primary TKAs performed by one surgeon (Dr. J. Insall). The Total Condylar series had an average annual failure rate of 0.46% and a 21-year success rate of 90.77%. The Posterior Stabilized prosthesis with an all polyethylene tibia had an average annual rate of failure of 0.38% and a 16-year success rate of 94.10%, and this prosthesis with a metal-backed tibial component had an annual failure rate of 0.14% and a 14-years success rate of 98.10%. The Posterior Stabilized series with modular components had an average annual rate of failure of 0.46% and a 21-year success rate of 90.77%.
year success rate of 98.10%. The Posterior Stabilized series with modular components had an average annual rate of failure of 0.59% and a 10-year success rate of 93.63%. The Constrained Condylar knee series had an average annual failure rate of 0.26% and a 7-year success rate of 98.12%.

Results from the Swedish knee registry of 41,223 primary arthroplasties, demonstrate decreased revision rates as the age at surgery increased. The overall cumulative revision rate (7.8% overall) decreased in the period 1976–1997 (7% decrease) primarily due to reductions in loosening (11%) and infection (7%). A 1.4 times increased risk of revision was noted with an uncemented tibial design. Overall loosening accounted for 44% of revisions. A satisfaction study in 27,372 patients operated on from 1981–1995 found that only 8% were dissatisfied at 2–17 years postarthroplasty, and that this was constant, regardless of when the procedure was performed over this 15-year period. A close review of population trends revealed a growing rate of total knee replacements, which is estimated to increase by at least one-third by 2030.

Review of the Norwegian Arthroplasty Registry demonstrated an 80.1% survival for unicompartmental knee replacements (n=2288), compared with 92% for total knee replacements (n=3032) and this value was lower in all age categories. Early failures in 7174 primary total knees implanted from 1994–2000 were examined. Five-year survival of tricompartmental total knees was 95–99% for different brands, and the differences were not statistically significant. When comparing bicompartamental to TKA, there was a higher rate of revision for patellar resurfacing following bicompartamental replacement, but a 2.5 times decrease in revision rates due to infection.

The Mayo Clinic Joint Registry, containing 11,606 primary TKAs, was analysed from 1978–2000. Higher survivorships in older patients, inflammatory arthritis, cruciate retention, and cemented all polyethylene tibial designs were noted. Survivorship was 91% at 10 years and 78% at 20 years.

An examination of 18,530 TKAs performed in Ontario, Canada from 1984–1991 was performed: 17,229 of these were primary total knees. Revision rates were estimated to be 4.3–8.0% at 7 years. Risk factors associated with significantly increased rates of revision included a younger age; an increased number of comorbid diagnoses; bilateral total knees; osteoarthritis; urban inhabitants; and having the primary knee surgery performed at a teaching hospital. The authors felt that the increased revision rate at teaching centres was likely due to the increased complexities of surgeries performed there, on patients with an increased number of comorbidities, but were not able to prove this.

Further reading

Complications of total knee replacement

Summary points

- 81–89% overall patient satisfaction following total knee replacement
- 1 in 8 patients experience unexplained postoperative pain
- Obesity, increasing age, and medical comorbidities increase the risk of postoperative complications
- Prosthetic infection rate at 1 year is 1–2%
- Preoperative range of movement often determines postoperative range
- Low risk of acute vascular event and neurological and ligamentous injury
- Duration and method of venous thromboprophylaxis remains controversial
- Periprosthetic femoral and tibial fractures require stabilisation. Fixation of periprosthetic patella fractures is not recommended
- New surgical techniques and innovations require long term evaluation.

Introduction

The number of total knee replacements implanted continues to rise rapidly. In the United Kingdom between 1994 and 1995 there were a total of 25,000 total knee replacements implanted compared with 52,416 in England and Wales alone between 2006 and 2007 and for the first time the total number of knee replacements performed exceeded that of total hip replacement.

The increase in total knee replacements being performed has resulted from an increasingly elderly population, better implant design, improving medical care, and consumer pressure. Postoperative complications may therefore be expected to rise and the practising surgeon is likely to encounter such problems in their surgical career.

Outcomes of the total knee replacement

Total knee replacement has an estimated success rate in terms of patient satisfaction of 81–89% and most patients achieve a decrease in pain and an improved range of movement of the knee. However, approximately 22.6% of patients still report significant pain at 3 months after total knee replacement. Infection, instability, patellofemoral problems, and prosthetic loosening are the most common causes of pain; however, one in eight patients will continue to complain of pain postoperatively despite there being no obvious clinical or radiological abnormality. Patients with a poor range of movement preoperatively are less likely to have a satisfactory improvement in motion. In addition, young, female, and obese patient subgroups and those with severe arthritis may not see significant gains in postoperative functional outcome scores.

General postoperative complications (Box 8.7.1)

The 90-day mortality after total knee replacement is less than 1% with a reported incidence of less than 0.001% of intraoperative death. The peak time for an adverse event such as infection, death, or pulmonary embolus is within the first 30 days postoperatively. The 90-day rate of adverse events is 3.6% and is higher in older patients, male patients, and those with medical comorbidities. The presence of medical comorbidities also increases the need for extended rehabilitation. When compared to younger patients, patients over 80 years of age have an increased risk of death, myocardial infarction, pneumonia, postoperative confusion, and urinary tract infection. Patients in this age group, however, still have a mortality of almost half that of the general population.

Box 8.7.1 General postoperative complications

- <1% 90-day postoperative mortality
- 3.6% risk of suffering an adverse event at 90 days postoperatively
- Risk of adverse event increases with age
- Obesity increases risk of infection, implant malalignment, and early arthroplasty revision
- 1 in 8 patients will continue to have significant knee pain after arthroplasty.

Impaired cognitive function increases the general postoperative complication rate and some degree of cognitive impairment is still demonstrable in 18% of patients at 3 months postoperation. Intraoperative cerebral microemboli have not been shown to influence postoperative cognition.
Obesity and morbid obesity are increasing and are associated with an increased risk of wound leakage, superficial and deep infection, suboptimal alignment, increased early revision rate, avulsion of the medial collateral ligament, and increased length of stay and rehabilitation requirements. In addition, whilst such patients can gain significant improvement in their surgical outcome scores these scores are generally lower than those of non-obese patients. A higher incidence of radiolucent lines on postoperative x-rays may mean reduced long-term implant survival in patients who are significantly overweight.

### Wound healing

Problems with wound healing can compromise a total knee replacement and prolonged wound drainage is associated with an increased risk of wound infection. Patients at risk of wound complications include those who are diabetic, obese, or immunocompromised through drug treatment or a systemic condition such as inflammatory arthritis (Figure 8.7.1). Eczematous skin lesions are heavily colonized with bacteria, incisions through psoriatic plaques are controversial, and, unless fully treated, incisions should avoid such areas.

Fig. 8.7.1  
Wound breakdown and infection after right total knee replacement.

A peripatellar anastomosis from the medial and lateral geniculates, anterior tibial recurrent, and supreme genicular arteries supplies the skin around the knee and midline or slightly lateral skin incisions are least likely to disrupt this supply. Small medial and lateral longitudinal scars can probably be ignored but if several longitudinal scars are present the most lateral should be incorporated into the incision. Transverse scars should be crossed as near to perpendicular as possible.

Attention to surgical detail with careful haemostasis, avoiding excessive skin retraction or undermining of the skin and accurate tension-free wound closure promote satisfactory wound healing. Maintenance of adequate patient hydration, haemoglobin concentration, and saturation all improve oxygen delivery to the skin edges.

Partial thickness skin necrosis can be observed but may occasionally require debridement and skin grafting. Complete wound breakdown may require plastic surgical intervention to provide cover with a medial gastrocnemius or fasciocutaneous flap.

### Infection (Box 8.7.2)

Approximately two-thirds of periprosthetic infections occur within 1 year of surgery with an infection rate of 1–2% at 1 year after total knee replacement. It is likely that such infections arise from bacterial contamination at the time of surgery.

Diagnosis is based on history, clinical examination, and further investigation. Not all infections appear as an erythematous, warm, swollen, painful knee with a discharging wound. No test is diagnostic for infection and a combination of investigations is often required. A rise in erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level have a high specificity and sensitivity for infection and a raised serum interleukin-6 is very sensitive for infection.

A joint aspirate should be obtained for culture, white cell count and white cell differential count. Antibiotics should be stopped for at least 2 weeks prior to joint aspiration to increase successful identification of the infecting organism. Gram stain of a joint aspirate is not of proven value.

Bone scan sensitivity can be improved by the combination of a delayed white cell scan or monoclonal antibody white cell scan but all scanning techniques, including positron emission tomography scans, have a specificity for infection of approximately 80%. A negative bone scan virtually rules out infection.

Once an infection is confirmed, treatment is determined by the organism and the time since operation. If the infection occurs within the first 4 weeks of the total knee replacement then debridement of the knee and exchange of the polyethylene bearing can be considered otherwise complete revision of the implants in one or two stages is most likely to achieve eradication of the infection. In patients who are deemed not fit for surgery then suppressive antibiotic therapy plus knee aspiration may allow retention of the
prosthesis. However this may lead to bacterial resistance causing further infective episodes. Identification of the causative organism is key to targeting any infection with appropriate antibiotics.

**Box 8.7.2 Prosthetic infection**

- 1–2% prosthetic infection rate at 1 year after surgery
- Two-thirds of prosthetic infections occur within 1 year of surgery and are likely to be the result of surgical bacterial contamination
- Debridement and polyethylene exchange within 4 weeks of surgery may allow retention of the knee prosthesis
- In comparison with a single-stage revision a two-stage revision gives a higher chance of eradication of prosthetic infection (75% vs 90%)
- Sensitivity and specificity for infection increased by combination of investigations including:
  - Serological markers (CRP, ESR, and interleukin 1)
  - Knee aspirate for white cell count and differential ± arthroscopic biopsy
  - Triple phase bone scan + white cell labelled scan.

**The stiff knee (Box 8.7.3)**

Postoperative stiffness is often accompanied by pain and although definitions vary, its prevalence ranges from 1.3–12%. The definition of a range of movement less than 90 degrees at 6 weeks after the operation is often used.

Each patient with postoperative stiffness requires careful evaluation to assess the relevant contribution of patient factors, surgical errors, implant design, knee kinematics, perioperative complications, and postoperative rehabilitation.

**Patient factors**

Factors predictive of stiffness are confounding and vary between sexes but include high body mass index, previous knee surgery, patients on disability, diabetes, depression, and pulmonary disease. Stiffness is also more common in women, and women of a younger age with a low body mass index, high femoral flexion angle, and patella baja.

Preoperative range of motion influences postoperative range which is independent of prosthesis design. The presence of a preoperative flexion contracture contributes more to decreased range of movement postoperatively than reduced overall preoperative motion.

**Intraoperative technical errors**

A tight extension gap may result in a flexion contracture and a tight flexion gap or incorrect collateral ligament balancing may limit flexion. Oversizing or posterior placement of the femoral component can tighten the flexion gap whereas undersizing or anterior placement can increase the flexion gap and create mid-range flexion instability. Excessive femoral component flexion may impinge on and tighten the extensor mechanism in deep flexion.

Internal rotation of the femoral component can cause asymmetric tightening of the flexion gap and cause patellofemoral dysfunction.

Retention of significant posterior femoral osteophytes and/or failure to restore posterior condylar offset causes earlier impingement of the femur on the posterior aspect of the tibial component and this may limit flexion.

**Box 8.7.3 The stiff knee**

- May be defined as ≤90 degrees range of movement at 6 weeks
- Aetiology variable and includes:
  - Patient factors
  - Intraoperative technical errors
  - Implant design
  - Postoperative complications
  - Postoperative rehabilitation.

Patella resurfacing with excessive polyethylene thickness and implants with an increased trochlea height or similarly an anteriorly placed femoral implant can lead to overstuffing of the patellofemoral joint.

Elevation of the prosthetic joint line can cause patellar–tibial component impingement or midflexion instability.
Incorrect positioning of tibial implants which have a posterior slope can create a coronal malalignment and collateral ligament imbalance. Internal rotation of the tibial component can cause patellofemoral dysfunction. Excessive tibial polyethylene tightens both the extension and flexion gaps.

**Implant design**

The influence posterior tibial slope has on knee flexion is controversial. *In vivo* studies vary and a cadaveric study has demonstrated a 1.7-degree gain in flexion for every 1 degree increase in posterior slope; conversely an anterior sloping tibial component may reduce posterior femoral rollback and also limit flexion.

*In vivo* kinematics studies demonstrate a similar pattern of femoral rollback in total knee replacements as in native knees. Implants which do not allow sufficient posterior femoral rollback create early posterior impingement of the femoral component on the tibial component and this can cause paradoxical anterior femoral translation with tightening of the extensor mechanism.

Weight-bearing kinematics have demonstrated a reduced range of flexion in posterior cruciate ligament retaining designs when compared with posterior cruciate ligament substituting designs. The evidence for increased flexion with ‘high-flexion’ knee implant designs and mobile bearings remains unclear and may be design specific.

**Perioperative complications**

Infection, periprosthetic fracture, component failure, complex regional pain syndrome (types 1 and 2), heterotopic ossification, and postoperative medical complications may all influence postoperative range of movement.

**Postoperative rehabilitation**

Positive preoperative reinforcement, multimodal pain management, and physiotherapy can improve postoperative range of motion although the last of these remains controversial.

**Treatment**

Treatment should be aimed at identifying any remediable cause. A careful history of perioperative events, review of patient risk factors, and appropriate further investigations including interventional procedures such as joint aspiration and specialized imaging techniques are often required.

Improvement in a fixed flexion deformity of certain implants can improve up to 3 years after surgery. Non-operative treatment consists of intensive physiotherapy including passive stretching devices. Botulinum toxin injections can be effective where tight muscle groups can be identified.

Certain diagnoses such as infection usually require surgery; however, with minor implant malposition the risks of removing a well-fixed implant versus the perceived benefit of successful surgery have to be assessed. The results of revision knee surgery remain poorer than those for primary knee surgery and patients may still require manipulation under anaesthesia. Furthermore, less invasive procedures such as patella resurfacing and isolated tibial insert exchange have unpredictable results.

In cases where there is no discernable cause for stiffness following total knee replacement, manipulation under anaesthetic has been the traditional treatment of choice. Controversy remains as to the timing, degree of stiffness prior to, and outcome following manipulation. Recently, no difference has been shown between manipulation within 12 weeks of surgery and manipulation thereafter with the improved flexion maintained at 5-years follow-up.

As a result outcomes vary and perioperative complications such as patella or quadriceps tendon rupture, patella fracture, and haemarthrosis can occur.

Arthroscopy of a total knee replacement allows direct visualization of the implant and soft tissue/implant-related problems can be identified; however, it can be a technically challenging procedure. Arthroscopic debridement, including posterior cruciate release and manipulation, has been shown to improve range of flexion, at least in the short term, and is usually preferable to formal arthroscopy and debridement.

**Patellofemoral dysfunction**

There remains conflicting evidence from prospective studies regarding the functional value of patellar resurfacing in primary total knee replacement.

Concerns regarding persistent anterior knee pain without patellar resurfacing favour patellar resurfacing but historically complications related to patella replacement have ranged from 4–50%. Better understanding of knee kinematics, including implant rotation, has influenced modern surgical technique and the need to resurface the patella may be more influenced by implant design. However, secondary resurfacing of the patella is the most common reason for reoperation in primary total knee replacements despite unpredictable results in the short term and poor long-term outcomes.

Careful evaluation of the patient with apparent anterior knee symptoms is therefore required before committing to surgery and should include an assessment for infection and femoral and tibial implant stability, alignment, and rotation.

**Peripheral nerve injury**
The incidence of clinical peripheral neuropathy is approximately 1.3% with isolated common peroneal injuries being more common than combined common peroneal and tibial nerve injuries. Risk factors for nerve injury differ; however, include rheumatoid arthritis, preoperative deformity (valgus/foot deformities), postoperative epidural anaesthesia, prolonged tourniquet time, and pre-existing peripheral neuropathy.

Individual experience in these injuries is low but expectant treatment is recommended with immediate local pressure relief and flexion of the affected knee to 20–30 degrees advised. Early neurophysiological investigations can be used to distinguish between nerve dysfunction and muscle dysfunction but are not prognostic of outcome. Immediate exploration of the nerve is not recommended unless a haematoma is suspected. Prevention of muscle contracture by early aggressive splintage and passive stretching is important regardless of the ultimate outcome.

Overall results are encouraging, in cases without nerve transection, with most patients showing some signs of recovery and up to two-thirds of patients with complete recovery occurring up to 18 months after initial injury. Dysaesthesia in the common peroneal nerve distribution can be improved by decompression of the peroneal nerve.

Nerve injury can occur during any knee replacement surgery therefore attention to surgical detail such as careful retractor placement and avoidance of over releasing of soft tissue and excessive polyethylene insert thickness and care when applying dressings should be exercised at all times. Exploration, identification, and protection of the peroneal nerve intraoperatively have not been shown to reduce the risk of nerve injury.

Dysaesthesia in the common peroneal nerve distribution can be improved by decompression of the peroneal nerve. Nerve injury can occur during any knee replacement surgery therefore attention to surgical detail such as careful retractor placement and avoidance of over releasing of soft tissue and excessive polyethylene insert thickness and care when applying dressings should be exercised at all times. Exploration, identification, and protection of the peroneal nerve intraoperatively have not been shown to reduce the risk of nerve injury.

Vascular injury (Box 8.7.4)

Acute occlusive vascular problems are rare (0.03–0.2%) after total knee replacement. Patients with a history of vascular disease, vascular calcification as seen on X-ray, previous vascular reconstruction, and possibly popliteal aneurysms are at risk of an acute vascular event.

Pedal pulses may be clinically impalpable in 36% of patients undergoing total knee replacement. The use of a tourniquet may cause further vascular compromise and should be used with caution in high-risk patients.

Patients with an acute vascular injury typically present with a pale, cool, pulseless, and painful limb. Emergent vascular surgical intervention should be sought. The reported rates of amputation after these vascular complications range between 25–43% with most occurring in patients who have pre-existing atherosclerotic disease. An above-knee amputation is very rarely required and provides a very poor functional outcome.

Direct vascular damage can occur intraoperatively. The popliteal artery and vein, and tibial nerve, lie close to the posterior aspect of the knee and below the level of the joint the popliteal artery bifurcates and the anterior tibial artery becomes most at risk at this point. If an axial section of the proximal tibia is thought of as a clock face with 6 o'clock being anterior and 3 o'clock being lateral any penetration of the posterior tibial cortex between 3 o'clock and 11 o'clock can potentially damage neurovascular structures.

Significant bleeding problems may not be apparent until the tourniquet has been deflated. Any suspected vascular injuries require to be dealt with urgently and are easier to control before implantation of the prosthesis.

Ligament injury (Box 8.7.4)

Intraoperative collateral ligament disruption, as demonstrated by sudden ligament laxity, traditionally required conversion to a constrained type of knee prosthesis. However, repair and appropriate tensioning with postoperative bracing has been shown to offer a functional alternative in cases of medial collateral ligament damage.

The incidence of extensor mechanism disruption is said to be 0.17–2.5% and can be assessed with ultrasound or magnetic resonance imaging if there is clinical uncertainty as to its integrity. Treatment is determined by the level of disruption, degree of tear (partial/full), timing of disruption (acute/chronic), quality of host tissue, availability of autogenous or allograft tendon graft, and the patient’s functional demands. A reduced functional outcome can be expected.

Box 8.7.4 Neurovascular and ligament injury

- Acute vascular injury rare (<0.2%)
- 1.3% incidence of clinical peripheral neuropathy
- Common peroneal nerve injury most often injured
- Two-thirds of patients with nerve injury may recover nerve function (excluding nerve transection)
- Medial collateral ligament transection can be repaired acutely
- ≤2.5% incidence of acute extensor mechanism disruption.

Patellar tendon ruptures invariably require surgery and augmentation with either an autologous or allograft tendon graft with protected rehabilitation.

Partial quadriceps tears can be treated satisfactorily operatively or non-operatively, whilst complete tears require operative
treatment often with tendon grafting as rerupture rates can be as high as 40%.

**Venous thromboembolism**

Venous thromboembolism (VTE) is potentially fatal. Without thromboprophylaxis the risk of asymptomatic imaged deep vein thrombosis is 40–60% after total knee replacement but symptomatic VTE rates occur in only 2–5% of patients. Symptomatic pulmonary embolism and DVT occur at a mean of 12 and 20 days after total knee replacement. Thromboprophylaxis can be pharmaceutical or mechanical and most trials have shown that thromboprophylaxis reduces the incidence of all VTE events, including fatal pulmonary embolism. However, the duration and method of treatment remains controversial. Extended prophylaxis may be required for up to a month and mechanical prophylaxis is often poorly tolerated. TED stockings have not been shown to be of benefit in VTE reduction. Anticoagulants may require monitoring or parental administration and the perceived risk of clinically important bleeding remains a concern to many surgeons. New oral thromboprophylactic anticoagulants such as direct thrombin inhibitor or activated Factor Xa inhibitor demonstrate efficacy at least comparable to low-molecular-weight heparin without the requirement to monitor coagulation.

**Knee joint dislocation**

Knee joint dislocation occurs in about 0.2% of all total knee replacement types. It is increased in patients with a Charcot joint, revision surgery, and complex primary surgery. The mechanism of dislocation is usually a high flexion movement and not trauma. Diagnosis is based on history and clinical examination and confirmed with x-ray. Manipulation alone usually results in a poor outcome and revision with careful attention to ligament balancing and implant sizing and rotation is advised.

**Periprosthetic femoral/tibial fracture (Box 8.7.5)**

Intraoperative fractures of the femur or tibia are rare. Periprosthetic femoral fractures occur in approximately 2% of total knee replacements whilst whilst the incidence of tibial fractures is much less. Femoral fractures have been classified into types I(a/b)–III based on distal bone quality, implant stability, and fracture reducibility. Notching of the anterior femoral shaft at the time of implantation may be associated with periprosthetic fracture (Figure 8.7.2).

![Fig. 8.7.2](Click to view larger)

Sagittal x-ray of right total knee replacement demonstrating excessive tibial slope and posterior placement of femoral component with resultant notching of femur.

Treatment should achieve a well-fixed and appropriately aligned knee replacement. Depending on the fracture configuration, quality of the bone, and the presence of an open femoral box, a retrograde intramedullary nail, a standard plate, or locking plate can be considered in cases where the femoral implant remains stable (type Ib). Early results with locking plates are encouraging particularly in cases where bone quality is poor however large clinical series and biomechanical data remain scarce. Type II fractures require a stemmed revision total knee replacement to achieve implant and fracture stability. In fractures which are not reconstructable and with poor bone (type III) a distal femoral replacement may be required.

Tibial fractures are treated on the basis of implant stability and may require a stemmed prosthesis with augments.

**Periprosthetic patella fracture (Box 8.7.5)**

The incidence of periprosthetic patellar fracture is 1.19% and occurs predominantly in resurfaced patellae though non-resurfaced patellae are also at risk. The majority of fractures are not associated with trauma and fracture classification is based on the integrity of the extensor mechanism, implant stability, and the state of the remaining patellar bone stock (Ortiguera and Berry types I–IIa/b). The most common type of fracture involves an intact extensor mechanism with loosening of the patella implant (type
Predisposing patient factors for fracture include osteoporosis, osteolysis, bone loss, high activity level, knee hyperflexion, and rheumatoid arthritis. Surgically-related predisposing factors include central peg fixation and cementation, metal-backed uncemented patellae, patellar maltracking, and prosthesis malalignment.

A lateral release should be performed at a distance from the patella and removal of the prepatellar fat pad avoided to prevent disruption of the vascular anastomoses between the peripatellar and polar patella blood supplies. Patellar bone removal should be restricted as a patella with a residual thickness of less than 10–15mm is at risk of fracture.

**Box 8.7.5 Periprosthetic fracture**

- Femoral periprosthetic fractures most common (2%). Classification types I(a/b)– III
- Patella periprosthetic fracture classification: Ortiguera and Berry classification (I–IIIa/b)
- Patella fracture associated with central peg fixation, a metal-backed patella, prosthesis malalignment, and patella maltracking
- 92% failure of internal fixation of periprosthetic patella fractures
- 10–15mm minimum residual patella thickness recommended to avoid fracture.

A periprosthetic patellar fracture with disruption of the extensor mechanism presents with loss of active knee flexion; however, most cases present with no extensor mechanism disruption and require a radiological diagnosis.

Periprosthetic patellar fractures with a stable implant and intact extensor mechanism require a period of immobilization until radiological healing is demonstrated.

In the more complex cases with a disrupted extensor mechanism, open reduction and internal fixation has a very poor outcome with failure rates of 92%. In this situation excision of the avascular fragments and repair of the extensor tendon should be considered. If revision of the patella is not possible then partial/complete patellectomy should be considered.

**Developments in total knee replacement surgery**

Recent advances have seen the introduction of computer assisted and minimally invasive knee surgery and these have led to an increase in the complexity of surgical technique. Such innovations raise concerns about the risk of both traditional intra- and postoperative complications as well as some new to the individual technique. There is a significant learning curve for each innovation and longer operative times can increase infection rates, blood loss, or thromboembolic events.

**Minimally invasive total knee replacement**

Various minimally invasive surgical exposures exist and evidence from larger series, performed by technique enthusiasts, show comparable complication rates to traditional total knee replacement. A learning curve has been defined; one study demonstrated a 16% decrease in the major complication rate for each additional 50 procedures performed. Decreased intraoperative exposure can increase the risk of ligament damage, neurovascular injury, and intraoperative fracture. Inferior radiological outcomes secondary to compromised cementation and implant malposition have been observed.

Furthermore, the improved early functional recovery reported in minimally invasive surgery may, in part, be a result of the concurrent development of newer pain control modalities and changes in postoperative rehabilitation.

**Computer-assisted knee surgery**

Evidence of postoperative outcome in computer-assisted knee surgery is restricted to small series and short-term data; however, an improvement in mechanical axis alignment of the navigated total knee replacement has been demonstrated and a reduction in polyethylene wear and subsequent revision rate is predicted as a result. A reduction in total blood loss and postoperative confusion has been shown using computer-assisted surgery but controversy exists as to the extent of fat emboli reduction which may vary depending on how the femur is instrumented in conventional knee surgery.

Computer-assisted surgery relies on surgeon input of data and an understanding of the computer-generated information as well as a general understanding of total knee replacement surgery is key. Poor data entry or misinterpretation of data can result in surgical error and inaccurate assessment of tibial prosthesis rotation is difficult with the majority of currently available systems. Potential complications exclusive to computer-assisted knee surgery include distal femoral stress fracture and vascular damage associated with tracker pin insertion.

**Conclusions**

The number of total knee replacements continues to rise as a result of increasing indications for surgery and the ageing population. Patient demographics are changing and the average body mass index continues to increase. As a result, postoperative complications may be expected to increase. However, improvements in general medical care and an increased awareness and attention to surgical detail should enable surgeons to avoid certain complications and better treat others.
The future challenge will be to reduce complication rates in a more complex patient population, embracing those technologies and techniques shown to be of benefit and identifying early those which may not, in order to prevent both immediate and late complications.

Evidence supports a reduction in complication rates with an increased individual volume of knee surgery and a future trend may be for more individual knee specialist surgeons. However, controversy remains regarding the incidence, appropriate diagnostic intervention, and treatment of certain complications and evidence from numerically large and appropriate studies is often lacking. The increase in available arthroplasty registry data may provide some answers and allow observation of trends and monitoring of the effects of changes in surgical practice and implant design.

Revision total knee replacement

Summary points

- Understanding the reason for failure of the original knee replacement is crucial prior to revision
- The surgery should be a revision and not a repeat of the failed arthroplasty
- There are eight reasons for failure of original knee replacements which should each be approached individually
- Unexplained pain relating to a knee replacement requires further investigation before revision surgery can occur
- Successful revision surgery is performed in three steps – preparation of a tibial surface, the knee in flexion and the knee in extension

Introduction

No aspect of knee arthroplasty surgery has advanced more in the last decade than revision surgery—although the comparatively few revisions performed have left much of this information unappreciated in the literature. Repeat surgery was initially not considered feasible, and was then performed (and reported) identically to primary replacements. Eventually, special implant techniques and prosthetic systems emerged. A strong argument can be made that (with the exception of cases of infection and extensor mechanism allograft) the results of contemporary first revision arthroplasty, with the techniques described in this chapter will prove at least as, if not more, durable than current primary replacement. The same cannot be said for a second knee revision, emphasizing the importance of the initial opportunity. Given current population demographics and primary arthroplasty rates, a significant increase is expected in the need for revision knee arthroplasty.

A detailed understanding of how knee replacements fail is central to planning a successful revision. This means that a clear diagnosis and a deep appreciation of pathophysiology and biomechanics are essential. This information comes from a comprehensive literature, which cannot be quoted in depth in this format. However, the reader is directed to a few pertinent review articles which are a broad guide to the published data.

New appreciation of the rotational positioning of tibial and femoral components, quantifiable by computed tomography (CT), has implications for all patellar complications and not just tracking, instability, stiffness, and pain. Revision implant systems differ fundamentally from those that work well in primary surgery, with stem extensions, modularity, porous metals, and constrained articulations that enable surgeons equipped with the correct information, to help patients who were once consigned to pain clinics, or worse, arthrodesis and amputation.

The role of revision surgery is not simply to treat the older patient with a ‘worn out’ arthroplasty. Rather, it is the key piece in a strategy to ensure that the younger active patient, who may now be receiving a unicompartmental replacement, can be assured or worse, arthrodesis and amputation.

Principles of revision total knee arthroplasty (Box 8.8.1)

Several principles underpin revision knee arthroplasty surgery:

1) Establish a diagnosis. This must emerge from a systematic, disciplined, and comprehensive approach to the problem knee replacement. The diagnosis should fit into a well-established ‘differential diagnosis’, and novel explanations for pain should be resisted. Infection must be considered in each case and a specific surgical plan should flow from the diagnosis. ‘Revision knee arthroplasty’ is not one, but several different operations depending on the cause of failure. A diagnostic algorithm may be established or a checklist consulted to ensure that nothing is overlooked (Figure 8.8.1)
2) ‘Revise’ the failed arthroplasty, do not simply perform a repeat operation. As such, revision describes a process of identifying what led to the initial failure and ensuring that an operation is conceived that will eliminate the causes of failure
3) Use revision implant systems. This does not mean a constrained or hinged implant every time. It does, however, mean a modular system that provides good options to ensure fixation with stem extensions, stability with a range of constraint options, and bone restitution with augments
4) The femur controls the soft tissues in the knee. That is to say, whatever we do with the tibial component will affect both the flexion and extension gaps of the knee equally. Furthermore, it is mainly the size (and to a lesser extent the position) of the femoral component that controls the flexion gap of the knee. By contrast it is the proximal-distal position of the femoral component that controls the extension gaps. This simple observation is the key to revision surgery technique (Figure 8.8.2)
5) Do a complete revision in virtually every case. Following from principle 4, if we do not revise the femur, we cannot control the soft tissues. If the tibia is exposed with the femoral component in place, collateral ligaments often stretch and sometimes fail. The resultant instability cannot be managed by revising the tibia alone, especially in the extreme case where constraint is required. Furthermore, the lateral condyle of a femoral component, with the knee flexed, impinges on the posterolateral corner of the tibial component threatening to rotate it internally.

- Revision of the femur alone can be considered if the tibial component is ideally rotated (with a confirmatory CT scan) and there is clearly no need for constraint. Cases of loosening usually result from osteolysis, which affects the entire joint and is not restricted to one component. Revising one loose component today is often followed by loosening of the
Complete revision, grafting of osteolytic defects, and elimination of an articulation that generates wear debris is more likely to succeed long term. Complete revision does not require finding compatible parts; it addresses the problem completely and is usually faster.

6) Employ a surgical technique that couples the tibia to the femur, using the existing soft tissues. Accept that these tissues may have stretched or contracted and cannot be expected to resemble either what used to be or what is on the contralateral joint. Accordingly, do not choose component size as a function of the prerevision radiographs of either knee.

**Box 8.8.1 Principles of revision total knee arthroplasty (TKA)**

- Establish a diagnosis
- ‘Revise’ the failed TKA—do not simply perform a repeat operation
- Use revision implant systems
- The femur controls the soft tissues and therefore the gap balance
- Do a complete revision
- Use a technique that ‘couples’ the tibia and femur through existing soft tissues.

**Fig. 8.8.1**
Revision TKA worksheet.

**Fig. 8.8.2**
Femoral component size and position. The key to revision TKA surgery.

**Failure modes and prerevision evaluation (Box 8.8.2)**

There is a coherent argument for eight modes of failure (see Figure 8.8.1) that are amenable to revision arthroplasty and a ninth category (unexplained pain) that is an indication for further investigation and temporizing, but not surgery. All the cases within one diagnostic category will present with similar problems and respond to similar techniques. All can be managed with the ‘3-step technique’ described in this chapter.

**Surgical exposure (Box 8.8.3)**

Early challenges and catastrophes resulting from difficult surgical exposures led to the development of special, more involved techniques to avoid damage to the extensor mechanism and yet provide full access to the joint. Some of these divide the soft tissue of the extensor proximally and others detach the tuberosity distally. Initially, the very old ‘Coonse–Adams’ quadriceps...
tendon ‘turn-down’ was adapted to knee arthroplasty surgery (Figure 8.8.3A). While sparing the patellar tendon attachment, it is aggressive and now largely obsolete, except for the most extraordinary circumstances. More limited manoeuvres, such as the ‘quadriiceps snip’ or quadriiceps ‘split’ often suffice (Figure 8.8.3B). An oblique (inferomedial to proximal lateral) arthrotomy of the quadriiceps tendon has been described, but does not differ substantively from the ‘snip’. Any transection of the quadriiceps tendon close to the patella should be avoided.

Some surgeons prefer proximal soft tissue procedures and others the tubercle osteotomies. The osteotomy, while providing superb exposure, is best employed where adequate tibial bone quality ensures union. This is often not the case in the difficult revision, with intramedullary stem extensions and methacrylate cement (Figure 8.8.3C). Calamity may ensue when an osteotomy fails, as the extensor mechanism is in jeopardy.

The danger of forcing exposure is primarily to the extensor mechanism, where avulsion of the patellar tendon from either the tubercle or the patella is irreparable. The common practice of placing a pin through the tendon and into the tubercle does not reduce the force applied by an aggressive approach and risks tearing the tendon when enough force is applied. ‘Peeling’ of the insertion, though not universally accepted, is preferable to a transverse tear.

Box 8.8.2 Modes of failure

1. Sepsis
2. Extensor mechanism rupture
3. Stiffness
4. Tibial–femoral instability
5. Periprosthetic fracture
6. Loosening
7. Patellar complications and malrotation
8. Breakage
9. No diagnosis (no surgery).

Collateral ligaments may suffer from forceful exposure where they are torn or ripped from the condyles. Though inelegant, this can be corrected with constrained implants and indeed a purposeful removal of the collaterals from femoral condyles has been described for arthroplasty in the stiff knee, where it is referred to as a ‘femoral peel’.

The best new information regarding surgical exposure in revision knee arthroplasty emphasizes the importance of patience and attention to detail. No aggressive manoeuvre should be invoked until there has been close attention to detail. The vast majority of cases, including stiff arthroplasties and reimplantations for infection can be exposed fully after:

1) Complete synovectomy
2) Resection of thick scar on the undersurface of the patellar tendon
3) Re-establishment of the parafemoral ‘gutters’
4) Transection of scar between the anterior femur and the deep quadriiceps with long-handled scissors
5) Release of the (deep) medial collateral ligament if indicated
6) External rotation of the tibia and
7) Gentle manipulation to stretch the quadriiceps and
8) Removal of the modular polyethylene.

It may not be necessary to fully evert the patella for revision surgery (Figure 8.8.4).
Numerous techniques and ‘tricks’ have been described for the removal of well-fixed arthroplasty components. A cautious approach that preserves bone is sound, but time must also be conserved as infection rates increase with longer surgery.

In general, the former sequence of component removal from cement followed by cement removal from bone can be expedited, in favour of sawing between the cement and bone. Simple techniques with a minimum of specialized equipment are useful. Very few components cannot be removed with standard reciprocating and oscillating saws, a narrow curved osteotome, half a dozen old flat osteotomes, mallet, punch, and perhaps one offset chisel.

Component removal (Box 8.8.4)

The femoral component is immediately more accessible and once off makes it simpler to remove the tibia. A ‘reciprocating saw’ fits easily into the anterior, distal, and chamfered interfaces of both cemented and uncemented femoral components (Figure 8.8.5). A narrow curved osteotome reaches between the posterior condyle and bone, where the saw cannot go. A mallet blow via a ‘punch’ placed on the most superior edge of the femoral flange will easily dislodge the component once the interface is disrupted. Gigli saws, once favoured by some, may be difficult to control—excess bone is removed if the saw strays. ‘Axial slap hammer extractors’ once considered essential are not always available and will be difficult to attach to (right and left) asymmetric femoral components. They tempt the surgeon to remove the component (and consequently bone) with force before fixation has been disrupted.
Fig. 8.8.5
Component removal. A) Reciprocating saw to anterior, distal, and chamfered interfaces. B) Narrow osteotome to posterior interface. C) Mallet and punch to anterior flange to remove femoral component. D) Stacked osteotomes to remove tibial component.

Special situations arise where femoral components must be removed (revision of a revision) that are attached to stem extensions. In general, if the modular junction can be unlocked by the removal of locking screws, it will be advantageous to remove the component itself first. This exposes cement around the stem extension. Uncemented stems may come out with the component but if not, removal of the component enables the surgeon to work on the stem extension fixation directly. Once this has been done, the component may be reattached to the stem, providing an excellent grip. Alternately, only the axial screw may be reattached to the stem and a ‘slip hammer extractor’ applied to the screw and stem. Ultimately, a fully cemented long stem (which is not recommended for precisely this reason) may require an extensive anterior femoral window to remove cement and extricate the stem.

Tibial components may be approached with the large oscillating saw first, cutting between the bone and the cement to save time. Access will be limited by appurtenances (keels, pegs, spikes) on the underside. At that point the reciprocating saw, with its narrow blade, helps but often cannot access the posterolateral corner, where an offset chisel works well, introduced from the medial side. The keel, though still fixed, will usually yield to ‘stacked osteotomes’ that gradually lift the component out of the residual cement mantle (Figure 8.8.5D). Special circumstances, such as extrication of the fully cemented porous-coated stem extension—now rarely encountered—may require creation of windows in the metal tibial surface to access the fixation interface.

Patellar components, if made exclusively of polyethylene are easily removed. An oscillating saw cuts between the cement and the bone, severing whatever posts penetrate into the patella. These are quickly dispatched with a burr, which can also be used to enlarge the diameter of the post hole and so remove all methacrylate, important in the treatment of the infected arthroplasty.

Uncemented metal-backed patellar implants may be more problematic. It is worth hammering a narrow (¼-inch) osteotome into the interface. The thicker portion of the instrument will disrupt fibrous ingrowth. True bone ingrowth may require a ‘diamond wheel’ cutting device on a ‘high speed, low torque’ hand piece to disrupt the interface and sever the ingrown posts. These can then be removed with a ‘pencil’ tipped cutting head on the same burr.

Box 8.8.4 Component removal

**Femur**
- Reciprocating saw: anterior, anterior chamfer, and distal interfaces.
- Narrow, curved osteotome: posterior chamfer and posterior interfaces
- Punch and mallet to anterior femoral flange.

**Tibia**
- Oscillating saw between cement and bone: anterior and anteromedial
- Reciprocating saw between cement and bone: anterolateral and posteromedial
- Curved osteotome from posteromedial to posterolateral interface
- Stacked osteotomies.

Key to revision total knee arthroplasty technique (Box 8.8.5)

The key to revision knee arthroplasty surgery is simple: ‘the femoral component controls the soft tissues’. This means that knee kinematics, the essential balance of stability and motion, can only be managed if the femoral component is revised. Furthermore, the flexion gap is controlled by the size and to a lesser extent, the position of the femoral component, while the extension gap is the product of the proximal distal position of the femoral component. Conventional soft tissue releases, integral to correction of deformity in primary arthroplasty, have a modest role in revision surgery—useful only when releases should have been performed in the primary, but were not.

Box 8.8.5 Femur controls soft tissues

- Flexion gap: function of femoral component size
- Extension gap: function of femoral component proximal distal position.

The ‘3-step technique’ that follows is based on these principles. The technique is really only practicable if diaphyseal engaging stem extensions are used, preferably for the entire technique but certainly for the trial reduction. These stems establish and
maintain trial component position independent of bone deficits. There are few primary instruments that work well in revision knee arthroplasty. It is almost dangerous to expect primary instruments to guide the reconstruction as the osseous landmarks that they reference from are no longer present. If the surgeon prefers fully cemented, shorter, narrower stems, they can be selected at the time of implantation—the longer tighter fitting trial components will have guided position and selection of augments.

**Fixation (Boxes 8.8.6 and 8.8.7)**

Cementless fixation has not supplanted methacrylate or the combination of methacrylate and ‘press-fit’ intramedullary stem extensions in general usage, as has been the case for revision total hip arthroplasty. A few committed practitioners have described techniques for revision knee arthroplasty without cement fixation.

Fully cemented stem extensions undoubtedly provide superb fixation (Figure 8.8.6A). They are, however, difficult to remove and by neither ‘fitting’ nor ‘filling’ the canal, they do not accurately guide position of the components. The arguments and literature against uncemented stem extensions (Figure 8.8.6B) is based on studies that have compared fully cemented stems with metaphyseal length uncemented stems. Clearly, the metaphyseal length stem is neither long enough to guide implant position nor improve fixation. Similarly, one would not expect the ‘dangling’ stem or one that does not contact the endosteum to aid fixation significantly.

**Box 8.8.6 Viable fixation strategies**

**Fully cemented metaphyseal stems**

- **Advantages:**
  - Solid fixation
  - Potential for antibiotic cement

- **Disadvantages:**
  - Does not guide position
  - Difficult removal.

**Press-fit diaphyseal stems**

- **Advantages:**
  - Guides position of components
  - Solid fixation
  - Easy removal

- **Disadvantages:**
  - Limited potential for antibiotic cement
  - Technique.

*Fig. 8.8.6*

If uncemented stem extensions are selected, cement that is limited strictly to the cut bone surface is probably inadequate as it does not provide fixation comparable to what is typically used in primary arthroplasty. The strategy that provides excellent fixation and alignment is the combination of asymmetric (to accommodate anatomy) diaphyseal length, modular stems with cement fixation extended a few centimetres, into the metaphysis (Figure 8.8.6C).
Three steps (Box 8.8.8)

Step 1: tibial platform

The tibial component, comprising one side of both flexion and extension gaps, is not useful for manipulating the dimensions of one gap relative to the other. It is, however, a ‘platform’ or ‘foundation’ from which the dimensions of both flexion and extension gaps can be established. Component position and fixation in the revision is not predicated on precise bone cuts as in the primary arthroplasty, but rather on a tight and accurate fit of an offset stem extension in the tibial canal, plus component contact with a majority of host bone. Small incongruities will be filled with cement. It will be the technique of inserting the stem extensions that determines component position. As a result, the sequence for preparing the tibial surface is:

1) A ‘rough cut’ to remove the component
2) Tibial reaming
3) An optional ‘fine cut’, based on an extramedullary guide attached to either the reamer or a trial tibial stem extension
4) Insertion of the trial tibial component.

Box 8.8.7 Non-viable fixation strategies

Fully cemented diaphyseal stems

♦ Disadvantages:
  • More fixation than necessary
  • Does not guide position
  • Destructive removal.

Press-fit metaphyseal stems

♦ Disadvantages:
  • Inadequate fixation
  • Does not guide position.

Box 8.8.8 Revision technique

1. Tibial platform
2. Knee in flexion
   • Femoral rotation
   • Femoral component size
   • Joint line
3. Knee in extension

Unless the primary knee has failed from varus alignment and loosening, most tibial components will, in this era of sound instrumentation, have been well aligned. As a result, the saw cut to remove the component should reproduce a reasonable alignment, including posterior slope, even without an instrument, by following the interface. Some surgeons will prefer a cut with minimal or no posterior slope for simplicity, but this is more likely to resect anterior bone and jeopardize the tibial tubercle. As is the case with much revision surgery, instruments that work well in primary surgery may not at revision. In the case of the tibia, extramedullary cutting guides cannot be pinned, between the existing tibial surface and the tibial tubercle and still enable resection of some bone. Pins hold poorly as the existing bone is deficient, soft, or sclerotic. Intramedullary guides are more promising in this situation, relating as they do, the position of the stem and that of the component.

The purpose of reaming is not to remove much tibial bone, but rather to measure the endosteal diameter as an indication of the best choice of stem extension. It paves the way for the insertion of a trial tibial stem and many systems may allow attachment of a tibial cutting guide to the reamer for the fine cut described earlier. The position of the reamer will ultimately be the position of a tightly fitting stem extension and as a result, the alignment of the component.

The correct reaming technique will vary with the design of the implant. However, two anatomical points are almost universally true: 1) the centre of the tibial diaphysis (on an AP radiograph) is medial to the centre of the cut bone surface and 2) the canal is anterior (on a lateral radiograph) to the centre of the cut tibial surface. For the reamer and stem extension to sit centrally in the diaphysis, the entry hole must be anterior and medial. The natural asymmetry of the tibia can be replicated expeditiously by placing an offset tibial stem extension in the canal medially, with the component oriented laterally on the cut bone surface above. When this trial component is inserted, the stem should fit nicely in the canal, the component will be centred on the cut bone surface, and neutral alignment preserved (Figure 8.8.7).
Fig. 8.8.7
Neutral alignment preserved with lateral offset of both tibial and femoral components.

Applying the trial component upside down to the proximal tibia is a quick way to assess component sizing. Tibial templates that position punches and drill guides often do not fit on the irregular bone surface or cannot be held by pins in bad bone. They can be dispensed with in many cases, and the proximal tibia shaped with a rongeur or broach.

Maximizing tibial coverage is far less important than achieving correct rotational positioning and soft tissue coverage. Surgeons intent on maximizing tibial coverage will be tempted to rotate the component internally, to cover the larger posteromedial corner of bone. Revisions of the stiff knee may be complicated by an uncomfortably tight closure of the medial capsule—a situation that can be improved by undersizing the tibial component slightly and removing a small amount of medial tibial bone.

Step 2: knee in flexion

We can build the flexion gap, with the tibia as a foundation, and then match the extension gap to it. With the knee flexed to 90 degrees, we will: a) establish the rotational position of the femoral component; b) select the size of femoral component (anteroposterior dimension) to restore stability through the collateral ligaments when possible; and c) evaluate how this femoral component and a tibial insert affect the relationship between the patella and the joint line.

Step 2a: rotational position of the femoral component.

Ideally, the medial to lateral axis of the distal femoral component will be placed parallel to the transepicondylar line. The epicondyles, obscure in ideal circumstances in the primary replacement, will be more difficult to locate in the revision. Nonetheless, they are the best indicators of correct rotational positioning, especially as there will be no posterior articulation and no trochlear groove or ‘Whitesides line’ to reference from. Preoperative CT will prove reassuring at revision surgery: the rotational position of the failed femoral component will have been quantified preoperatively and either replicated if acceptable or corrected if not.

Another, somewhat vague guide to rotation will be the residual posterior condylar bone, palpable in the back of the femur. Once the internally rotated component is removed and assuming symmetric bone loss, there will be more residual bone on the posteromedial side. This finding indicates a need for a posterolateral augmentation block to correct internal rotation. Finally, if rotation is off, the patella will track laterally; another indication for a corrective posterolateral femoral augment, assuming the tibial component has been oriented to the tibial tubercle.

An expedient way to visually and mentally commit to the desired rotational position for the femoral component is to create the intercondylar box cut at right angles to the epicondylar axis before reconstructing the flexion gap. Virtually every revision knee component will require some type of box cut and a minimum of instrumentation is required. The width of the box can be marked on the distal bone and a modest depth created. By the technique described here, we will not yet have decided where to seat the femoral component, proximally to distally until Step 3. The box bone, once removed, can be used as graft, whereas if the canal is drilled or reamed early, this bone will be destroyed. The notch, once created, is an unmistakable reminder of the desired rotation.

Step 2b: choose femoral component size to stabilize knee in flexion

The first of our ‘keys to revision surgery’ has not yet been implemented: the flexion gap will be ‘controlled’ by the (anteroposterior) size of the femoral component and to a lesser extent by its position. The largest component that can be sensibly implanted will be the one that extends from medial to lateral across the distal femur—any larger and it would overhang unacceptably. The maximum size might be necessary in the revision of a knee with flexion instability, where the flexion gap needs to be reduced. In most cases a size similar to the failed component will suffice. Sometimes (especially in revising the stiff knee with poor flexion) one or two sizes smaller may be appropriate. An easy way to assess the largest usable component is to place the trial component, articulation against distal bone, to compare medial lateral dimensions. It should be clear that the femoral component is never
selected primarily for its medial–lateral fit, but rather for the effect that the anteroposterior dimension has on the collateral ligaments.

When the femoral canal is reamed, there is a tendency to enter the bone posteriorly and to lower the arm holding the reamer. As a direct result, the reamer assumes a ‘flexed’ angle relative to the medullary canal. This leads to impingement of the tip of a long press-fit stem on the anterior endosteum, which may give the impression of a tight press-fit, but which actually limits the diameter of the stem extension to something smaller than would be accomplished with parallel implantation. Most revision knees, if the femur is reamed parallel to the anterior cortex, will require some form of anterior augmentation on the femoral component (Figure 8.8.8).

Fig. 8.8.8
Anterior entry point of femoral reamer often results in need for anterior augmentation.

Press-fit stem extensions ultimately become ‘implantable instruments’. By lodging in the diaphysis, they ascertain alignment relative to the (distal half) of the femoral canal. Even if a surgeon prefers shorter, smaller diameter stems that will be fully cemented, using longer (i.e. 200mm for the femur) trial stems at this stage, as a means of determining alignment, position, and accordingly, the necessary augmentation, will help achieve the desired component position. The reaming technique can be manipulated (described later), to alter intramedullary stem position and arthroplasty alignment. If greater modification is required, then smaller diameter fully cemented stems will be required. At this point the stems in the femoral canal position the femoral trial reproducibly. A trial tibial articular polyethylene is required to stabilize the joint in flexion.

If the knee cannot be stabilized in flexion despite the use of the largest possible (extends from medial to lateral) femoral component, a very thick articular polyethylene and perhaps even block augments on the tibial baseplate, it is clear that the collateral ligaments are absent or have suffered plastic deformation. This is the first of two, specific indications for a constrained implant. If the extent of instability in flexion exceeds the ‘jump distance’ of a non-linked constrained articulation, this is an indication for a ‘linked constrained’ device or ‘hinge’.

Step 2c: assess joint line relative to the patella

With the femoral component size and anteroposterior position established, the tibial articular surface that provides stability will also create a ‘joint line’ in flexion. There should be no confusion about the concept of joint line—it is not simply a two-dimensional ‘line’, but rather a three-dimensional ‘shape’ corresponding to where the tibia and femur articulate—from full extension to maximal flexion. For the purpose of revision knee arthroplasty and assuming a relatively ‘normal’ patellar tendon length, the joint line can be evaluated relative to the inferior pole of the patella.

A sound revision can be created from more than one size of femoral component, even if positioned identically in the anteroposterior plane (as viewed on a lateral radiograph). The flexion gap can be stabilized with a larger femoral component and a thinner articular polyethylene or alternately with a smaller femoral component and a thicker polyethylene. Both will be stable, but in the latter scenario, additional distal femoral bone would need to be resected to accommodate the thicker polyethylene in extension. The sequence of events becomes: smaller femoral component, more spacious flexion gap, thicker polyethylene, higher joint line in flexion, additional distal femur removed to accommodate thicker polyethylene, and so higher joint line in extension. The preferred combination of femoral and tibial components will be that with the best ‘joint line’. Our recommendation is that this choice be made relative to patellar height and not a landmark on the femur or tibia (Figure 8.8.9).
Step 3: Knee in extension

This final step is simple and invokes the second key to revision arthroplasty surgery: the extension gap is controlled by the proximal–distal position of the femoral component. At this point all the components have been selected and positioned on press-fit stems. The tibia cannot move, but by slowly and gently extending the knee, the femoral component will be pushed into the distal femur to precisely the point that it needs to be in order to make the extension gap equal to the flexion gap. If we push too far and place the knee in recurvatum, the femoral component will have migrated too far proximally into the femur. If we fail to eliminate a flexion deformity, the femur will be ‘too proud’ on the distal femur and the deformity will persist. Trial femoral components that include cutting slots facilitate this step. Small cuts on the residual, irregular bone once the knee is fully extended will create, millimetre for millimetre, the correct space to accommodate an augment that guarantees the position we require (Figure 8.8.10).

How important is joint line height?

The earliest revision knee arthroplasties were performed with primary implants under challenging circumstances. With neither stem extensions nor augments in that era, surgeons were almost obligated to select the femoral component size that would fit the residual bone, once the failed implant had been removed. As we know from Step 2c of the revision technique described in this chapter, a smaller femoral component would necessitate a thicker polyethylene insert and inevitably an elevated joint line in flexion. To stabilize this knee, distal femoral bone loss either would have to be ignored to accommodate the tibial insert or, perhaps, distal femoral bone might be resected to achieve full extension. The results of early revisions were poor and the most glaring abnormality on postoperative anteroposterior radiographs was bizarrely thick polyethylene and an elevated joint line. The first efforts to remedy this situation led to a surgical technique that began by establishing the distal position of the femoral component, i.e. the (distal) joint line (or the joint line at full extension) as a preliminary reference point for the entire reconstruction. This was usually a calculated distance from an osseous landmark—often the fibular head. This strategy, though an improvement, did not address stability of the knee in flexion or recognize that there is a joint ‘line’ for every position of the knee from full extension to maximal flexion, because of the state of the soft tissues.

An illustration of the challenges of revision knee arthroplasty is to visualize a very badly failed knee replacement—perhaps a second revision or even a resection arthroplasty about to be reimplanted. The cruciate ligaments will have been long gone and the soft tissue balance is likely to have suffered plastic deformation or contracture. The hypothetical questions then become: if all normal bone and articular cartilage were restored in such a knee, and the compromised soft tissues left as they are, would this knee function well? Would it be both stable and mobile? After all, the original anatomical joint line would have been restored perfectly in all three dimensions. The reality is that the state of the soft tissues limits the ability of such an anatomical restoration of the joint line to work well in every case.

In contrast, a surgical technique that accepts that the envelope of soft tissue around the knee joint is likely to have changed, and that is based on the selection of femoral component (controlling as it does soft tissue tension) is much more likely to be succeed. Revision arthroplasty then becomes very much like pitching an unfamiliar circus tent, where poles are brought inside the collapsed structure and the outer fabric is erected. Simply stated, the joint ‘line’ is not a line but rather a complex three-dimensional construct corresponding to the contact of the tibia with the femur through an entire arc of motion. It corresponds to the shape of the femoral component articular surface. There will be a joint line in flexion and extension and everywhere in between. Even restoration of a joint line that is normal in three dimensions may not produce a good joint. Pragmatism with respect to the state of the soft tissues is needed.
Step 4: the patella

The patella is best reserved for the end of the case because once the old patellar implant is removed the patella itself is more vulnerable to fracture. A treatment algorithm can be established (Figure 8.8.11) initially based on whether the implant is loose. A well-fixed patellar component that articulates compatibly with the revision femoral component should be left in place, unless the revision is being performed for stiffness and the entire construct is inordinately thick. Patellae with loose components may have adequate bone that would make revision feasible. If the residual bone is thin and perhaps scaphoid in shape (if only the anterior cortex is left) then reconstitution with particulate bone graft and a tensor fascia lata cover can restore thickness. Alternatively the residual patella can be split from superior to inferior and both halves of the shell ‘cracked up’ to recreate a more conforming shape—the so-called gull-wing osteotomy. Newer porous metal implants, though more expensive and time consuming, produce excellent results and have largely supplanted the first two options. If the patella is too small, it may be left as is or reshaped slightly to enhance tracking. The patient with an extremely small or no patella, who suffers an extensor lag postoperatively, may benefit from an extensor mechanism allograft.

Mode of failure 1: infection (Box 8.8.9)

Diagnosis of infection

Infection continues to be one of the most perplexing calamities to complicate knee arthroplasty surgery. The infection rate should be no greater than 2% and in most centres 0.5–1.0%. An aggressive and organized approach to the management of wound problems is essential to mitigate the risk of deep sepsis. The surgeon should also surrender early to the idea that the arthroplasty might be infected and act decisively so that a diagnosis will be established and not simply obscured by undisciplined use of antibiotics.

This means that all wound problems be taken seriously, as many cases of deep sepsis originate with superficial problems. Whilst many surgeons hesitate to aspirate an arthroplasty for fear of introducing infection, it is only by knowing what is inside the joint that therapy is likely to prevail. There is a strong rationale to aspirate any arthroplasty with late pain or an early wound problem before any antibiotic is administered. Introducing antibiotic without an aspirate compromises the prompt diagnosis of sepsis.

The knee presenting with pain months to years after the primary, whose history does not specifically arouse suspicion of infection and whose peripheral blood test for erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) is normal, may not require aspiration. When fluid is aspirated it should be sent not only for culture and sensitivity, but also for a cell count and differential. Solid evidence exists in the chronically painful knee, that white blood cell (WBC) counts in excess of 2500/mL, especially where there are more than 50% polymorphonucleocytes are consistent with deep sepsis. This may not pertain in the first few weeks after surgery.

Two stage versus one stage

There is almost universal agreement that a two-stage reimplantation protocol cures more infected knee replacements. Nonetheless, the appeal of ‘single-stage’ reimplantations is undeniable and is the practice of some surgeons. The debate lies in the relative success rates of both procedures. Common to both procedures is the importance of a precise bacteriological diagnosis and antibiotic sensitivity as well as an aggressive and complete debridement. It is good practice to obtain a radiograph (that images to the ankle) in the operating theatre with the patient still anaesthetized, once the surgeon feels that all foreign material has been removed. This often reveals more cement, frequently in the patella lug holes or the tibial metaphysis. Ultimately, and judicially, a radiograph that demonstrates ‘no foreign material’ is compelling evidence that the surgeon has understood and complied with a principle of treating infected arthroplasties: that all foreign material be removed. In addition, this radiograph will show bone deficiency in a way that is not feasible once a spacer has been implanted, and facilitates planning the reimplantation.

Two-stage reimplantation protocols represent the standard of care in most countries. Eradication of sepsis and acceptable knee function have been achieved with, in general, a 6-week period after the infected arthroplasty was removed during which the patient receives antibiotic therapy. Most surgeons use some type of antibiotic-impregnated methacrylate spacer and good results have been described with solid (non-articulating) spacers as well as those that resemble an arthroplasty and permit some motion.
surgeons endorse autoclaving and reimplanting one or both of the implants that have been removed using limited fixation and antibiotic-impregnated cement. The rationale is to maintain motion and facilitate the reimplantation. To date, no compelling evidence exists that would suggest that any particular approach to ‘spacers’ has either better function or increased survival. While early reports on two-stage protocols included reimplantation at 6 weeks, immediately after antibiotic therapy was concluded, recent practice has included waiting, with the patient off of therapy for durations of weeks to months and reaspirating prior to reimplantation. No data demonstrate superiority of that concept to date.

Reimplantation surgery will challenge even the most experienced surgeon. Careful attention to detail in the surgical exposure (see earlier) will pay dividends. Tubercle osteotomies in this situation may be problematic—especially if performed for both the removal and reimplantation. Bone quality is compromised and any hardware, even wires, left to hold the osteotomy runs against the principle of removal of all foreign material. The tubercle, ultimately implanted against stem extensions may not heal solidly, representing then a case of prior sepsis and extensor mechanism rupture.

**Box 8.8.9 Mode of failure 1: infection**

**Diagnosis**
- Suspicious history
- Aspiration:
  - WBC > 2000 WBC
  - Polymorphonucleocytes > 50%
  - Positive culture.

**Treatment**
- Remove all foreign material
- Confirm radiographically
- Spacer: static or articulating.

**Reimplant**
- After 6 weeks of antibiotic therapy
- ± Period off antibiotics.

The aggressive debridement, necessarily including curetting of the canal and wholesale removal of suspicious bone often leave the surgeon with challenges of bone defects and fixation. Porous metal augments advantageously address both issues and are very useful in reimplantation surgery. Fully cemented stem extensions have the advantage of excellent fixation and can include antibiotic, though less of a dose than can be used in spacers, because of the compromise to the mechanical properties of the cement. If the reimplantation suffers persistent or recurrent infection, removal of fully cemented stems may be a destructive prelude to amputation.

My preferred technique is a disciplined approach to establishing a bacteriological diagnosis, aggressive debridement on the removal, reimplantation at completion of the course of antibiotics without cessation of antibiotic therapy, long uncemented stem extensions and porous metal conical augments to enhance fixation whether large defects are present or not.

**Mode of failure 2: extensor mechanism rupture (Box 8.8.10)**

Acute or intraoperative ruptures of the extensor mechanism, often become chronic extensor ruptures until some tissue substitute, either an allograft (complete tibial tubercle, patellar tendon, patella, and quadriceps tendon construct) or autograft (semitendinosis) has been introduced. Ruptures anywhere from the tibial tubercle to the superior pole of the patella suffer similar results and this includes transverse, displaced patellar fractures with an extensor lag. This last entity should be removed conceptually from the category of fracture and treated as a chronic extensor rupture.

This is generally regarded as one of the most difficult problems to treat. The extensor rupture often occurs in an arthroplasty that is in some ways unstable. Then, when the extensor fails, global instability or posterior tibial dislocation (in flexion) often ensues. At other times, the patient with a chronically ruptured extensor will hyperextend the knee to prevent buckling. With time, this results in a recurvatum deformity. Maltracking is a common accompaniment to any patellar problem. Accordingly, revision knee arthroplasty is usually required when the extensor mechanism is reconstructed. Extensor mechanism allografts are used more frequently than other techniques and are generally successful in the short term if the graft is implanted under considerable tension. This is most likely due, not to stretching of the graft itself, but chronic retraction of the quadriceps up into the thigh during the period of rupture. If the graft is placed loosely, when the knee bends ands stretches the muscle, the lag recurs.
Mode of failure 3: stiffness (Box 8.8.11)

The stiff knee replacement is often accepted, with disappointment, by both surgeon and patient. Indeed, the patient who had very poor flexion prior to the arthroplasty probably has an extensor that is chronically scarred and tight. This cannot easily be completely overcome with revision surgery or therapy. In addition, the patient who truly has ‘arthrofibrosis’ and mounts an aggressive scar response to any surgery is unlikely to respond well to revision arthroplasty. Fortunately this is a very small minority of individuals. The majority of patients with good preoperative flexion who either bend less than 105 degrees or develop a flexion contracture exceeding 10 degrees will probably benefit from revision surgery, in particular if there is also pain. The scar that the surgeon confronts at surgery is then the result and not the cause of stiffness.

Revision is demanding for surgeon, patient, and the rehabilitation team. Once stiffness is chronic, very little will succeed short of a complete revision operation, with aggressive soft tissue release, and alteration of every feature of the knee away from stiffness towards mobility. For example, femoral components usually need to be reduced in size and implanted in neutral position (as viewed on the lateral radiograph), not flexed where they encroach on the flexion gap. Internal rotation of femoral and tibial components will be observed in the majority of stiff knees arthroplasties. The resultant tendency to patellar dislocation inhibits many patients from flexing past about 60 degrees. Those who succeed in regaining motion suffer patellar dislocations—those that don’t become stiff. CT scanning, prior to revision, to quantify rotational position is urged. Patients who undergo expert and complete revision arthroplasty, with constructive alteration of component position and size may expect welcome pain relief, full extension and flexion on average to about 100 degrees.

Mode of failure 4: tibial–femoral instability (Box 8.8.12)

The unstable knee arthroplasty is at once the most intellectually challenging and, if approached successfully the most gratifying. Central to the problem of instability are four questions:

1) In what way is the knee unstable?
2) What forces have made it that way?
3) How can surgery mitigate those forces?
4) What means are available to stabilize the knee?

The frequent and unfortunate strategy to instability is often only: ‘What constrained implant should I use?’ If the deforming forces are not reduced, instability will recur, often with dire consequences.

Box 8.8.11 Mode of failure 3: stiffness

♦ Indications for revision:
  • Flexion <105 degrees
  • Flexion contracture >10 degrees
  • Pain

♦ Assess: CT scan for malrotation
♦ Complete revision required.

The patient who reports ‘that their knee arthroplasty is unstable is suffering from one or more of the following:

♦ Buckling from extensor mechanism failure, which either belongs in ‘Mode of failure 2: extensor mechanism rupture’ or ‘Mode of failure 7: patellar complications and malrotation’
♦ Recurvatum which always raises the suspicion of extensor mechanism failure and compensatory ‘back-kneeing’. If this originates from neurological compromise of the extensor, the prognosis is bleak and arthrodesis should be considered. Extensor rupture belongs in ‘Mode of failure 2’. Structural recurvatum without neurological compromise, is generally from subsidence of a component, bone loss, and perhaps stretching of the posterior structures. This type of recurvatum will respond to revision arthroplasty
♦ Flexion instability: results from a flexion gap that is larger than the extension gap. Revision following the three steps described earlier will yield satisfying results, either by diminishing the flexion gap (larger femoral component) or by increasing
described earlier will yield satisfying results, either by diminishing the flexion gap (larger femoral component) or by increasing the extension gap (posterior capsular release with or without resection of additional femoral bone).

Varus–valgus instability from failure of one or both collateral ligaments usually requires a constrained revision prosthesis, along with realignment in the coronal plane (e.g., less valgus in the patient with medial collateral ligament failure) to reduce the deforming force. These cases may be further complicated by deformity at the hip, (developmental dysplasia or hip abductor weakness), the foot (tibialis posterior rupture and acquired flat foot deformity), and even in the spine where scoliosis can shift the centre of gravity, resulting in potent destructive forces at the deformed knee.

Some have postulated that a linked constrained device (hinge) will be necessary if the collateral ligaments have failed completely and that a non-linked device will suffice if some remnant of soft tissue envelope is present. While this may be a useful guide to some, it will fail if all the factors listed here are not taken considered.

**Box 8.8.12 Mode of failure 4: tibial–femoral instability**

- **Varus–valgus: alignment and collateral ligaments**
- **Flexion instability: flexion > extension gap**
- **Recunatum:**
  - Structural: possible to revise
    - posterior laxity
    - component subsidence
  - Non-neurological quadriceps weakness:
    - i.e. patellectomy
    - correct at revision
  - Neurological quadriceps weakness:
    - i.e. polio
    - avoid revision
    - consider arthrodesis
- **Buckling:** correct patellar instability

**Mode of failure 5: periprosthetic fracture (Box 8.8.13)**

Fractures requiring surgery are more common in the supracondylar region of the femur than any part of the tibia. Patellar fractures, if transverse, represent a chronic rupture of the extensor mechanism and belong in ‘Mode of failure 2’. Vertical patellar fractures can be treated non-surgically at first, to allow swelling and acute pain to subside. If a lag persists, or if the patellar component of a resurfaced knee is loose, surgery will be required. In most cases of vertical fracture, there will be a tendency to maltracking and these cases belong in ‘Mode of failure 7’.

Supracondylar fractures usually occur in the patient with: a) osteoporosis; b) a stress riser (in the form of a supracondylar notch), and c) limited flexion so that during a fall the knee reaches its limit of motion and then the porous bone yields. These fractures have been treated successfully in the past with both blade plates and plates with sliding screws. This was superseded by supracondylar locking nails and most recently have been replaced by locking plates with or without minimally invasive approaches.

Some low-demand patients with comminution and poor quality bone may require a revision arthroplasty either with a distal femoral allograft or more typically a tumour-style distal femoral replacement implant. Tibial fractures are generally the late sequel to extensive osteolysis and tibial component loosening. These require revision arthroplasty, not fracture fixation.

**Mode of failure 6: loosening (Box 8.8.14)**

Aseptic loosening was once thought to result from ‘micromotion’ at the interface that gradually increased in amplitude until the component came loose. Alternately, it has been attributed to bone overload and collapse. It has been correctly associated with varus alignment and the results of medial compartment overload since 1977. While some uncemented or partially cemented tibial components loosen early from failed ingrowth or inadequate fixation, and some femoral components loosen from gaps that are left between the posterior femoral bone and the femoral flange, virtually all late loosening will result from wear, particle generation, osteolysis, bone loss, and subsidence.

While partial revision with bone grafting may be appealing, the process of osteolysis is likely to progress through the joint and loosen the other components. Accordingly, complete revision is almost universally recommended. As with the unstable arthroplasty, causative factors must be identified and corrected specifically. Varus alignment is problematic, inducing inordinate forces on the medial component. A full-length radiograph showing hips, knees, and ankles is important; not only to appreciate the mechanical axis, but to plan how much valgus alignment can be tolerated to unload the medial compartment at the revision. Wear results not only from the articular surface, but the modular interface. A substandard modular locking mechanism and poor quality polyethylene may be implicated and should be replaced. CT scans depict the extent of osteolytic lesions with distressing...
Failures from osteolysis and loosening have constituted the majority of revision arthroplasties. Loosening of the revision is likely unless realignment reduces destructive forces, and fixation is supplemented by stem extensions that are either fully cemented or uncemented and fill the diaphyseal canal. The interface itself can be a problem—methacrylate cement against poor quality, sclerotic bone enjoys no interlock. By contrast, porous metal augments enhance fixation by providing a transition of interfaces from poor bone (that will yet grow into porous metal) and porous metal that on its other side accepts bone cement which provides an excellent bond to the implant. The porous implants can be impacted into the medullary canal of the tibia or femur without concern for rotational, flexion–extension or varus valgus position, so long as the augment does not impede the positioning of the component. Structural allografts, useful for massive bone defects are required less frequently as porous metal is commonly available.

**Mode of failure 7: patella and malrotation (Box 8.8.15)**

There is an ineluctable relationship between patellar maltracking and internal rotation positioning of the femoral and or tibial components. The relationship is additive, not compensatory. Furthermore, the effect of maltracking is responsible for virtually every patellar complication; as the patellar bone tries to slide off laterally and the polyethylene component stays in the trochlear groove, they may inevitably dissociate, yielding patellar fractures and component loosening or breakage. Maltracking invariably requires complete revision—the only way to correct rotational positioning of the components.

The tibial component will be correctly rotated when positioned directly behind the tibial tubercle. As the conforming articular polyethylene necessarily aligns itself under the femoral condyles, the only way that the tubercle and in turn the patellar tendon and patella itself can be positioned in the femoral trochlear groove, is to line the tibial component with the tubercle. Femoral components are most reliably aligned parallel to the transepicondylar axis—this being the only landmark available at revision surgery. A posterolateral augment will generally ensure more external rotation. These conclusions are not only logical but confirmed by the published data on CT scanning of knees with maltracking.
Mode of failure 8: breakage (Box 8.8.16)

Component breakage is far less common than previously. Some cases of tibial baseplate fracture were in fact cases of wear, osteolysis, and bone loss such that the component was unsupported and fractured. Posterior femoral condyles that have broken probably did so because of a gap between the posterior bone and an unsupported posterior condyle. Catastrophic polyethylene breakage is seen far less commonly as a result of better production methods, conforming articulations, and avoidance of thin modular inserts. Complete revision to improve both is mandatory, except perhaps in one of the few indications for partial revision—late wear of a tibial polyethylene insert in an elderly, low-demand patient.

Fractures have been reported of posterior stabilized tibial spines. Closer evaluation confirms that the mechanism is generally hyperextension of the knee so that the anterior femoral flange strikes sharply against the base of the spine. In these cases the cause of recurvatum is usually (femoral) component subsidence. These cases require a complete revision with considerations appropriate to ‘loosening’ above.

Box 8.8.16 Mode of failure 8: component breakage

- Relatively rare
- Do not include cases of wear and osteolysis—loosening
- Broken posterior stabilized spine invariably secondary to hyperextension
  - Subsidence after loosening
  - Recurvatum
  - Implantation with flexed femur and excess posterior tibial slope
- Poly wear and loss of conformity presents as late instability.

Breakage of the more prominent (and vulnerable) tibial spine on non-linked constrained implants results either from alignment leading to potent varus or valgus forces, or malrotation that can ‘twist’ the spine off the baseplate. In each case complete, corrective revision is required.

Mode of failure 9: no diagnosis (no surgery) (Box 8.8.17)

The problem arthroplasty without a coherent diagnosis should not undergo revision surgery as the results are likely to be poor. This situation is a strong indication to evaluate the patient more thoroughly. Failure to identify a problem in the knee should be a strong reminder to revisit the hip and spine, perhaps even with a bone scan. Recent ESR and CRP, as well as an aspiration for cell count and differential are appropriate. A CT scan should be obtained to quantify tibial and femoral component position.

Radiographs that predate the primary, to answer whether the patient actually had sufficiently severe cartilage loss to expect that arthroplasty would be useful, are in order. Methodical palpation of anatomical landmarks on the knee may identify neuromas or tendinitis that will more likely respond to cryoablation or physical therapy. While always dangerous to attribute physical suffering to mental anguish, there is nonetheless a literature that correlates lower satisfaction with depression.

Box 8.8.17 Mode of failure 9: no diagnosis

- No surgery—results poor
- Methodical physical examination: spine and ipsilateral hip
  - Consider:
    - Chronic regional pain syndrome
    - Tourniquet palsy
    - Limited arthritis prior to TKA
    - Occult infection
- Investigations:
Conclusions

The conceptual appreciation of how knee arthroplasties fail, the surgical technique, and the implants themselves have improved dramatically over two decades. Any one surgeon performs relatively few revisions and so many of these advances have not been incorporated into their practice. The understandable, though at times misguided, desire to perform less surgery at revision has led to worse than better results. Diagnosis, and the coherent surgical plan that flows from it, is absolutely essential. Revision knee arthroplasty is not one procedure but rather about eight different operations depending on the cause of failure. The ideas, technique, and implants that work well for primary arthroplasty generally do not apply to revisions. New ideas and a methodical approach to surgical exposure, even for stiff arthroplasties has made the need for quadriceps snips infrequent and both patellar turn-downs and tibial tubercle osteotomies almost obsolete. While attention to the level of the joint line is appropriate, using it as the guiding principle in revision surgery complicates the technique unnecessarily and should be abandoned, remembering that this ‘line’ is actually a three-dimensional concept corresponding to the shape of the femoral articular surface.

The unsolved problems in revision knee arthroplasty are still infection and extensor mechanism ruptures. While strategies exist for these problems, the long-term results are less good.

By establishing a tibial platform, stabilizing the knee in 90 degrees of flexion and then selecting the proximal–distal position of the femoral component to balance the knee in extension, with a judicious use of constrained implants, the results of first-time revision knee arthroplasties may exceed those of primary knee replacement.

Summary points

- Intra and extra-articular
- X-ray for bone or soft tissue origin
- Solid tumours consider malignancy
- MRI for diagnosis.

Introduction

The causes of knee pain are most often related to overuse or trauma. Other conditions can mimic common knee disorders and should be considered in the differential diagnosis in patients who present with a history and physical findings inconsistent with mechanical knee pain.

Synovial and bursal conditions

Synovial chondromatosis

Synovial chondromatosis is a monoarticular disease presenting more often in males, in the third and fourth decades of life. Clinically, patients present with knee effusions and episodes of locking and grinding. Radiographically, in the early stages of this disease, an effusion is present, but as the disease progresses, characteristic ‘popcorn’ calcifications are found in and around the joint (Figure 8.9.1).

Click to view larger

Fig. 8.9.1
Synovial chondromatosis—‘popcorn’ calcifications within the posterior knee joint.

Synovial chondromatosis is a metaplastic disease process whereby synovium modulates into cartilage. Hyaline cartilage coalesces on the fronds of synovium and becomes intra-articular loose bodies. When these cartilaginous loose bodies mineralize, this is called synovial osteochondromatosis.

If unrecognized, cartilage damage can occur from repetitive mechanical trauma resulting in joint arthrosis. Treatment involves either synovectomy (arthroscopic or open) and rarely in recalcitrant disease, chemical or radiation synovectomy. If intra-articular osteocartilaginous loose bodies are present, their removal in addition to synovectomy is necessary. Recurrences after synovectomy are relatively uncommon.

Rarely, malignant transformation occurs, usually marked by underlying osseous destruction and intra-articular nodular masses. Early diagnosis is important and either extra-articular resection or amputation is necessary to achieve local tumour control. Histologically, loss of the clustering growth pattern, myxoid stromal changes, necrosis, and spindling of cells in the periphery of the lobules are suggestive of malignant change. Pulmonary metastases may occur following malignant transformation.

Pigmented villonodular synovitis (Box 8.9.1)

Pigmented villonodular synovitis is a rare benign disorder affecting synovial joints and tendon sheaths. The knee is the most
commonly involved large joint. It has been regarded as a reactive process, but recent cytogenetic evidence suggests a neoplastic aetiology. Two types of pigmented villonodular synovitis exist—a localized form is characterized by a solitary lesion, whilst the diffuse form is more aggressive in nature and usually involves the entire synovial membrane.

Local disease is usually heralded by mechanical symptoms such as locking and catching. Diffuse disease is characterized by pain, swelling, stiffness, and eventually deformity. Diffuse pigmented villonodular synovitis can invade local structures extensively, including muscle, tendon, and bone, with periarticular cysts, erosions, and narrowing of the joint space. Magnetic resonance imaging (MRI) is useful in determining the nature of the disease (Figure 8.9.2). Multinodular intra-articular disease is characterized by patchy areas of fat and haemosiderin specific for pigmented villonodular synovitis.

Fig. 8.9.2
MRI demonstrating multifocal pigmented villonodular synovitis with subarticular joint destruction.

With local disease, treatment is frequently successful with marginal complete arthroscopic or local excision, but with diffuse disease recurrence is greater than 45%. Arthroscopy and open total synovectomy alone may not relieve symptoms in these patients. With active diffuse disease confined to synovium, total synovectomy can give good short-term results. However, where the disease has extended out of the joint and into bone, local disease control is difficult. Arthrodesis and total joint replacement may be necessary for patients with diffuse and destructive disease.

Radiotherapy using intra-articular instillations of fibrosing agents is effective for refractory cases. External-beam radiotherapy has been used successfully as a salvage procedure for residual diffuse disease.

Even in patients with active disease, total synovectomy with total knee replacement will give good long-term results with recurrence of disease unlikely.

Box 8.9.1 Pigmented villonodular synovitis

- Reclassified as giant cell tumour of joint
- Benign metaplastic disease
- Nodular and diffuse forms
- MRI for diagnosis
- Open synovectomy and total knee replacement for recalcitrant disease.

Cystic lesions

Soft tissue ganglia arise from capsular, aponeurotic, bursal, and ligamentous structures as a result of myxoid degeneration of collagen fibres.

Extra-articular lesions

Extra-articular ganglia are usually painless or minimally symptomatic soft tissue masses located behind the knee in the popliteal fossa and originating from the posterior capsule. These masses do not communicate with the joint and insinuate around the semimembranosus tendon and the medial head of the gastrocnemius muscle. Popliteal or Baker’s cysts are reported incidentally in 10–41% of MRI examinations of the knee. These masses can be found in children but are more commonly seen in adults, and the incidence increases with patient age. They are usually diagnosed incidentally and more commonly in adults with underlying mild to moderate arthritic changes in one or more compartments of the knee.
Synovial cysts can also arise in the tibiofibular joint and present as a painful effusion associated with restricted knee flexion and potentially compressive and invasive neuropathies of the common peroneal nerve.

**Intra-articular lesions**

These encapsulated fluid collections can also arise within the knee joint, most commonly the tibial insertion of the anterior cruciate ligament and can cause mechanical pain, restriction of motion, and locking of the knee.

Meniscal cysts arise from degenerative horizontal tears of the menisci. Lateral cysts are three to four times more common than medial cysts; however, medial cysts tend to be larger.

The best diagnostic study for evaluating cystic and cyst-like structures about the knee is MRI. These lesions appear uniformly hyperintense on T2-weighted sequences and hypointense on corresponding T1 images. Meniscal tears are also well visualized on MRI. It is important to establish a connection to the joint or aponeurotic structure because other lesions like myxoid sarcomas or synoviosarcomas can occur in the popliteal fossa and be mistaken for a common ganglion. Neurilemmomas arising from the nerve sheaths passing through the popliteal fossa can also mimic ganglia. However, these lesions are typically painful and are associated with dysesthesias when compressed or percussed. On MRI they have an elongated appearance attenuated above and below (comet sign) and are in continuity with a nerve, often exhibiting a target sign (Figure 8.9.3). Moreover, on T2-weighted sequences, they appear to be more heterogeneous with alternating bright and dark signals corresponding to intermixed cellular areas (Antoni A) and hypocellular areas (Antoni B) with superimposed haemorrhage and haemosiderin deposition in more longstanding lesions (ancient schwannomas).

Giant cell tumour of the tendon sheath is an occasional extra-articular mass occurring about the knee. Typically patients are in the fourth to sixth decade and present with pain and swelling that is mostly activity related. Giant cell tumour of the tendon sheath is a nodular form of pigmented villonodular synovitis and arises in tendons and aponeurotic structures. It is also heterogeneous on T2-weighted sequences with varying degrees of dark signal depending on the degree of haemosiderin and collagen deposition within the tumour. Histologically, there are monomorphic round to spindled stromal cells and interspersed giant cells within a collagen matrix with moderate vascularity and haemosiderin-laden macrophages. The aetiology of this tumour is unknown. Local recurrences are uncommon after marginal or even intralesional excision.

**Subchondral cysts**

These fluid-filled voids are often adjacent to cruciate or meniscofemoral insertions. Most are asymptomatic but can, on occasion, be quite extensive and painful due to subchondral insufficiency.

Radiographs show a small well-defined radiolucent abnormality that is subchondral with sclerotic borders. MRI may show a fluid-filled abnormality that is bright on T2 with little oedema in the adjacent dome. Subchondral cysts are reported in 1% of routine MRIs of the knee and treatment is not necessary.

**Congenital conditions and osteochondromatosis (Box 8.9.2)**

Congenital and developmental anomalies may result in morphological changes that clinically and radiographically can be confused with neoplasia.

Dwarfing conditions, such as achondroplasia, thanatophoric dysplasia, and spondyleepiphyseal dysplasia, because of abnormal phsyseal maturation, can cause peculiar changes in epiphyseal or metaphyseal development that may be mistaken as a tumour. Other conditions, such as chondroectodermal dysplasia or Ellis–von Creveld syndrome are associated with proximal diaphyseal exostoses. This is an autorecessive condition characterized by short stature, polydactyly, wide but dysplastic lateral tibial
plateaux, and hypoplastic nails.

Chondrodysplasia punctata or Conradi–Hunermann syndrome is an autosomal dominant condition marked by asymmetric shortening with punctate mineralization of the epiphyses among other characteristic clinical features.

Metaphyseal destruction can be observed in patients with congenital syphilis, rubella, cytomegalovirus, and toxoplasmosis. Metastatic neuroblastoma and Wilms’ tumour can also present as knee pain with corresponding destructive radiographic changes that require further clinical and radiographic staging followed by biopsy to diagnose and treat appropriately.

Multiple hereditary exostoses is also an autosomal dominant condition caused by a defect in the ossification groove of Ranvier or perichondral ring resulting in horizontal physeal growth and multiple periarticular osteocartilaginous excrescences that can be painful. These patients are of low to normal stature with abnormalities of the paired bones associated with valgus deformities of the elbows, wrists, knees, and ankles. Pain may result from tendonitis, bursitis, fracture through the exostosis, osteonecrosis of the cartilaginous cap, and malignant transformation which can occur in up to 5% of affected individuals. Malignant transformation is rare before skeletal maturity and is usually marked by increased growth of the mass associated with pain that is present with activity and rest. Other rare complications of osteochondral exostosis are compressive neuropathies, particularly around the knee, and vascular claudication, especially large lesions in the popliteal fossa.

Radiographically, osteochondral exostoses are metaphyseal or metadiaphyseal based at the ends of long bones. They typically grow away from the physis pointing away from the joint. On computed tomography (CT), a diagnostic feature is corticomedullary continuity between the tumour stalk and underlying medullary canal. The cartilage cap is usually thin, with a thickness of less than 1.5 cm; however, in a growing child and in proximal appendicular and axial sites, it can exceed 1.5 cm and raise suspicion for malignant transformation. In patients with malignant change, apart from an excessively enlarged cap, there is underlying destruction of bone and mineralization within the cap appearing as arcs and rings, stipules, or flocculations. Dystrophic calcification can be seen in tumours undergoing osteonecrosis, and the clinical appearance of acute pain along with these radiographic changes which evolve over several weeks or months can arouse suspicion for malignant transformation. Ultrasound scanning and MRI are useful in screening for malignant changes. Osteochondral exostoses can be prodigious in the proximal humerus and proximal femur, but most commonly occur as solitary masses about the knee.

Treatment is observation for asymptomatic lesions. For patients with pain, excision through the base of the stock to include the cartilage and overlying bursa is necessary. Axial imaging is important for preoperative assessment of the relationship of the mass to adjacent neurovascular structures. If malignant transformation is suspected, staging studies are necessary prior to biopsy and definitive surgical management.

**Box 8.9.2 Osteochondromatosis**

- **Autosomal dominant**
- **Paired bones**
- **Metaphyseal**
- **CT demonstrates corticomedullary continuity**
- **<1% malignant transformation.**

**Dysplasia epiphysealis hemimelica (Trevor’s disease)**

This is a rare condition characterized by epiphyseal-based osteochondral proliferation of tissue that causes pain, joint incongruity, and early arthrosis if untreated. This condition may involve more than one joint.

Radiographically, there is intra-articular osteochondral tissue growth resulting in joint asymmetry and incongruity. Fluid sensitive Short Tau Inversion Recovery (STIR) MR images show hypointense signal in the periphery reflecting the high fluid content in articular cartilage. Treatment involves resection and contouring of the joint surface to create a congruous joint. Early arthrosis is likely despite treatment and certain without.

Enchondromas are 'cartilaginous rests' arising from physeal cartilage (Box 8.9.3). The cells do not undergo scheduled apoptosis and calcification, but instead become entrapped in bone and migrate away from the physis with continued growth (Figure 8.9.4). The size varies from a few centimetres to involvement of nearly the entire shaft of a long bone. Most enchondromas are asymptomatic and recognized incidentally in the evaluation of more common traumatic and degenerative knee conditions. However, they may be biologically active following skeletal maturation and cause pain and discomfort, and thus are considered ‘active enchondromas’.

**Box 8.9.3 Enchondromas**

Endosteal scalloping of >2/3 of cortex = active disease.

Fig. 8.9.4
Typical enchondroma with extensive mineralization.

Rarely, a solitary lesion can undergo malignant transformation over time, marked clinically by increased pain, occasional pathological fracture, and a soft tissue mass. Radiographically, deep endosteal scallops, greater than two-thirds of the cortex, cortical destruction, and the presence of a soft tissue mass strongly suggest malignant transformation.

Patients with multiple enchondromas (Ollier’s disease) or multiple enchondromas associated with haemangiomasa (Maffucci’s disease) are at increased risk of developing chondrosarcoma; this risk is reported to be 25% in affected individuals.

Osteogenesis imperfecta, a disease of abnormal bone collagen, is manifest by frequent fractures and bowing deformities. In the tarda form of disease the clinical manifestations, and hence diagnosis, may not be as apparent, raising the possibility of child abuse in some children. Occasionally, fractures about the knee, particularly the distal femur, may heal with exuberant callus associated with massive swelling and be confused with an aggressive sarcoma. This diagnosis is particularly difficult for the unsuspecting pathologist, since large atypical osteoblasts with hyperchromatic nuclei coupled with mitotic activity arouses suspicion of osteosarcoma.

**Enthesiopathies—osteochoondroses**

**Cortical desmoid**

This is a common variant found in adolescent patients at or near the insertion of the medial gastocnemius muscle in the posterior medial aspect of the distal femur. Almost all are found incidentally. This abnormality is commonly mistaken for an aggressive neoplasm, specifically osteosarcoma. Radiographically, it is a cortically-based radiolucent abnormality without matrix production but with an internal sclerotic border. The well-delineated border is best seen on CT, while MRI shows a small soft tissue mass and surrounding oedema. They can be quite large and are often bilateral. Observation is the preferred treatment.

**Osgood–Schlatter disease**

This common condition occurs in young active adolescents, presenting with activity-related anterior knee pain and mild aching discomfort when sitting for periods of time. It is most common in males and is a traction apophysitis with occasional fragmentation and hypertrophic bone formation at the insertion of the patellar ligament.

Pain can be elicited by resisted quadriceps contraction and direct pressure over the tibial tubercle. Treatment consists of rest, activity modification, anti-inflammatory medicines, and isometric quadriceps exercises. Steroid injections should be avoided to prevent later patellar ligament rupture.

**Pellegrini–Stieda disease**

Avulsion injuries of the medial collateral ligament with subsequent repair may result in mineralization at or near the femoral insertion of the ligament, known as Pellegrini–Stieda disease. It is asymptomatic and found incidentally on trauma radiographs for other conditions. A remote history of injury is usually elicited, while physical examination may yield normal to mild valgus opening on stressing the knee. It should not be confused with a periarticular soft tissue mass such as synovial sarcoma or a periosteal osteosarcoma. The mineralization pattern is smooth regular and consistently located at the insertion of the medial collateral ligament in the distal femur.

**Bipartite patellae**
This is a common condition often confused with fracture and primary tumours. Unlike fracture, the edges of the bipartite patellar fragments are smooth, non-tender to palpation, and located in the superolateral aspect of the patella. This condition is best appreciated on oblique knee radiographs. There is no joint effusion unless there is an unrelated intra-articular injury or other knee pathology. In most cases, the lesion is bilateral.

### Traumatic and vascular conditions

#### Myositis ossificans

Blunt and, less commonly, penetrating injuries of the soft tissue can result in haematoma, inflammation, and necrosis of muscle and fat, which, in the process of repair, can modulate into bone formation. Patients relate a history of fairly significant trauma, most often a deep contusion. Over several weeks to months, this indurated area becomes a firm, sometimes fixed, mass which becomes progressively less painful. Restricted joint motion is common immediately after an injury but improves with time. Late pain and discomfort is usually secondary to mechanical irritation, whereas night symptoms and rest pain are not present.

Generalized soft tissue myositis with joint contractures and ankylosis can be seen in patients with acute pancreatitis and burns. Fibro dysplasia ossificans progressive can present with generalized soft tissue periarticular masses as well as joint ankylosis. This disease is transmitted in an autosomal dominant fashion, though most cases are sporadic. It is generally manifested in early childhood as a large, rapidly progressive soft tissue mass that is often confused with sarcoma. The diagnosis can be made by inspecting the hands and feet, which reveal shortened first rays. In the foot, a common feature is brachymesodactyly with a portion of the proximal phalanx fused to the head of the first metatarsal giving the appearance of a hallux valgus deformity. It is important to recognize these constellations of physical and radiographical findings to avoid biopsy or attempted resection of the soft tissue mass which may worsen the condition.

Other radiographical findings include exostoses, hypoplastic posterior spine elements, a shortened anteroposterior diameter of the cervical spine, and a shortened femoral neck. Radiographical mineralization is observed in the axial and appendicular skeleton. Knee contractures and ankylosed joints occur later in the disease. Patients generally succumb to pneumonia and respiratory failure due to involvement of the intercostal muscles and marked spine and chest wall deformity. The heart and diaphragm are spared.

Isolated myositis around the knee must be distinguished from other mineralized soft tissue masses such as surface-osteosarcoma. Radiographically and histologically, myositis is characterized by a ‘zonation phenomenon’ whereby maturation progresses from the epicentre of the lesion to the periphery. For malignant tumours, maturation proceeds from peripheral to central, thus the periphery of the tumour is least differentiated. The mineralization pattern in soft tissue sarcomas is disorganized and the radiographical pattern is ‘dystrophic’.

Like parosteal osteosarcoma, myositis ossificans can be separated or densely adherent to bone giving it a ‘pasted on’ appearance. Parosteal osteosarcoma invades the cortex of bone in over two-thirds of cases and involves the medullary canal in one-third. Both parosteal osteosarcoma and myositis ossificans can be differentiated from osteochondral exostoses by the absence of corticomедullary continuity.

#### Osteochondritis dissecans

Osteochondritis dissecans lesions are relatively common in young patients and adolescents. The typical manifestations of the disease are knee pain and an effusion; occasionally mechanical symptoms occur in patients with loose bodies or detached osteochondral fragments. The aetiology remains unclear. The majority of lesions are in the weight-bearing portion of the lateral aspect of the medial femoral condyle. Lateral femoral condylar lesions are less common and felt to be post-traumatic in nature resulting from patella subluxations and dislocations. Tibial osteochondral defects are rare.

These lesions are typically seen on radiographs as subchondral lucencies with internal sclerotic borders; occasional loose osteochondral bodies can be seen in the lateral or medial gutters or the suprapatellar pouch. Both CT and MRI are useful in discerning the exact size and location of the chondral defect. The appearance and location are characteristic and should not be confused with chondroblastoma, subchondral cysts, or Brodie abscess. Treatment depends on the size and degree of displacement of the osteochondral fragment.

#### Osteonecrosis (Box 8.9.4)

Spontaneous osteonecrosis of the knee (SONK) most commonly involves the medial femoral condyle and medial tibial plateau and is generally idopathic. Secondary osteonecrosis is associated with systemic conditions such as rheumatoid disease, Caisson’s disease, alcohol consumption, renal transplantation, steroid therapy, and systemic lupus erythematosus.

SONK is characterized by the presence of dead bone in the subchondral area of the weight-bearing portion of the femoral condyle. It is associated with subchondral fracture and collapse.

The aetiology remains uncertain but local trauma in a diseased joint causes ischaemia and disturbance of local circulation leading to increased subchondral pressure and ultimately necrosis.

Radiographs may appear normal in the early stages of osteonecrosis but with progression of the disease an area of radiolucency in the subchondral bone with a halo of sclerotic bone becomes evident (Figure 8.9.5). MRI detects early changes in the bone marrow, whilst technetium bone scans are less reliable. MRI findings include a well-defined area of low signal, best seen on T1-weighted images. Patients with condylar lesions greater than 5cm² or a width of greater than 40% develop pain, deformity, and secondary destruction of the joint often requiring surgical intervention.
Click to view larger

Fig. 8.9.5
Osteonecrosis of the medial femoral condyle.

Non-operative treatment in the early stages of the disease includes pain relief and supportive physiotherapy exercises to improve quadriceps and hamstring strength, resulting in full resolution of symptoms in 80% of cases. Effective surgical options include arthroscopic debridement, drilling and bone grafting, and proximal tibial osteotomy. However, total or unicompartmental knee arthroplasty is indicated for lesions evolving into subchondral collapse and significant arthrosis. Success rates are 55% for arthroscopic procedures and up to 95% for arthroplasty (Figure 8.9.6).

Melorheostosis

A rare periosteal or cortically based hyperostosis involving the long bones of the lower extremity. It can be very extensive or more limited about the knee. In those lesions where it is more focal it can be confused with other bone-producing conditions such as juxtacortical osteosarcoma or myositis ossificans.

Radiographically, melorheostosis involves only one side of the cortex and only one lower extremity. It often crosses joints, especially the knee. It has been described as having the appearance of ‘dripping candle wax’.

Pain is a constant feature of this disease. Often patients will present with a mass and knee effusion. With disease progression, ankylosis can supervene, and pain due to progressive hyperostosis may rarely require amputation for palliation.

The patellofemoral joint

Summary points

- The symptomatic patellofemoral joint is difficult to manage.
- It is difficult to be certain that the pain felt by the patient is actually arising from the joint.
- The majority of symptomatic patients should be managed conservatively with exercises aimed at improving muscle control.
- Surgical treatment gives best results in patellofemoral instability when there are defined anatomical abnormalities that are then corrected.
- Surgical treatment of patellofemoral arthritis has uncertain outcomes.

Introduction

Disorders of the patellofemoral joint present in one of two ways:

1) Anterior knee pain and/or
2) Extensor mechanism instability.

Anterior knee pain may arise from the patellofemoral joint, or may arise remotely—typically the hip. Surgical management of anterior knee pain has uncertain outcomes. On the other hand instability may be mechanical or functional. If mechanical then successful surgical correction should be considered.

Around 40% of elective referrals to an orthopaedic department are for knee pain, of which about a third are for pain felt anteriorly. Accurate assessment and appropriate management is therefore essential. The algorithm for elucidating the likely problem starts with the age of the patient (see Figure 8.10.1).

Anatomy

The patellofemoral joint has evolved in man in response to bipedal gait. To effect hip abductor power the greater trochanter of the upper femur has become more lateral. This has resulted in the quadriceps line of action becoming more valgus with respect to the insertion of the patellar ligament into the tibial tubercle, creating an angle (the quadriceps or Q-angle). To overcome the resulting lateral pull to the patella, the lateral trochlear facet of the femoral sulcus has become more flared, to act as a buttress against lateral patella displacement.

The patellofemoral joint is made up of the quadriceps tendon, patella and patellar ligament, and tibial tubercle along with the medial and lateral retinaculum within which lie the medial patellofemoral ligament and lateral patelloiliotibial band ligament. Other condensations within the medial and lateral retinaculum (e.g. the medial and lateral patellotibial bands) are also described, but are of less clinical relevance. The soft tissue envelope (including the patella) is known collectively as the ‘extensor mechanism of the knee’. Recently it was realized that the distal femoral sulcus may develop abnormally resulting in trochlear dysplasia.

The patella is a sesamoid bone that acts as a marker for the alignment of the extensor mechanism. The trochlear groove and an arch of articular cartilage around the intercondylar notch make up the femoral side of the joint. Except in deep flexion, the tibial articular surface comes into contact with a different part of the femur to the patella and the majority of intercondylar notch osteophytes result from patellofemoral disease. The femoral sulcus acts like a pulley for the extensor mechanism. The forces exerted through the normal patellofemoral joint depend on activity such that at level walking it is half body weight, on going upstairs is three to four times body weight, and on squatting it is seven to eight times body weight.
Kinematics

The movements of the patellofemoral joint are complex. In full extension only the distal part of the patella articular surface is in contact with the femoral groove. It mainly rests on the synovium overlying the supracondylar fat pad. As flexion increases, the contact area on the patella sweeps proximally as a broad strip until 90-degree flexion, when the proximal part is in contact with the distal groove. From 90-degree flexion the odd (or extreme medial) facet articulates with the lateral edge of the medial femoral condyle, and the lateral facet articulates with the medial edge of the lateral femoral condyle. The medial facet lies in contact with the synovium overlying the anterior cruciate ligament. In deep flexion the patella effectively bridges the intercondylar notch. At 135 degrees of flexion the patella articulates with parts of both the medial and lateral femoral articular surfaces that also come into contact with the anterior meniscal horns (Figure 8.10.2).

Wherever there is uncovered articular cartilage, a synovial fold, usually enveloping fat, covers the articular surface. These folds include the peripatellar fringe of synovium, the supracondylar fat pad, and the infrapatellar fat pad with its alar folds. In extension, the supracondylar fat pad has a distal leading edge (abolished at arthroscopy by the introduction of fluid) which descends into the femoral sulcus as the knee flexes. It moves proximally as the knee extends, aided by the intra-articular negative pressure, and the action of the articularis genu muscle. As the patella articular surface contact sweeps superiorly during flexion, the synovium of the infrapatellar fat pad covers the exposed part. Specifically the alar folds point proximally in the midline. Beyond 90-degree flexion the alar folds move away from one another. It should be noted that the articular surfaces are swept by synovium during knee movement. This is probably important for cartilage nutrition.

Imaging

Standard plain radiographs are adequate as a screen for patellofemoral problems. The anteroposterior (AP) standing view gives the least information. The lateral view should have the posterior femoral condyles strictly overlapping. The trochlear groove can then be properly assessed. Figure 8.10.3 shows the normal groove. The skyline view (tangential patella) may be taken in various degrees of knee flexion. The sulcus angle is useful as a screening tool. If greater than 140 degrees, this is associated with patellar instability. The angle changes according to knee flexion (Figure 8.10.4) and therefore is not useful for research purposes, as this is difficult to control.
Computed tomography (CT) is helpful, and shows the shape of the subchondral bone. It can measure the rotational alignment of the lower limb as well as the patellar tilt angle, and tibial tubercle–trochlear groove (TTTG) distance (Figure 8.10.5). The TTTG is more useful than the Q-angle as it measures where the patella should be, rather than where it is. The normal TTTG is 10mm.

Magnetic resonance imaging (MRI) is very useful. It gives information on the chondral shape, as well as bony and soft tissue abnormalities, not only within the patellofemoral joint, but also the tibiofemoral joint.

Isotope bone scanning can be useful in unexplained anterior knee pain, and can confirm abnormal metabolism within the bone.

Clinical presentation (Box 8.10.1)

Anterior knee pain

Anterior knee pain is the term used to describe pain in and around the patella. Until the 1970s, the term 'chondromalacia patellae' was synonymous with patellofemoral pain, because softening was noted on the undersurface of the patella. This term has now been replaced by 'anterior knee pain', which is a symptom and not a diagnosis. Other terms used are: patellofemoral syndrome, patellofemoral pain syndrome, patellofemoral joint syndrome, and extensor mechanism disorder.

Aetiology

There are two principal views as to the aetiology of anterior knee pain. The first is patellar malalignment with respect to the femoral sulcus. This causes localized peak loading of the articular cartilage which results in chondral damage and pain. Correction of the
malalignment should therefore decrease the patient’s symptoms by offloading the affected area. However, there is poor correlation
between articular cartilage lesions and pain. Patellar malalignment may only explain some patellofemoral pain symptoms.

Until recently it has been suggested that anterior knee pain may be due to a wide range of physiopathological processes such as
an increase in intrasosseous pressure and increased bone remodelling. However, the most recent view is that the tissues of the
patellofemoral joint are in balance at a molecular level (tissue homeostasis) and supraphysiological mechanical loading and
chemical irritation of the nerve endings has a direct effect on unbalancing this. An inflammatory cascade then occurs resulting in
peripatellar synovitis. The peripatellar synovium is richly innervated and has been shown to be extremely sensitive to light touch.
Once the synovium is inflamed, it will be continually aggravated by activities of daily living, resulting in prolonged symptoms.

However deciding what causes the pain and which structure is involved is still controversial. Many patients with marked patellar
malalignment never experience pain, whilst others, with apparently no malalignment, or changes to their activities, experience
problems. Disorders that can present as anterior knee pain are outlined in Box 8.10.2.

Box 8.10.2 Disorders that can lead to anterior knee pain

- Adolescent anterior knee pain
- Patellar malalignment syndromes including dislocation
- Patellofemoral arthritis
- Patellofemoral pathology:
  - Infections
  - Tumours
  - Osteochondritis dissecans
- Extensor mechanism pathology:
  - Patellar tendonitis
  - Sinding–Larsen, Osgood–Schlatter syndromes
  - Quadriceps tendonitis
- Patellofemoral chondropathy
- Tibiofemoral pathology:
  - Meniscal tear
  - Pathological plicae
- Hip pathology
- Tumours:
  - Osteoid osteoma
  - Osteosarcoma/Ewing’s sarcoma
- Disorders of posture:
  - Tight quadriceps/hamstrings
  - Hyperlordotic lumbar spine
  - Pronated feet
- Complex regional pain syndromes
- Psychological problems.

Adolescent anterior knee pain (Box 8.10.3)

Pain felt at the front of the knee is common in adolescence, affecting both a third of boys and girls. Of these, a third of the girls and
a tenth of the boys present to primary care physicians. Adolescent anterior knee pain should not be considered a disease. In this
group it is important to confirm that there is no abnormality in the knee. Despite symptoms, examination of the knee is normal.
Specifically there is no effusion, the vastus medialis obliquus is present and functioning, there is no patellar apprehension, the
patellar tracks normally, there is no evidence of meniscal pathology, the ligaments are intact, and the patient can squat. Variations
and abnormalities that may be found are: hypermobility syndrome, spine or hip pathology, tight musculature, and rotational or
postural abnormalities of the lower limb. The long-term prognosis is good.

Box 8.10.1 Presentation of patellofemoral disorders
Anterior knee pain (exclude hip and spine disorders):

- Extensor mechanism pathology
- Hypermobility syndrome
- Postural problems
- Psychological
- Extensor mechanism instability.

Patellofemoral instability (mechanical and functional)

The commonest cause of instability of the patella is poor muscle power and/or coordination that results in a functional instability. Various anatomical abnormalities may be present that increase the risk of patellar dislocation, but if functional stability can be achieved, the surgical correction of the abnormalities is unnecessary. This is similar to the situation found in anterior cruciate ligament rupture.

Box 8.10.3 Adolescent anterior knee pain

- Exclude serious disease
- Exclude osteochondritis dissecans
- Anatomy of knee is normal
- Related to sports
- Settles with rest
- Expectant treatment.

Patellar dislocation is the extreme of a continuum of malalignments of the extensor mechanism which include a tight lateral retinaculum with a lateral tilt of the patella, and subluxation of the patella. The displacement is laterally. Medial displacement of the patella is typically iatrogenic. It is important to note that although the patella may be subluxated or dislocated, the problem is not the kneecap. Various factors may lead to patellar instability:

- Extensor mechanism malalignment
- Trochlear dysplasia
- Hypermobility syndrome.

The single biggest risk factor for recurrent patellar dislocation is a positive family history.

Extensor mechanism malalignment

Epidemiology

The incidence of patellofemoral dislocation is reported to be 5–43 per 100,000. The factors associated with dislocation are listed in Box 8.10.4. Of those patients who present with a primary dislocation, about 17% will go on to have a recurrence. Of those who present with a dislocation, 50% have a history of previous dislocation or subluxation. However, in a recent randomized controlled trial the only factor that was associated significantly with recurrent dislocation was a positive family history.

Box 8.10.4 Risk factors associated with patellar dislocation

- Female adolescents
- Following primary dislocation
- History of subluxation or dislocation
- Younger
- More severe dislocation
- Family history
- Risk factors for developmental dysplasia of the hip:
  - First-born girl
  - High birthweight
  - Breech delivery
  - Caesarean section.
Classification

There are many ways to classify joint dislocation/subluxation. In the patellofemoral joint it is important to appreciate the difference between a dislocation in a joint with pre-existing normal anatomy, from one where the anatomy is abnormal. To dislocate a normal patellofemoral joint requires significant force to be applied to the medial side of the patella (typically in a tackle in football). Because the femoral sulcus is normal, the risk of an osteochondral fracture is high. If an osteochondral fracture occurs, prompt treatment is needed if long-term disability is to be avoided. These can be considered as a true ‘traumatic’ dislocation. Those with abnormal anatomy can be considered to sustain an ‘atraumatic’ dislocation. This is not to say that there has not been an injury, but usually there is no direct blow to the patella, or it has occurred with minimal force. Atraumatic dislocators have a low risk of osteochondral fractures. In the acute setting, examining the opposite knee will show whether there are anatomical abnormalities, as these are bilateral.

Extensor mechanism maltracking may also be classified according to whether the patella dislocates in extension or flexion. The former is more common. The latter is always due to a tight lateral retinaculum, and usually tight quadriceps. Both have to be addressed if surgical correction is anticipated. The terms ‘habitual’ and ‘obligatory’ are also used. They can be defined as voluntary dislocation in the former and involuntary in the latter although they are frequently used interchangeably.

Dejour classified extensor mechanism malalignment into major, objective, and potential patellar instability. Major is when dislocation has been documented and is associated with significant abnormalities, objective is when instability symptoms are associated with abnormalities, and potential is in the asymptomatic patient with anatomical abnormalities. He has a further group called ‘painful patellar syndrome’ where there is pain, but normal anatomy. This is the group where operative intervention is unlikely to be helpful. Abnormal anatomy can be stretched medial structures, especially the medial patellofemoral ligament (hypermobility syndrome), patella alta, or trochlear dysplasia. A combination of these is typical in major and objective patellar instability.

Trochlear dysplasia

In the last 10 years the importance of the shape of the femoral sulcus in patellofemoral pathology has been realized. Abnormalities in shape can lead to pain, and also increase the risk of an unstable extensor mechanism. The normal femoral sulcus has an angle of under 140 degrees, when measured from the subchondral bone. It is present at birth as cartilage, and continues into adulthood. Dysplasia may occur with overgrowth of the distal physes, which may abolish or, in extreme cases, reverse the angle. It is most important in the first 20 degrees of knee flexion, and may not be obvious on standard skyline films because they are taken at more than 30 degrees flexion. Dejour classified trochlear dysplasia on the plain lateral x-ray into types I, II, and III (Figure 8.10.6). The normal groove runs smoothly into the anterior cortical line of the femur. If it passes anterior to this, crossing the medial condylar line to reach the lateral condylar line anterior to the anterior condylar line, then this shows trochlear dysplasia. If the patella tracks normally, it raises the joint reaction force.

It should be noted that the groove in the dysplastic trochlea lies medial to the normal groove position. CT scans can also measure the patellar tilt angle, and the TTTG distance. If the TTTG distance is greater than 20mm then either the tibial tubercle may be moved medially 10mm or the trochlear groove laterally to correct it to normal. The former is achieved by a tibial tubercle osteotomy, and the latter by trochleoplasty. A trochlear boss of greater than 6mm and a Dejour type III dysplasia would indicate that a trochleoplasty may be beneficial.

Rarer is a lateral condylar hypoplasia. The groove line does not pass anterior to the anterior femoral cortical line, and neither does the lateral condylar line. There is therefore no lateral buttress to resist lateral translation of the patella secondary to the Q-angle. This can be corrected by the Albee troehleoplasty, which elevates the lateral femoral condyle. If performed for hyperplasia, it precipitates patellofemoral osteoarthritis (PFPOA).

It can therefore be seen that patellar instability is associated with anatomical abnormalities. Figure 8.10.7 shows the differences in trochlear shape, patellar position, length and thickness of the medial structures, most notably the medial patellofemoral ligament (MPFL), and also indicates laxity or tightness in the lateral retinaculum. Note that the lateral retinaculum is lax in the figure, and therefore lateral release is not appropriate.
Hypermobility syndrome

This is a genetically-based disorder of collagen covering a wide variety of genetic abnormalities from the extreme of Marfan’s and Ehlers–Danlos syndromes to benign joint hypermobility syndrome. Screening involves assessing the Beighton score. This tests joint flexibility. True hypermobility syndrome is assessed using the Brighton criteria (Box 8.10.5).

Box 8.10.5 Brighton criteria for diagnosing hypermobility syndrome

- **Major criteria:**
  - Beighton score of 4 out of 9 or greater (currently or historically)
  - Joint pain for >3 months in 4 or more joints

- **Minor criteria:**
  - Beighton score of 1–3 out of 9
  - Joint pain (>3 months) in 1–3 joints or back pain (>3 months), spondylitis, spondyloysis/spondylolisthesis.
  - Dislocation/subluxation in >1 joint, or in 1 joint on >1 occasion
  - Soft tissue rheumatism >3 lesions (e.g. epicondylitis, tendinosis, bursitis)
  - Marfanoid habitus (tall, slim, span/height ratio >1.03, upper: lower segment ratio <0.89), arachnodactyly
  - Abnormal skin, striae, hyperextensibility, thin skin, papyraceous scarring
  - Eye signs: drooping eyelids or myopia or antimongoloid slant
  - Varicose veins or hemia or uterine/rectal prolapse.

Hypermobility syndrome is diagnosed in the presence of two major criteria/one major and two minor criteria/four minor criteria. Two minor criteria will suffice where there is an unequivocally an affected first-degree relative.

Patients who are hypermobile may experience pain that will not be improved by an operation. Given that they have very elastic tissues, the folly of performing a lateral release becomes evident in this group. Operations for instability have a poor outcome, mainly because the operative repair stretches over time. However, a medial patellofemoral ligament reconstruction with a hamstring graft shortens the lever arm enough to stabilize the patella. Lateral release should not be performed. Because of the tissue elasticity, it is not usually necessary to perform a trochleoplasty for a shallow or flat dysplasia, since there does not seem to be a significant increase in the joint reaction force after stabilization.

Surgical procedures (traditional) (Box 8.10.6)

Surgical interventions to correct patellar maltracking are traditionally divided into proximal realignment (lateral release and medial reefing) and distal realignment (Roux–Goldthwait and tibial tubercle transfers). The traditional management is a lateral release, combined with a double-breasting medial reefing proximally, and Roux–Goldthwait or medialization of the tibial tubercle (Elmslie) distally. This works and normally controls the dislocation. However, in the presence of a significant trochlear dysplasia, there is no groove for the patella to track in, then the risk is that either the patella redislocates, or the increase in the joint reaction force caused by the patella tracking over the trochlear boss leads to pain and later PFOA. Few patients partake in sports after this treatment, and the risk of later PFOA is higher than non-operated patients. It should be noted that operated patients, however, have had more symptomatic knees.

Box 8.10.6 Operations for instability

- **Traditional:**
• Proximal re-alignment
  — Lateral release
  — Medial reefing
• Distal re-alignment
  — Roux–Goldthwaite
  — Tibial tubercle osteotomy

♦ Current:
  • Medial patellofemoral ligament reconstruction
  • (Trochleoplasty)

More popular in the USA is proximal realignment with a Fulkerson osteotomy. This moves the tibial tubercle anteromedially and therefore reduces the joint reaction force. This helps if there is a trochlear dysplasia.

**Surgical procedures (new)**

**Medial patellofemoral ligament reconstruction**

Over the last 10 years newer surgical procedures have been introduced. The importance of the MPFL has led to a number of different variations to reconstruct or repair it. One method is a free hamstring graft anchored to the upper medial border of the patella, and inserted into the origin of the MPFL between the medial epicondyle of the femur and the adductor tubercle.

This is a proximal realignment and avoids the need to do other procedures, especially if the patient is hypermobile. MPFL reconstruction has the advantage over traditional proximal realignment procedures in that it can be performed as a day case, does not interfere with the quadriceps, and so allows earlier return to function, and does not need splintage.

**Trochleoplasty**

In the last decade there has been increasing interest in addressing hyperplastic trochlear dysplasia by deepening the trochlea. A number have been described, but the consistent feature is that the excess subchondral bone is removed and the ‘boss’ lowered. The articular surface is not removed, unlike some older described excision or abrasion procedures. The trochleoplasty can be subdivided into those that create a flexible osteochondral flap and those that create a thick one (Figures 8.10.8 and 8.10.9). In the former the articular surface has to be normal. The flap or flaps created are then anchored to the subchondral bone by a variety of methods. The aim of the trochleoplasty is to remove the boss, recreate the lateral buttress, and lateralize the trochlear groove. It is hoped that it will avoid later-onset PFOA.

![Fig. 8.10.8](image-url)

Pre- and post-operative images of trochleoplasty.
Summary of patellar instability

Acute patellar instability is managed conservatively, where the aim is to achieve functional stability with strong coordinated muscles. Traditional treatment with plaster casting for acute dislocation is falling out of favour to temporary orthosis and early physiotherapy. There is no evidence that this improves or worsens the outcome but patients prefer it. Recurrent instability may not need surgical treatment as patients may develop coping strategies. If operative treatment is decided upon, then patellar tracking can be controlled by MPFL reconstruction alone. It is now felt that lateral release should be avoided, especially in hypermobility syndromes. This also may be unnecessary when a deepening trochleoplasty is performed as this slackens the lateral structures.

Dysplasia may need to be addressed if the patella tracks over a significant trochlear boss.

Patellofemoral osteoarthritis (Box 8.10.7)

PFOA affects an older age group than patellofemoral instability. Since the patellofemoral joint sustains the highest loads of any joint, it is no surprise that wear of the bearing surface is a common finding as age increases. However, symptomatic isolated PFOA is uncommon. It appears that about 5% of patients with radiographic changes of patellofemoral degeneration are actually symptomatic, which interestingly matches the anterior knee pain rate following unresurfaced patellae in total knee replacement. In a population of symptomatic osteoarthritic knees presenting over the age of 60 it was found that 19% of men and 17% of women had isolated patellofemoral disease as compared to 5% of men and 10% of women between the ages of 40–60 years. This emphasizes that failure of the bearing surfaces increases with age. It is useful to consider PFOA as present when both surfaces of the joint have exposed bone. Lesser articular cartilage loss or damage can therefore be considered as a chondropathy. However, it must be emphasized that radiological changes in the patellofemoral joint do not always equate with pain or loss of function. This means that a patient may have anterior knee pain and marked radiological changes, but the pain may arise from elsewhere, notably the hip.

Box 8.10.7 Patellofemoral osteoarthritis

- Radiological changes are common over 50 years old
- Hip osteoarthritis must be excluded as source of anterior knee pain
- Selected patients may benefit from patellofemoral replacement
  - PFOA secondary to trochlear dysplasia has best outcome.

It would be anticipated that trochlear dysplasia would lead to PFOA. The evidence for this is increasing and it is interesting that patellofemoral arthroplasty is most successful in this group. Pre-existing trochlear dysplasia is difficult to assess in patients with PFOA and bone loss.

Management of patellofemoral osteoarthritis

Conservative

The majority of patients with radiographic changes of PFOA (Figure 8.10.10) have no symptoms. If symptomatic, most will improve by building up quadriceps strength and coordination. However there is no evidence that any particular rehabilitation regimen is beneficial.
Clinical outcomes for the surgical management of isolated PFOA are sparse, and usually case series are not exclusive to isolated PFOA. Traditionally total patellectomy was the operative treatment of choice, but the outcomes were poor due to loss of extensor power, and continuing pain. More recently, excising any lateral osteophytes or part of the lateral facet (partial lateral facetectomy) with a lateral release has been reported with variable success (Figure 8.10.11). Tibial tubercle osteotomy moving the tubercle anteriorly (Maquet) has been done with generally poor results, and more recently the Fulkerson osteotomy has been used. However, as with osteotomies for tibiofemoral osteoarthritis, more certain outcomes seem to be had from joint arthroplasty. Recently figures for significant numbers of patients undergoing patellofemoral joint replacement with medium-term outcomes are encouraging (Figure 8.10.12).
Intra-operative photograph with knee viewed from lateral side showing rongeurs protecting the two osteochondral flaps, just after the new groove has been fashioned with an osteotome.

**Patellofemoral pathology**

The patella may present with pathology in the bone. Infections including tuberculosis, Paget’s disease, secondaries and primary bone tumours have been reported, but are rare. Management depends on the pathology and is not specific to the patella.

**Osteochondritis dissecans**

Osteochondritis dissecans (OCD) affecting the patellofemoral joint is described as ‘anterior’ OCD and is rare. It more commonly affects the patella than the trochlear groove. It is thought to occur secondary to trauma, and may lead to a loose body. Treatment is as for OCD in the tibiofemoral joint.

**Patellofemoral chondropathy**

Considerable efforts have been expended on repairing localized damage to articular cartilage. The standard method is microfracture. Other techniques have been described including carbon-fibre patches (matrix-support prosthesis), autologous periosteal transplantation, osteochondral plugs (mosaicplasty), and autologous chondrocyte implantation (ACI). Observational case series give good results, but as the quality of the scientific methodology improves the results look less good when compared to microfracture, although the latter may be worse in larger lesions. As stated earlier there is poor correlation between pain and the site of any lesion. Many of the lesions are traumatic in origin and secondary to trochlear dysplasia. Attempts at repairing the articular surface without addressing the dysplasia are therefore doomed to failure. The poor results of ACI in the patella probably reflect this. There is currently interest in the use of stem cells to repair damaged articular cartilage, but this is in its infancy.

**Extensor mechanism pathology**

**Osgood–Schlatter/Sinding–Larsen syndromes**

Pain arising from the soft tissue envelope is usually due to mechanical overload. In adolescence this may present as elongation of the tibial apophysis (Osgood–Schlatter syndrome) that may become symptomatic where the pathology is described as an osteochondrosis. The patients are usually sporty and in Osgood–Schlatter syndrome present with a prominent tibial tubercle that may be tender. Treatment is aimed at activity modification to reduce the symptoms to a level the patient can tolerate. Any pain should settle with rest and not keep the patient awake. If it does, and after excluding a tumour, a period resting in a cylinder cast may be tried. This enforces rest and discourages teachers from over-exercising the pupil.

Osteochondrosis of the distal pole of the patella (Sinding–Larsen syndrome) is rarer but behaves similarly. In adult life the residual effect is an elongated distal pole, and implies an enthusiastic athlete in adolescence.

**Jumper’s knee**

Older patients, typically over 30 years old, may develop pain in the patellar ligament, or less commonly in the quadriceps ligament, when it is described as a tendinitis. It is also called jumper’s knee and is similar to tennis elbow. The pathology is not inflammatory but a tendinosis. It is associated with tight musculature, typically the quadriceps. It reflects the loss of elasticity in the tissues with increasing age, thus causing stiffness. Typically it occurs in patients who are trying to maintain their athletic abilities and results in extensor mechanism overload. Treatment includes addressing the psychological aspects of the patient’s desire to stay young.

**Infrapatellar fat pad pathology**

Tumours such as ganglia and osteochondromata, arising within the infrapatellar fat pad are rare and present as anterior knee pain. Clinically there is fullness present either side of the patellar ligament, compared to the opposite side, which is tender. More difficult to diagnose is a haemangioma as this does not cause a swelling. Diagnosis is usually made on MRI scanning, which is the ideal way to investigate fat pad pathology.

All these lesions are easily investigated using MRI, especially when there is a doubt in the diagnosis, and concern about infection or tumour.

**Stress fracture and bipartite patella**

Stress fracture of the patella can occur in osteoporotic bone or more rarely in normal bone. Transverse fractures may need surgical intervention. The risk seems to occur if there is a tight lateral retinaculum (with a tilted patella on skyline x-ray) and a significant force is applied as in jumping, or tripping over a dog. The result is an autolateral release. Excision of the fragment is advised. A childhood variant is a sleeve fracture with loss of the articular surface. This needs early surgical repair.

It may be difficult to distinguish this fracture radiographically from a bipartite patella. The bipartite patella may have more than one fragment. Typically the fragment lies superolaterally, and occurs in 1% of knees. On skyline view it may be non-fused part of the patella, or a separate fragment that overhangs the lateral condyle. If symptomatic, an MRI scan may show oedema in the fragment, or reveal the cause of the anterior knee pain.
The symptomatic patellofemoral joint is difficult to manage, principally because it is difficult to be certain that the pain felt by the patient is actually arising from the joint. The majority of symptomatic patients should be managed conservatively. Surgical treatment gives best results in patellofemoral instability with defined anatomical abnormalities that are then corrected.

Summary points

- The principal indication for ACL reconstruction is instability, either existent or predicted
- In general, it is crucial that the knee has settled and motion has been restored prior to surgery
- Accurate tunnel position is the most important aspect of surgery

Anatomy

The primary function of the anterior cruciate ligament (ACL) is to control anterior tibial translation relative to the femur. The ligament also plays a role, however, as a secondary restraint to internal rotation of the tibia on the femur, particularly towards extension. The axis of this internal rotation is within the medial compartment where the convex medial femoral condyle articulates with the concave medial tibial plateau. There is greater anteroposterior translation of the convex lateral femoral condyle on the somewhat convex tibial plateau during flexion and extension of the knee. This translation can increase with disruption of the ACL.

This can be clearly demonstrated by the typical pattern of ‘bone bruising’ seen on magnetic resonance imaging (MRI) following an ACL rupture (Figure 8.11.1). There is bruising on the posterior aspect of the lateral tibial plateau beneath the posterior horn of the lateral meniscus and corresponding bone bruising over the distal lateral femoral condyle where the posterior horn of the lateral meniscus and subjacent posterolateral tibia have impacted during subluxation of the knee. In ACL deficient knees it is this translation that occurs with twisting and turning, that can give rise to the patient’s symptoms of giving way.

![Click to view larger](image)

Fig. 8.11.1
Sagittal MRI showing typical lateral compartment bone bruising.

The translation can be reproduced by the pivot shift test. In this test the iliotibial band passes from anterior to the axis of knee flexion when the knee is extended, to posterior to this axis as the knee is flexed beyond about 30 degrees. As this occurs, the tibia, particularly its lateral half, reduces from its anteriorly subluxed position. The test is accentuated by a valgus stress being placed on the knee and therefore requires intact medial structures to resist this valgus force.

Two discrete bundles of the ligament have been described. They are the anteromedial and posterolateral bundles. Their attachment sites on the femur and tibia are such that the two bundles change their orientation to one another in varying degrees of flexion. Both bundles appear to contribute to both sagittal and axial plane stability but to varying degrees depending on the angle of knee flexion. There has been recent interest in trying to reconstruct both bundles separately to improve knee stability.

Natural history

The natural history of an untreated ACL rupture remains unclear, but there is clearly an increased risk of osteoarthritis (OA) that increases with the time from injury. There appear to be a number of factors that influence the outcome of an ACL rupture. These can be broadly classified as associated injuries, biochemical consequences, and biomechanical consequences (Box 8.11.1).

Box 8.11.1 Factors leading to OA following ACL rupture
Associated injuries can include meniscal tears, chondral damage, injury to the subchondral bone, and other capsuloligamentous disruptions. Meniscal tears, particularly those of the medial meniscus, appear to increase the risk of subsequent OA. Given the poor capacity of articular cartilage to heal, any concomitant chondral injury will also increase this risk. The role of bone bruising seen on MRI is still somewhat uncertain but does appear to be associated with subsequent articular cartilage degeneration. Although some ACL ruptures may appear to be ‘isolated’, it seems doubtful that the ACL can in fact rupture without some concomitant damage, even though this may not be apparent at arthroscopy or on MRI.

A number of degradative enzymes, degradation products, and inflammatory markers have been found to be elevated following ACL rupture, and to remain elevated many months after the injury. Some of these biochemical changes may lower the threshold of the articular cartilage to injury, thereby making it more susceptible to the effects of trauma during episodes of giving way. There may also be some individuals who have a more aggressive biochemical response that increases their risk of developing OA.

If the individual goes on to have repeated episodes of giving way, the menisci and articular surfaces will be put at further risk of injury. Even if the individual is able to avoid episodes of instability, there are more subtle but persistent biomechanical changes in the knee following an ACL rupture. Abnormal kinematics and kinetics in day-to-day activities such as walking may impose abnormal loads on the articular cartilage that has already been compromised by injury or which has a lower threshold to injury because of associated biochemical changes.

It is unclear whether ACL reconstruction can reduce the subsequent development of OA. The evidence is limited and conflicting. Intuitively, one would imagine that by stabilizing the knee and preventing subsequent instability, further meniscal and chondral damage can be avoided, thereby protecting the knee. However, some studies have shown a somewhat alarming incidence of OA in football players who have suffered an ACL rupture. The incidence increases with time from injury and is not influenced by whether an individual has an ACL reconstruction or not.

One of the difficulties in interpreting the few studies available that do look at the longer-term outcome of ACL reconstruction, is that surgical techniques have evolved considerably over a relatively short time and indeed continue to change. One can always hope that new and apparently improved surgical techniques may be more effective in reducing the subsequent development of OA.

Nonetheless, the risk of OA will always be influenced by the presence of associated injuries as well as by more general predisposing factors such as young age at the time of injury, female gender, weight, and a familial tendency towards OA. In addition, a successful ACL reconstruction allows the individual to return to sporting activities that put the knee at risk of reinjury and also potentially allow the threshold for injury to the articular cartilage to be exceeded.

**Indications for surgery (Box 8.11.2)**

Given the uncertainty surrounding the natural history of ACL rupture and the effect of reconstructive surgery on it, the principal indication for ACL reconstruction at present is to eliminate instability symptoms.

In the chronic situation this is relatively straightforward as the individual presents with recurrent episodes of giving way.

In the acute setting the situation is much less clear. For active individuals who wish to continue in sports that involve twisting and turning, an initial trial of non-operative management may not be attractive or appropriate. In this situation the aim of an ACL reconstruction is to avoid predicted instability. The likelihood of instability will depend not only on the sports to which the patient wishes to return, but also the laxity of the knee on examination.

It should, however, be noted that the laxity of the knee does tend to change with time. In the first weeks or even months after injury there is often a general healing response of the knee and specifically the ruptured ACL. This can result in more subtle signs of ACL insufficiency than 3 or 6 months following the injury, when the examination findings are frequently much more obvious.

Some efforts have been made to assess the likelihood of an individual being able to cope without reconstructive surgery based on their response to an initial period of rehabilitation. The broader application of this research remains to be established.

At the present time, the literature does not support ACL reconstruction solely to protect the menisci and reduce the risk of OA. However, if a meniscal tear is repaired in the setting of an ACL rupture, the knee should probably be stabilized by ACL reconstruction in order to improve the chances of a successful meniscal repair.

Once the decision to perform an ACL reconstruction has been made, it is important that the chances for a successful outcome are optimized. This means that the knee needs to be in an appropriate state for surgery to be performed and that the patient is prepared for both the surgery and the subsequent rehabilitation. In the chronic situation, these considerations are less of an issue. In the acute situation, however, the knee is often stiff and swollen and the patient anxious about the diagnosis and outcome.

It is important to remember that ACL reconstruction is essentially an elective procedure. The main reasons for performing surgery on a relatively urgent basis are the presence of a locked knee or significant associated capsuloligamentous injuries that are deemed to require primary repair.
Box 8.11.2 Indications for ACL reconstruction

- Instability
  - Current
  - Predicted
- Protection of a meniscal repair.

Before embarking on surgery, it is preferable that knee swelling has largely resolved, or that the haemarthrosis or effusion is no longer tense, and that a good range of motion has been restored. Particular attention should be paid to extension. Patients who have not achieved near normal active extension preoperatively often find it difficult to actively achieve full extension after surgery. Difficulty regaining active extension preoperatively is usually a result of inhibition of quadriceps function secondary to pain and/or a haemarthrosis and swelling of tissues within the intercondylar notch. A true mechanical block to extension is relatively uncommon with the first injury and full extension can usually be restored by appropriate physiotherapy. This makes the subsequent restoration of extension after surgery much faster and easier for the patient.

Similarly, it is helpful to have good quadriceps function prior to surgery, even though there may be relative quadriceps weakness and reduction in bulk. It is much easier to restore quadriceps function following the trauma of surgery if it has been restored preoperatively.

Even in the professional athlete, a case can be made for letting the knee ‘settle’ prior to surgery as this may well result in a reduced rehabilitation time and a better overall outcome.

Anterior cruciate ligament rupture in the skeletally immature

ACL rupture can occur at all ages although the peak incidence is in the late teenage years and early twenties. ACL ruptures in the skeletally immature pose a number of additional considerations.

Children and adolescents often recover very quickly following a musculoskeletal injury. As such, the diagnosis of ACL rupture may go unrecognized as may the significance of subsequent giving-way episodes. As in adults, irreparable meniscal lesions in the young are associated with an increased risk of OA, but because of the young age at which the index injury occurs, the age at which the OA becomes symptomatic will also be early. Advanced OA in a young patient remains a problem with no easy solution.

Whether a child with an ACL rupture should be managed non-operatively is unclear. The success of non-operative management will depend on the laxity of the knee, adequate rehabilitation, the use of a brace, and the compliance of the child in avoiding situations that put the knee at risk of giving way. The latter is more difficult if a prolonged period of non-operative management is planned. The potential advantages and disadvantages of non-operative management need to be weighed against those of operative management. The main potential problem associated with early surgical reconstruction is damage to the growth plates.

For patients within 1 or perhaps 2 years of skeletal maturity, the risk of injury to the growth plates from ACL reconstruction using standard techniques is minimal. Although it may be prudent to use a soft tissue graft with no hardware crossing the growth plate, satisfactory results have been reported with patellar tendon grafts where either the bone block or the interference screw lies across the growth plate.

However, when there is considerable remaining growth, the potential for injury to the physis is more significant. As a result, alternative strategies have been suggested, such as extra-articular reconstruction or an intra-articular reconstruction in which the tunnels are entirely within the epiphyses. If the latter approach is taken, it must be recognized that the growth plate has a somewhat undulating morphology and any bone tunnels should be placed well clear of the growth plate.

Despite these concerns, however, there are surprisingly few complications reported from using a standard technique of soft tissue reconstruction with routine bone tunnels that pass through both the tibial and femoral growth plates. Although it has been suggested to make the tunnels slightly more vertical in orientation in order to reduce the cross sectional area of a tunnel at the level of the growth plate, the surgeon needs to be aware that such a strategy may also affect the positioning of the tunnels in both the tibia and femur. There is the potential to place the tibial tunnel too posterior and the femoral tunnel too high in the intercondylar notch (Figure 8.11.2).
Following ACL reconstruction in the adolescent or child, a number of studies have shown that there is probably an increased risk of graft rupture in teenagers compared to those in their twenties. Whether this increased instance of rerupture can be reduced by more conservative rehabilitation or the use of a brace has not been established at the current time.

**Principles of anterior cruciate ligament reconstruction**

The key principles of intra-articular ACL reconstruction are to take an adequate graft and insert the ends into appropriately placed bone tunnels in the femur and tibia using fixation that is able to withstand the forces applied during the first few months of rehabilitation, until integration occurs.

Errors in surgical technique probably constitute the commonest cause of early graft failures. Of the various errors in technique that are possible, poor placement of the bone tunnels is the most likely to lead to graft failure.

Intra-articular reconstructions can be combined with an extra-articular procedure, either involving the rerouting of the iliotibial tract or use of a free graft. However, there is little evidence to indicate that this provides a superior result compared to an intra-articular reconstruction alone.

The operative procedure should always be preceded by an examination under anaesthesia to not only document the degree of ACL insufficiency, but also to identify associated ligamentous pathology. If the preoperative examination has resulted in consideration of repair of a medial collateral ligament injury, it is worth re-examining the knee after performing the ACL reconstruction to determine whether the medial laxity has been reduced to a level where non-operative management is deemed appropriate. In the author’s view, this means where there is no medial laxity at zero degrees of extension and laxity in flexion is less than 5mm greater than the normal side.

Similarly, arthroscopic inspection of the whole of the knee joint should be undertaken as part of the reconstructive procedure. If the meniscus is to be repaired using inside to out sutures, it is generally easier to harvest hamstring tendons prior to the passage of sutures.

**Graft options**

In selecting a graft, the strength and fixation options available for that graft need to be considered against the morbidity associated with graft harvest.

The range of available grafts varies from one country to another. Autograft tendons are the most commonly used, although in some centres allografts are readily available and therefore frequently used as a first choice.

Autograft tendons may be harvested from the same side as the injured knee (ipsilateral) or from the contralateral knee. Contralateral tendon harvest is more frequently used in revision surgery, but is an option for primary surgery and may be associated with a more rapid overall recovery of function.

The middle third of the patellar tendon with bone blocks from the adjacent patella and tibial tuberosity and the semitendinosus tendon either alone or in conjunction with the gracilis tendon make up the bulk of autografts. Usually four strands of hamstring tendon are used, either a quadrupled semitendinosus tendon or a doubled semitendinosus tendon and a doubled gracilis tendon. However, three- and five-strand grafts have also been used. Other autograft options include quadriceps tendon and fascia lata.

The choice between patellar tendon and hamstring tendons continues to be debated. Satisfactory results have been reported with both graft types and although meta-analyses have generally shown slightly less anterior knee laxity with patellar tendon grafts, this may not be the case if hamstring grafts of fewer than four strands are excluded. Both grafts can be associated with morbidity that can be significant to the patient. Patellar tendon grafts are associated with an increased incidence of pain on kneeling whereas hamstring grafts are associated with reduced hamstring strength.

A variety of allograft tendons can be used including Achilles tendon, patellar tendon, and tibialis anterior or posterior tendons.
Allografts have the advantage of no harvest morbidity but have the disadvantage of cost, potential for disease transmission, and possibly greater knee laxity in the longer term. The results of allograft reconstructions appear to be less satisfactory in younger and more active patients.

Synthetic grafts have largely fallen out of favour due to long-term mechanical failure.

**Graft strength**

The relative strength of hamstring and patellar tendon grafts depends on the dimensions of the graft that is harvested and how many strands of hamstring construct are used. It appears that a four-strand hamstring graft is generally stronger than a 10-mm wide patellar tendon graft, but it is unclear what impact this has on the long-term function of the graft and the risk of reinjury. All commonly used grafts, however, appear to be of sufficient strength to withstand the forces generated in the early rehabilitation period.

**Graft harvest**

There are many techniques described for harvesting of the middle third of the patellar tendon or the hamstring tendons.

Patellar tendon grafts can be harvested via traverse or longitudinal incisions which can be single or double. Transverse incisions or two separate longitudinal incisions are designed to reduce the risk of damage to the infrapatellar branches of the saphenous nerve and thereby preserve sensation on the anterior and anterolateral aspects of the knee and proximal leg. The bone plugs from the adjacent patella and tibial tuberosity are usually harvested with the aid of a small oscillating saw and osteotome. The blocks can then be shaped into cylinders or other shapes.

The hamstring tendons are generally harvested via an anteromedial incision over the distal attachment of the pes anserinus. The incision can be longitudinal, oblique, or transverse. The sartorius fascia needs to be incised to expose the underlying gracilis and semitendinosus tendons. These are harvested using a tendon stripper. The fascial bands which attach the semitendinosus tendon to the medial gastrocnemius must be divided under direct vision. If a closed tendon stripper is used, the tendons need to be detached distally and secured with a whip stitch to allow passage of the stripper. If an open tendon stripper is used, this can be done with a distal attachment intact. When passing a tendon stripper, it is important to keep in mind the orientation of the tendons. When the gracilis tendon is being harvested, the tendon stripper should pass along the medial aspect of the thigh. When the semitendinosus tendon is harvested the orientation should be in a more lateral direction. The harvested tendons are then cleaned of extraneous tissue and attached muscle. Depending on the type of fixation being used they are then whip stitched at one or both ends.

For hamstring grafts it has recently been suggested that harvesting some of the adjacent peristeum and incorporating this into one or both ends of the graft can improve subsequent healing of the tendon wall of the bone tunnel. Whether or not this translates into better long-term clinical results remains to be seen.

**Intercondylar notch preparation**

Intra-articular ACL reconstruction can be performed via an arthrotomy or using arthroscopy. In general, better visualization of the intercondylar notch can be obtained using arthroscopy but the surgeon should have the appropriate arthroscopic skills prior to embarking on arthroscopic ACL reconstructive surgery.

Surgeons vary in terms of their preference for preservation of native ACL tissues. The first principle should be to have adequate vision to ensure good tunnel placement. This may mean removing all of the remnants of the torn ACL. However, with experience the surgeon may well be able to leave much of the native tissue intact, but still remove any tissue that may impinge and result in so-called Cyclops lesion. Whether this has any functional benefit is difficult to determine but it may be associated with better revascularization of the graft, and possibly restoration of some proprioceptive function.

Although notchplasty was previously regarded as a routine component of ACL reconstruction, it has become apparent that a well-positioned graft is unlikely to impinge in the intercondylar notch in extension and therefore the role of notchplasty is limited to removing osteophytes or enlarging an intrinsically narrow or ‘gothic notch’, essentially to improve visualization to the postero-lateral wall of the notch.

**Bone tunnel preparation**

Most commonly, the ACL is reconstructed using a single-bundle technique. Previously the ideal attachment sites on the femur and tibia were thought to be those which resulted in an isometric graft. However, it appears that relatively few fibres of the ligament are truly isometric and that different parts of the ligament are under tension at different angles of knee flexion. Because of this, emphasis has been placed on trying to reproduce the anatomy of the native ligament in order to more closely reproduce its biomechanical characteristics.

In recent years there has been increased interest in using a double-bundle or even a triple-bundle technique in an attempt to even better recreate the complex biomechanics of the intact ACL. Double-bundle techniques aim to reconstruct the anteromedial and posterolateral bundles of the ACL separately. Whilst cadaveric studies have indicated restoration of more normal biomechanics, clinical results to date do not demonstrate any clear functional outcome benefit compared to a well-performed single-bundle reconstruction. Further prospective randomized studies are required to clarify the role of double-bundle reconstruction. This chapter
deals only with the technique of single-bundle reconstruction.

There are a variety of drill guides available for use in the preparation of the bone tunnels. However, it is important to remember that they are only used to improve the ability of the surgeon to place the tunnels in the positions which the surgeon believes to be correct. The guides do not in themselves indicate the correct position of the bone tunnels. The same applies to computer navigation of tunnel placement.

In general, the tibial tunnel is drilled from outside in over a guide wire, although retrograde drilling has been used. More options are available for the femoral tunnel. The tunnel can be drilled from inside to out or from outside to in. If drilling inside to out, the tunnel can be created by drilling through the anteromedial arthroscopic portal or by using a transtibial approach, drilling through the tibial tunnel. Retrograde drilling can also be used.

The essential principle is to align the graft in such a way that it controls both anterior tibial translation and internal tibial rotation without compromising terminal extension or full flexion of the knee (Figure 8.11.3).

In the coronal plane, a more vertically orientated graft (Figure 8.11.4) provides less chance of controlling rotation but may have a better chance of controlling anterior tibial translation, provided the sagittal plane alignment is satisfactory i.e. not too vertical (Figure 8.11.5). If too vertical, the graft may impinge on the posterior cruciate ligament and limit full flexion. A more horizontally placed graft (in the coronal plane) will be better able to resist rotation but less able to resist anterior tibial translation. Hence the interest in a double-bundle technique which allows for two bundles to be inserted in different alignments.
If a graft is too anterior on the femur or tibia, there will impingement of the graft on the anterior margin of the intercondylar notch in extension, resulting in either a restriction of extension, or amputation or failure of the graft (Figure 8.11.6).

The aperture of the tibial tunnel should lie in the footprint of the native ACL and should be as medial and anterior as possible without causing impingement of the graft on the roof of the intercondylar notch when the knee is extended. It should be noted that the anterior limit of the tibial footprint of the native ligament extends to the anterior attachment of the medial meniscus. The native ligament does not impinge in the intercondylar notch because of the shoe or foot shaped nature of its anterior extent. Grafts tend to be more cylindrical and therefore cannot extend as far anteriorly if impingement on the roof of the intercondylar notch in extension is to be avoided.

The aperture of the femoral tunnel should also be within the footprint of the native ACL and preferably towards its posterior margin as viewed arthroscopically. It is important to recognize that ‘posterior’ from an arthroscopic perspective is in fact superior from a strictly anatomical perspective. There has been a general trend to move the aperture of the femoral tunnel ‘down’ the lateral wall of intercondylar notch, once again when viewed arthroscopically with the knee flexed. Again, this results in an orientation of the graft that is better able to reproduce the function of the intact ACL. Using the analogy of a clock face, with the knee flexed to around 90 degrees, the aperture of the femoral tunnel of the left knee would be at the 2 o’clock position.

Although it is common practice, many experts feel that such a position cannot be achieved using a transtibial drilling technique and therefore recommend drilling via the anteromedial portal. In order to achieve a satisfactory femoral tunnel length to allow for an adequate length of graft to be placed in the tunnel, the knee needs to be flexed considerably, usually 110 degrees or more. This can make visualization of the back of intercondylar notch difficult. Drilling via the anteromedial tunnel also puts the articular surface of the medial femoral condyle at risk and care must be taken not to damage it with the drill tip.

If the femoral tunnel is drilled via the tibial tunnel careful attention needs to be paid to the angle of the knee flexion, the angle of the drill guide, and medialization of the starting point on the tibia during drilling of the tibial tunnel. In order to achieve a satisfactory position of the femoral tunnel, the tibial tunnel must start at the anterior margin of the superficial medial collateral ligament.
Depending on the type of tibial drill guide that is used (tip aimer or elbow aimer), the guide needs to be set at a relatively shallow angle such as 45 degrees and the knee flexed to only 75–90 degrees to subsequently be able to obtain a satisfactory femoral tunnel position.

Generally cannulated drills are used to create the bone tunnels and are passed over a guide wire. Whichever technique is used for the femoral tunnel, it is helpful to mark the desired starting point on the lateral wall of the intercondylar notch with a curette or an awl, thereby creating a depression which helps to capture the tip of the guide wire.

Consideration should be given to the type of drills being used, whether these result in impaction or extraction of the bone and whether they have an ‘acorn’ or expanded type tip or are of a constant diameter. Impaction drilling may improve the strength of interference fixation devices. Using acorn-tipped drills can result in the tunnel walls not being parallel throughout their entirety if the guide wire loses fixation as the tip of the guide wire is approached.

Once the tunnels have been drilled and bone and articular cartilage debris removed from the joint, the graft is usually passed into the tibial tunnel, through the knee joint, and into the femoral tunnel by use of some kind of lead suture or tape exiting through the anterolateral cortex of the femur and distal and lateral aspect of the thigh. It is helpful to ensure that the external mouth of the tibial tunnel is clear of soft tissue to aid graft passage.

**Graft fixation**

Various forms of fixation are available. These can be broadly classified as aperture fixation or suspensory fixation. Aperture fixation typically involves the use of an interference screw or plug which is inserted longitudinally into the graft tunnel either between the graft and the wall of the tunnel or through the central portion of the graft, in either case pushing the remaining graft tissue hard against the wall of the tunnel. Suspensory fixation relies on a device being situated on the cortex of the femur or tibia and attached to the graft via some kind of loop. Suspensory fixation does have the advantage of being flexible and for use in most situations but it has been suggested that, being less rigid than aperture fixation, it might contribute to bone tunnel enlargement. This is more commonly seen with hamstring grafts than with patellar tendon grafts. Although most studies have not shown any deleterious effect of bone tunnel enlargement, more recent evidence does indicate it may be associated with increased graft laxity.

Transcondylar fixation is an alternative that can be used on the femoral side with a rod or pin passing through the proximal end of the graft. In the case of hamstring tendons, this is essentially a form of suspensory fixation with elimination of the loop between the fixation hardware and the graft itself, the aim of this being to reduce the effect of creep in the construct.

Many of the available fixation devices are offered in either metallic or bioabsorbable forms. Concern about metallic implants relates to their impact on subsequent MRI and the possible need for removal at the time of revision surgery, should this be required. Bioabsorbable devices do not interfere with MRI and it is possible for them to be ignored in a revision procedure depending on their position. There are various polymers that can be used in the manufacture of bioabsorbable implants and these can be combined with hydroxyapatite in attempts to improve bony incorporation. The rate of reabsorption varies considerably from one combination of polymers to another. In general, most bioabsorbable devices have been shown to provide initially similar biomechanical characteristics and clinical outcomes as metallic implants.

Whatever fixation type is used, pretensioning of the graft construct should be considered in an attempt to eliminate creep from the system. Pretensioning can be in the form of static pretensioning prior to graft insertion, or with cyclic loading of the graft following insertion and proximal fixation just prior to distal fixation.

The angle of knee flexion and the amount of tension applied to the graft at the time of distal fixation remains somewhat arbitrary. If the graft excursion in the tibial tunnel is minimal throughout extension and flexion, then there is probably little to indicate that one angle of knee flexion is preferable to another. It is unclear what the ideal tension within the graft should be at the time of distal fixation and it is also unclear whether this tension is maintained in the early postoperative period.

**Perioperative management**

Surgery can be undertaken on a day case or inpatient basis. It is usually performed under general anaesthesia, but can be undertaken with regional anaesthesia. Most patients can be discharged within 24h.

Initial postoperative analgesia can be aided by injection of local anaesthetic into the knee and graft donor site, femoral nerve, or iliacus block, or by single-shot epidural injection. Use of epidural anaesthesia may preclude management as a day case. Use of a femoral nerve block may require the use of a splint to compensate for quadriceps weakness.

Drain tubes, if used, can generally be removed within 6h postoperatively.

The use of splints and braces varies widely from one centre to another. Bracing may assist with analgesia and aid initial ambulation. Later in the rehabilitation period, bracing may protect the graft and reduce the incidence of bone tunnel enlargement following hamstring tendon grafts. There is little evidence to suggest that bracing results in an improved clinical outcome.

**Rehabilitation**

The principles of rehabilitation are to eliminate swelling, restore a full range of movement, restore adequate muscle strength, especially of the quadriceps and hamstring muscle groups, and to restore adequate neuromuscular control. Progression through the various stages should be based on the state of the knee, rather than just on the time since surgery.
Patients can weight bear as tolerated from immediately postoperatively but crutches are generally required for up to 3 weeks. Emphasis should be placed on restoration of full extension, equal to the normal opposite knee. Riding a stationary bicycle can usually be commenced by 4 weeks along with closed kinetic chain quadriceps strengthening exercises. The role of open kinetic chain quadriceps strengthening exercise is unclear. They may impose a potentially deleterious anterior strain on the graft and it probably safer to avoid such exercises in the first 12 postoperative weeks. Light jogging can be commenced by 12 weeks together with balance and landing drills. This is followed by the introduction of sport specific drills and a return to light training. A return to full training can start after 6 months.

The timing for a safe return to competitive sport is contentious. There are no proven criteria on which to base the decision. Although many surgeons recommend waiting until 12 months, many surgeons, including the author, feel 9–10 months is safe provided there is no effusion, an essentially full range of motion, no significant graft laxity, good strength, particularly of quadriceps, and good neuromuscular coordination.

### Results of anterior cruciate ligament reconstruction

Overall satisfactory outcomes are achieved for the majority of patients, although normal static stability may only be achieved in as few as 50% patients depending on the type of graft and type of fixation used. Most studies do, however, report good or excellent results based on both a variety of outcome scales and also objective measures such as range of motion, anterior knee laxity, and muscle strength.

Rates of return to the same level of pre-injury sport are less than one would anticipate from the aforementioned results. Typical rates of successful return to the pre-injury level of sport are in the order of 60–70%, but may be as low as 50%. There are a number of reasons for this. Rotational stability is difficult to measure objectively and may be present despite other parameters being essentially normal. Patients may change their aspirations regarding return to sport after surgery. They may not want to face the risk of reinjury and further surgery and rehabilitation. Increasing age is also associated with reduced involvement in pivoting and contact sports. Patient confidence has also been shown to influence rates of return to sport, independent of knee function.

ACL reconstruction has yet to be shown to protect the knee from the development of OA, although protection of the menisci does seem to be achievable to some degree.

The results of surgery are best if both the patient and the knee are properly prepared prior to surgery, the surgery is done well (particularly tunnel placement), and appropriate postoperative rehabilitation is completed by the patient.

Combined ligament injuries around the knee

Summary points

- Any knee with major disruption of two ligaments is likely to have been dislocated at the time of injury
- Knee dislocations are associated with high risk of neurovascular injury. Angiography or vascular ultrasound is mandatory
- In knee dislocations, following immediate reduction and stabilization usually with a brace, acute repair of the ruptured soft tissue structure within 2–3 weeks of injury is likely to provide superior results compared to later reconstruction
- Management of most multiligament injuries is complex and requires surgical intervention therefore specialist centres are best to be involved early
- In cases with associated malalignment, osteotomy can improve the results of ligament reconstruction.

Introduction

These injuries include a spectrum of severities ranging from a cruciate ligament rupture plus a minor tear of a collateral ligament to frank dislocation of the tibiofemoral joint (Box 8.12.1). Since most dislocations spontaneously reduce, their incidence is considerably higher than was once thought. Any knee with ruptures of three or more ligaments or a major disruption of two ligaments has likely to have been dislocated at the time of injury. Awareness of this is important because of the risk of neurovascular injury associated with knee dislocation. Although the majority of these major injuries are associated with major trauma, in the morbidly obese, knee dislocation can occur with relatively minor injury.

Box 8.12.1 Knee dislocation

- Associated with ruptures of three or more ligaments or a major disruption of two ligaments
- High risk of neurovascular injury. Angiography/vascular ultrasound mandatory
- More common with major trauma, but associated minor trauma especially in the obese.

Acute management

This is dealt with in detail elsewhere in this book, but some important points need to be made. Firstly, awareness for the potential for a knee dislocation is important. Any knee that has multiple plane laxity may have dislocated, particularly one in which there is not a tense haemarthrosis from leakage of blood into the soft tissues through capsular tears.

Neurovascular injury should be ruled out. The authors’ preference is that all such knees should have an angiogram as Doppler assessment cannot identify intimal flap tears of the artery that may need surgery.

If the knee is dislocated at presentation, it should be reduced immediately. Very rarely it is irreducible if the femoral condyle (usually medial) has protruded through a rent in the soft tissues. The initial management for the knee joint is then to maintain congruent reduction. If the posterior cruciate ligament (PCL) is ruptured, a fixed posterior subluxed contracture can develop. Regular x-rays to ensure maintenance of congruent reduction are important.

Usually an adequate brace will suffice, and allows early joint motion and icing to reduce swelling and avoid early contracture formation. Bridging external fixation should really only be used to protect arterial repairs or reconstructions. In other circumstances, an external fixator interferes with the ability to treat the soft tissues properly, runs the risk of pin tract infections, and frequently holds the joint in a subluxed position.

Magnetic resonance imaging (MRI) helps to establish the anatomy of the injury, but is no substitute for clinical assessment which gives greater detail about the severity of any instability.

Surgical management (Box 8.12.2)

There are few justifications for non-surgical management of a knee that has actually dislocated as this tends to lead to an unfortunate combination of stiffness, instability, and rapid deterioration with chondral damage. There is still considerable debate as to whether surgical repair or reconstruction of the injured ligaments should be undertaken within the first 2–3 weeks, or delayed 6–12 weeks following injury. Certain factors may determine the options available. If vascular reconstruction has been undertaken or there has been an open injury, then delayed treatment of the ligaments may well be necessary. Best results from treatment occur when surgery is undertaken around 2 weeks from injury. Any time after this the repair of ruptured soft tissues is often impossible and only reconstructive procedures can be undertaken. Posterolateral corner injuries, in particular, are amenable to repair. The results of successful repair are always superior to reconstruction, presumably due to the restoration of normal anatomy with...
concomitant proprioception. In addition, where the cruciate ligaments are avulsed from bone, they too can be repaired with possible success. By reconstructing all injured ligaments simultaneously there is less risk of overload of the repair or reconstructions undertaken. The provision of congruent range of motion with stability allows the soft tissue envelope to heal at appropriate tension throughout the range of knee motion and is protective of the chondral tissues. Early mobilization also helps restoration of neuromuscular control of the limb.

**Box 8.12.2 Acute management**

- Immediate reduction and stabilization usually with a brace
- Bridging external fixation if vascular repair/reconstruction
- Acute repair within 2–3 weeks of injury likely to provide superior results compared to later reconstructions, especially the posterolateral corner.

**Management of ligamentous injuries (Box 8.12.3)**

These injuries are complex and specialist centres are best to be involved, particularly if early surgery is required.

Careful preoperative assessment is crucial in making the necessary surgical plans. Although most multiligament injuries associated with dislocation require early surgery, a number of injury patterns involving the medial collateral ligament (MCL) and more minor PCL injuries are best treated conservatively at first to allow these structures to heal with bracing. This greatly reduces the amount of surgery that is subsequently required.

Clinical evaluation of the knee includes observation of patterns of bruising and clinical tests of ligament laxity. Plain x-rays including long leg alignment films in chronic cases are essential. MRI scanning is helpful and also highlights significant osteochondral lesions or meniscal pathology.

**Management of each component of the ligament injury**

**Anterior cruciate ligament**

The management of anterior cruciate ligament (ACL) ruptures is covered elsewhere in this text (see Chapter 8.11). Even with an isolated ACL rupture, the majority of young active patients benefit from reconstructive surgery. In the context of a multiple ligament injury to the knee, however, ACL reconstruction is essential.

**Posterior cruciate ligament**

The extra-synovial nature of the PCL means that it does have some capacity to heal, particularly if the other ligament injured is the MCL which also has significant healing capacity. Bracing many of the combined PCL/MCL injuries for 6 weeks will restore normal stability and if any subsequent surgery is required it may be much more minor than if undertaken at the very early stage. Nevertheless, if it is clear that clinical assessment shows gross disruption of the PCL then early reconstruction is usually preferable. Clinical examination, which may require an anaesthetic in the acute situation, is best performed by the posterior drawer test. With the foot and therefore tibia in the neutral rotation position and the knee at 90 degrees of flexion, the tibia is pushed posteriorly. If a tibiofemoral ‘step off’ is present but less than the normal side, then this represents Grade 1 laxity. If the tibia is level with the front of the femur (i.e. there is no step off) then this is Grade 2 laxity. If the tibia has sagged behind the distal femur then this represents Grade 3 laxity. If Grade 3 laxity is present then there is virtual certainty of concomitant injury to one or both collateral ligament complexes.

Isolated Grade 1 injuries of the PCL need non-surgical treatment and invariably do well. Grade 3 ligament injuries have a poor prognosis and will require early reconstruction or repair (Figure 8.12.1). This will invariably involve treatment of at least one other ligament disruption. Controversy still reigns regarding the isolated Grade 2 lesions. Patients will often function well with this injury, but there is mounting evidence of significant arthritic damage in the longer term. There is as yet no evidence, however, that early stabilization in this way reduces the long-term risk of arthritis.
The PCL has two functional bundles of fibres, the anterolateral, which is more important, and the posteromedial bundle. Even in cases of complete rupture of both bundles of the PCL, in vitro 'bench' testing shows that the addition of a second posteromedial bundle to the reconstruction offers only modest benefit. In the context of acute reconstructions for knee dislocation, most surgeons would only undertake a single-bundle reconstruction. The question remains whether the addition of a posteromedial bundle in the reconstruction is of long-term advantage for more chronic cases.

In the case of a knee with multiligament injury, it is illogical to address all other ligaments apart from the PCL assuming that one will render the knee an isolated PCL-deficient one. Isolated PCL injuries do not involve extensive damage to the capsular structures nor the proprioceptive deficit that occurs with a PCL rupture in the dislocated knee. If one was to reconstruct only one cruciate ligament the PCL should always take precedence. The ACL can always be dealt with at a later stage.

Medial collateral ligament complex

Most MCL injuries of all severities can be treated non-surgically. Those requiring early repair are those in which an MRI scan shows curling up of an avulsed MCL which clearly would not heal well, or cases in which the MCL is 'flipped' into the joint or where the meniscus has been extruded with the avulsed ligament. In addition, in cases where both cruciate ligaments are ruptured and require early surgery, failure to undertake early MCL repair is likely to overload the cruciate ligaments' repairs or reconstructions.

The MCL complex provides the primary restraint to valgus force, which needs to be assessed both in flexion and extension. Opening at all in extension indicates a failure of the posteromedial corner/posterior capsule. In addition, the deep MCL restrains external rotation. A secondary sign of MCL laxity in the presence of ACL laxity, is failure of tibial external rotation to abolish the anterior drawer sign. Knowledge of the anatomy of the medial ligament complex is critical to undertake an effective repair that does not render the knee joint stiff. This anatomy has been described by Warren and Marshall as being in three layers. The most superficial layer 1 can remain intact unless there is major disruption and only once this is incised is the magnitude of the MCL injury visible. The ligament can usually be repaired with suture and suture anchors.

In the chronic setting, most MCL laxity can be dealt with by opening layer 1 and undertaking plication of the loose deep MCL if the laxity is above the meniscus. If braced appropriately this double breasting of the tissue usually leads to good healing. If at arthroscopy it is clear that the laxity is inframeniscal, then layers 2 and 3 may need to be elevated from the tibia before reattachment in an appropriate position. The soft tissue quality may be poor and a simple plicating technique doomed. Although recent focus has been on the posterolateral corner, uncontrolled medial ligament laxity is far more challenging surgically. The superficial MCL and posteromedial corner can be stabilized using a four-strand hamstring tendon or patellar tendon allograft.

Posterolateral corner/lateral ligament complex

The structures involved include the lateral collateral ligament (LCL), the popliteus tendon and associated popliteofibular ligament, biceps tendon and gastrocnemius tendon, and the posterolateral capsule. The primary restraint to varus stress is the LCL. The popliteofibular ligament and attached popliteus tendon form the main restraint to external rotation. Significant injuries to the posterolateral corner are best evaluated by clinical assessment although with improved understanding of the structures comprising this region of the knee, MRI now is increasingly useful.

The LCL is tested by applying varus stress to the knee at 30 degrees but also in extension. Laxity in extension indicates disruption of the posterior structures/capsule. To assess the popliteofibular ligament there are a number of tests. Most knee specialists agree that the ‘Dial test’ is the most reliable. This can be undertaken in the clinic with the patient prone with external rotation of both legs applied simultaneously with the knee at 90 degrees and also, most specifically, at 30 degrees. An isolated posterolateral corner injury will reveal an excess of external rotation most clearly at 30 degrees. If the PCL is involved this increases the sign at 90 degrees. The test is said to be significant if there is more than 10 degrees side-to-side difference in excursion. Also with a PCL rupture, a so-called reverse pivot shift may be present. With the knee flexed and the leg externally rotated to cause posterior subluxation of the lateral tibia, the knee is then extended with concurrent applied valgus to compress the lateral articulation. A ‘clunk’ as the lateral tibial plateau comes forward into reduced position represents a positive result. It is essential to check the
opposite knee since around 20% of normal knees have a similar finding. In the chronic case, assessment of gait is essential as significant posterolateral corner injury in the naturally varus aligned limb can lead to a dynamic varus thrust as a patient goes through the stance phase of gait. Particularly bad injuries also have hyperextension present. In these cases, lifting the limb with the great toe will lead to hyperextension, varus and external rotation (a positive Hughston test).

Determining the site of injury to the ligament complex can be helped by MRI scanning and also at arthroscopy where examination of the lateral compartment can show proximal avulsion of the popliteus from direct observation or identify whether opening up occurs above or below the lateral meniscus or indeed both.

Posterolateral corner injuries are best treated acutely since many of the structures can be repaired. This is particularly true in avulsion injuries of the fibular head (Figure 8.12.2). When the biceps, LCL, and popliteofibular ligament all come off as one, or the fibular head is fractured, simple reattachment restores normal laxity to the posterolateral corner. Fibular head fracture fixation is not easy. The common peroneal nerve should be identified and dissected free. The senior author has found that the tension band wiring technique is the most efficient way of fixing the fracture. In other cases in which there are midsubstance ruptures or proximal avulsion-type injuries the structures involved can be repaired directly. At the end of the repair stage of surgery it is essential to check the quality of repair as a reconstruction is usually also required to support the repaired tissues. There are a number of ‘anatomical’ reconstructive procedures described, but unfortunately none of them can provide the dynamic tensioning effect of the popliteus. It may be reasonable therefore to accept non-anatomical compromises such as the modified Larson procedure. This involves taking hamstring tendons from the lateral epicondyle of the femur through a tunnel in the fibular head (Figure 8.12.3). The advantage of this procedure is that it is more peripheral to the centre of the knee at which rotation occurs and therefore its lever arm for effectiveness against external rotation is maximal. If the lateral soft tissues are in reasonable condition then, in chronic cases, a useful option is to detach the lateral epicondyle which is then advanced to retension the posterolateral corner.

Posterolateral corner injuries have a significant rate of common peroneal nerve damage. In a series of 54 cases of posterolateral corner disruption the incidence of injury was 17% and in all but one case this occurred with distal injury to the ligament complex involving avulsion of the biceps’ tendon with or without a fibular head fracture. If a common peroneal nerve injury does occur, then it is essential that an equinus contracture is not allowed to develop and that stretching and splintage are started early.
The role of osteotomy

The main use of osteotomy for multiple ligament injury to the knee is in chronic cases involving a posterolateral corner disruption and natural varus alignment of the limb. In patients who naturally stand in varus, if the soft tissues are simply reconstructed alone then the dynamic stress applied to the reconstruction causes stretching out of the reconstruction or repair over time. In the normal varus knee, this stretching out does not occur since normal proprioception is present through the dynamic contraction of structures such as the biceps, popliteus, and lateral gastrocnemius and the lateral joint is kept closed down under limb loading. Unfortunately, after ligament injury this proprioceptive control is impaired and deliberate realignment of the limb in the coronal plane with osteotomy can be very useful. This is essentially a treatment for PCL laxity, although some authors have suggested that it may enhance restoration of rotational control.

The need for an osteotomy is determined by the presence of dynamic thrust seen on gait or excess varus alignment on long leg x-rays. In osteotomy for osteoarthritis a deliberate deformity is produced to shift the weight-bearing axis to the unaffected compartment of the tibiotalar joint. When undertaking osteotomy for dynamic laxity for ligament problems, the correction needs to be much less aggressive. The aim is simply to bring the weight-bearing line through the centre of the joint. Calculation of the correct correction is, of course, important. A common error producing overcorrection occurs when there is a failure to recognize that part of the excess varus measured on long leg x-rays may be due to opening of the lateral joint compartment because of PCL laxity. As soon as the weight-bearing line comes across the midline, the lateral compartment will close down as it is loaded, so removing the lateral soft tissue laxity component of the deformity. It should therefore not be included in the calculation of the angle of correction required. A good working rule is that for every excess opening of 1mm, 1 degree of osteotomy correction should be subtracted. The addition of a valgus high tibial osteotomy in the treatment of posterolateral corner insufficiency can be dramatic. It can be undertaken as a preliminary procedure or at the same time as the ligament reconstruction.

The need for distal femoral osteotomy to produce varus in cases of chronic MCL laxity is much less common, but can also be very helpful.

It is easy to think simply in terms of the coronal plane, but the sagittal alignment of the tibial slope is also of great importance in treatment of multiple ligament injury to the knee. The steeper the tibial slope, the greater the tendency there is to anterior tibial translation under knee loading. Equally a flatter than usual or reversed tibial slope will lead to posterior subluxation. Deliberate control of tibial slope at the time of osteotomy can aid ACL or PCL laxity. In cases of ACL deficiency it is preferable to reduce the tibial slope and this is easily accomplished during lateral closing wedge upper tibial osteotomy. Since the approach to the tibia is lateral, the posterolateral corner is easily reconstructed at the same time. If as well as posterolateral corner insufficiency there is PCL deficiency present, then a medial opening wedge osteotomy is preferable. Since this osteotomy is anteromedial, increasing the tibial slope tends to occur when undertaking this procedure.

Realignment of the lower limb with an osteotomy can dramatically improve the quality of results from ligament reconstruction. It is a potent tool in the management of these complex problems.

Box 8.12.3 Chronic management

♦ Most chronic multiligament injuries require surgical reconstruction
♦ Grade 3 PCL injuries always associated with other ligament disruptions and usually require surgical repair/reconstruction
♦ Osteotomy can improve the results of ligament reconstruction in cases with associated malalignment.

Rehabilitation (Box 8.12.4)

This is complex and recovery will take place over 2 years following surgery for a knee dislocation. Most of the recovery occurs in the first 6 months, but patients should be counselled about the long process. Soft tissues should be dealt with early on with icing and passive mobilizations to prevent fat pad contractures. Early motion is also important to reduce stiffness and help protect the joint surfaces. If a PCL reconstruction has been undertaken then flexion should be restricted to 60 degrees in the first few weeks as further flexion increase tension and may stretch the reconstruction. By 6 weeks from surgery, 90 degrees should be achieved in these cases with full flexion allowed by 12 weeks. To help protect the collateral ligaments, restricted extension can be helpful but tends to lead to a fixed flexion deformity which inevitably results in a poor outcome. As a result many surgeons now insist on full extension (not hyperextension) as soon as possible after surgery.

Unlike ACL reconstruction, PCL reconstruction has a tendency to stretch and therefore the calf should always be supported when at rest for the first 3 months from surgery. In addition, when undertaking active flexion exercises, the therapist should apply an anterior tibial drawer to protect the PCL. The rehabilitation must progress much more slowly than that for ACL reconstruction.

Box 8.12.4 Rehabilitation

♦ Rehabilitation is complex and will take place over 2 years following surgery
♦ Most patients can manage activities of daily living and work following surgery
♦ Return to sport possible but carries significant risk of chondral damage.
Weight-bearing status is dependent upon the confidence in the reconstruction, but is generally encouraged as it helps restoration of normal lower limb muscle function.

A strengthening regimen should be started early but must avoid excess stress on the ligament. Proprioceptive drills start early on and become more challenging after 3 months.

Results

With an experienced surgeon the expectation is that at the end of surgical reconstruction in acute or chronic cases, normal laxity of all ligament groups should be obtained (and no more than grade I laxity by end of healing process). The long-term result is usually dependent on the presence or absence of significant chondral damage. In chronic cases, unfortunately most patients will have accumulated some chondral damage from the excess laxity in the ligament complexes, but even in acute cases chondral injury can mitigate against a good result. Although ligament laxity can be restored to near normal, the proprioceptive loss can never be fully addressed. Rehabilitation allows the patient to refine proprioception of the joint by enhanced feedback from structures around the joint. Unfortunately this is never normal and one must never forget what occurs in the situation of a Charcot joint. Some patients who are determined will certainly get back to sport, but particularly where long periods of running are involved, the risk that this will lead to chondral degeneration is high. Most patients are able to undertake activities of daily living and work without difficulty.

Summary points

- Ideal treatment option for end-stage osteoarthritis affecting a single compartment of the knee
- Unicompartmental knee replacement has many advantages over total knee replacement
  - Restores near normal kinematics
  - Usually gives a better range of movement
  - Patients require a shorter hospital stay
  - Fewer serious complications

Introduction

Primary osteoarthritis (OA) is common and predominantly presents after the fifth decade of life or later. In the USA, 12% of the adult population have signs and symptoms of the disease. It is a condition of the articular cartilage characterized by morphological, biochemical, molecular, and biomechanical changes to the cells and matrix which lead to softening, fibrillation, ulceration, and loss of cartilage. There is also sclerosis and eburnation of subchondral bone, with osteophyte and subchondral cyst formation. The aetiology is poorly understood and is believed to be multifactorial, with genetic and mechanical factors playing a major role. The characteristic manifestations of the disease are progressive pain, swelling, stiffness, and deformity which impede normal function and produce disability. The knee joint is one of the most commonly affected joints with an estimated incidence of 240/100 000 person-years. A number of characteristic patterns have been recognized in the knee: bilateral disease is more common than unilateral, tibiofemoral disease is more common than isolated patellofemoral disease, and finally with unicompartmental tibiofemoral disease, the medial side is more often affected than the lateral side.

Anteromedial OA of the knee was described as a pathological condition by White and colleagues in 1991. The cartilage erosion in the medial compartment is typically anterior or central in the tibial plateau, with preservation of cartilage posteriorly. There is a corresponding lesion on the distal femoral condyle. In extension, the femoral condyle sits within the tibial defect producing a varus deformity. The varus deformity corrects on flexing the knee as the preserved cartilage over the posterior part of the medial femoral condyle rides over the intact cartilage of the posterior tibial plateau. As a consequence, the medial collateral ligament is not shortened and the varus deformity remains correctible near extension. The anterior cruciate ligament (ACL) is usually preserved and it is postulated that retention of this structure prevents the OA from progressing to other compartments. This pattern of OA is believed to account for one in four osteoarthritic knees presenting for replacement in some centres. Knee replacement can be total or partial. In total knee replacement (TKR), both the medial and lateral tibiofemoral compartments are replaced with or without patella resurfacing. In partial or unicompartmental knee replacement (UKR), only the medial or the lateral (MCL) or the patellofemoral compartment is replaced.

The first UKRs used in clinical practice were the McIntosh (1954) and McKeever (1960) prostheses. More modern designs followed with the introduction of the Marmor (1972) and St Georg Sled (1976) implants. They have been widely used in both the medial and lateral compartments of the knee. Most UKR designs have a fixed polyethylene bearing (with or without a metal-backed tibia) and a polycentric femoral component. The medial Oxford UKR was designed by Goodfellow and O’Connor and was first used as a unicompartmental device in 1982. The design employs a spherical metal femoral component and a flat tibial base plate. Between the two an unconstrained polyethylene bearing is inserted. As the femur is spherical the bearing has fully congruent contact with both femur and tibia in all positions of flexion and extension. It therefore mimics the normal meniscus. The Oxford is the only UKR design which employs a fully congruous mobile bearing (Figure 8.13.1).
Surgical indications (Boxes 8.13.1 and 8.13.2)

In order to obtain good long-term results after UKR, the correct indications must be used. These are OA in the medial or lateral femorotibial compartment which may be primary OA or secondary due to osteonecrosis. In 1989, Kozinn and Scott suggested that the ideal candidate for a fixed bearing UKR is older than 60 years, not obese, and not extremely active with a preoperative range of motion of at least 5–90 degrees, a deformity of less than 15 degrees, and a clinically stable knee. According to Kozinn and Scott, contraindications for UKR are inflammatory arthropathy (e.g. rheumatoid arthritis), patello-femoral arthritis ligamentous instability, and tibial subluxation. The flexion deformity should be less than 15 degrees and the intra-articular angular deformity should be correctible suggesting that the collateral ligament is not shortened. The indications for the mobile bearing Oxford are different from those of fixed bearing UKR. There should be significant symptoms and anteromedial OA (or AVN). By this it is meant that there is full thickness medial OA with an intact ACL. There should also be full thickness lateral cartilage and a correctable varus deformity indicating that the MCL is functionally intact. These are best shown on a varus stress x-ray. The Oxford group ignore the accepted contraindications as for the mobile bearing device they do not comprise the outcome. They therefore ignore age, obesity, chondrocalcinosis, activity, and patellofemoral joint damage. Previous high tibial osteotomy (HTO) is a relative contraindication as the failure rates of UKR with previous HTO are higher.

Surgical technique

Until 1997 UKR was usually performed through a surgical approach similar to TKR. In 1997, Repicci and Eberle showed that it was possible to resurface one compartment of the knee through a smaller incision extending from the proximal border of the patella to the proximal end of the tibia and that such an approach minimized the postoperative morbidity. This minimally invasive surgical (MIS) technique is now widely used to implant UKRs. Price and colleagues demonstrated that with a medial Oxford UKR, the average rate of recovery (as measured by time taken to achieve straight leg raise, 70 degrees of knee flexion, and independent stair climbing) was twice as fast as after an open incision UKR and three times faster than an open incision TKR. With MIS techniques, surgical damage to the soft tissues is reduced, injury to the quadriceps is minimal, patella is not dislocated, and the synovial reflections of the suprapatellar pouch remain intact.

Box 8.13.2 Contraindications for UKR

- Inflammatory arthropathy
- Previous HTO
- Ligamentous instability
- Tibial subluxation.

Box 8.13.1 Prerequisites for UKR

- Isolated compartment arthritis (patellofemoral joint can be ignored)
- Intact ACL
- Correctible varus deformity
- Full thickness cartilage loss on both femur and tibia in the affected compartment.

Results

The most commonly used unicompartmental prostheses, apart from the Oxford UKR have been fixed bearing devices. The early results of fixed bearing UKRs were not encouraging. Insall and Aglietti reported results of 32 fixed bearing UKRs. At 6 years postoperation only one was rated as excellent, seven knees as good, four as fair, and ten knees as poor. Seven knees (28%) had been revised. Similarly, Mallory and Danyi found a revision rate of 30% in a group of 42 procedures. More contemporary studies have also documented poor outcomes for some series of fixed bearing UKR—in particular the poor performance of the PCA fixed bearing UKR. This device has been shown to have poor survival and clinical outcomes, in association with catastrophic polyethylene wear.

Data from the Swedish Knee Arthroplasty Register illustrates that most commonly used contemporary fixed bearing devices in Sweden between 1990 and 1999 were the St Georg Sled, the Marmor, the Brigham, and the Miller–Galante prostheses. All four prostheses have a femoral component with polyradius geometry articulating with a flat polyethylene surface on the tibial side. Good clinical outcomes have been reported for each of these prostheses. The St Georg Sled is a fixed bearing device with an all
It was introduced into clinical use in 1985. Using the Bristol Knee Score system, Ansari and colleagues found that 92% of St Georg Sled prostheses reviewed had good or excellent outcome. More recently Ackroyd et al. reported the results of a series of 280 knees followed for a mean of 6 years, with excellent or good results were found in 77.9% of patients using the same knee scoring system. The designer of the Marmor implant has published the results of a series of 60 knees followed for 10–13 years. Using the HSS (Hospital for Special Surgery) rating system, 30 were excellent, eight good, four fair, and 18 poor. Seventy per cent of the patients had satisfactory results and pain relief was accomplished in 86.6% cases. Squire and colleagues published an independent series of Marmor prostheses that had been followed for a minimum of 15 years with a mean HSS score of 82. The Brigham prosthesis was introduced to clinical practice in 1981. Scott et al. reported 100 consecutive Brigham UKRs reviewed after 8–12 years, 64 knees (51 patients) being reviewed clinically at last follow-up. Of these, 87% had no significant pain. Angenson reported on the results of a series of 160 consecutive Miller–Galante prostheses with a mean preoperative HSS score of 59 improving to 97 at the final review (mean follow-up 5.5 years; range 3–10).

Various studies have been published demonstrating excellent results of the medial Oxford UKR with survival rates at 10 years of 94–100%. Suward and Price described a 95% survival of the implant at 15 years. Rajasekhar et al. reported on 135 Oxford UKRs implanted in a district general hospital by a single surgeon. The mean follow-up was 5.8 years (2–12 years). Five knees have been revised giving a cumulative rate of survival of the prosthesis at 10 years of 94% (95% confidence interval (CI) 84.0–97.8). Knee rating and patient function were assessed using the modified Knee Society scoring system. The mean knee score was 92.2 (95% CI 51–100) and the mean functional score 76.2 (95% CI 51–100). Although not all centres have achieved such good results, the Swedish Knee Arthroplasty Register has shown that those undertaking at least two replacements per month achieved a survival of about 93% at 9 years. These long-term results have also shown that with this device if the failures do occur, they tend to occur early. This is in part because of the fully congruous mobile bearing, which reduces the risk of long-term failure due to wear.

Table 8.13.1 summarizes the majority of the published 10-year survival results from series of 100 or more medial and/or lateral UKR.

**UKR versus HTO**

HTO is an accepted treatment for unicompartmental OA of the knee. A well done osteotomy should overcorrect the deformity of the mechanical axis of the limb to pass through the lateral side of the knee which unloads the medial compartment of the knee and reduces symptoms. This can overload the lateral compartment which in turn may fail. The advantage of HTO is that it maintains the native knee so patients can undertake any activities they want. Conventional HTO, however, can be a technically demanding procedure with potential for complications. Rehabilitation is usually prolonged and patients may have to use crutches for an extended period of time. The clinical outcome and survivorship after HTO tends to be inferior when compared to UKR. One study compared groups of patients with osteoarthritic knees who had either a St Georg Sled UKR or a HTO at a minimum follow up of 12 years. The authors reported a significantly lower revision rate and better functional outcome for the UKR group.

**UKR versus TKR**

UKR preserves all undamaged structures within the joint, in particular the cruciate ligaments, and can therefore restore knee function nearly to normal. After UKR the range of movement is better than after TKR, the knee feels more natural, and pain relief is
as good or better. In terms of morbidity, infection is less common as is the requirement for postoperative blood transfusion. Recovery is more rapid and the postoperative gait is more physiological. Knee kinematics after UKR are restored to normal, unlike after TKR.

However, UKR has the disadvantage that the medium- and long-term revision rates are generally higher than for TKR. The primary reason for this is that UKRs are easier to revise than a TKR so they tend to be revised for less severe symptoms. Other reasons include:

- The high polyethylene wear rate of thin tibial components subjected to incongruous loading
- Imprecise (and inappropriate) patient selection
- Lack of instruments to accurately implant the device.

The issue of high polyethylene wear is dependent on the design of the implant. Fixed bearing devices tend to fail early because of wear in young active patients. The Oxford UKR maintains high contact area (about 6cm²) throughout the range of knee movement and therefore the contact pressure is low with this device. Measurement of retrieved bearings has shown a mean linear wear rate of 0.03mm/year and even less (0.01mm/year) if the knee had been functioning normally with no impingement.

Over the years, the surgical technique and instrumentation have been refined. Provided a good UKR device is implanted correctly in correct patients, the long-term survival can be similar to that of TKR.

**Revision of UKR to TKR**

Revision of a UKR to a TKR is technically less demanding than revision of a TKR. This is primarily due to preservation of native bone in the retained compartment. The use of constrained or stemmed TKR implants is rarely necessary and bone graft if needed can be obtained from the revision cuts, thereby allowing the surgeon to use patient’s own bone. Martin et al. reported the outcome of 23 Oxford UKRs revised to TKRs with a mean follow-up of 4.1 years. Only one patient needed rerevision for infection. In addition, in all the cases except one routine implant could be used without the addition of any augments or constraints.

**Lateral UKR**

Isolated lateral compartment arthritis is less common than its medial counterpart. It can occur as a sequel to a previous lateral meniscectomy or significant trauma and is usually associated with femoral valgus. Therefore, lateral UKR only account for around 10% of all UKRs. In the lateral compartment of the knee during flexion and rotation there is a large amount of movement of the femoral condyle on the tibia. Many designs of UKR do not account for this increased translation and the kinematics can be suboptimal. The increasing movement offered by a mobile bearing would seem ideally suited to address this problem and a mobile bearing lateral UKR would be a sensible choice. However, in the past, results of a mobile bearing lateral UKR have been disappointing with a 5-year survival of 82% with commonest reason for failure being bearing dislocation. Dislocation is thought to be much more common in the lateral compartment because in flexion, the lateral collateral ligament is slack whereas on the medial side MCL remains tight. This allows the lateral compartment to be distracted on average 7mm, whereas the medial can only be distracted on average 2mm. Recently a new design of Oxford Knee has been introduced specifically for the lateral side (Figure 8.13.2). This has a domed tibial component and a biconcave mobile bearing. When used with a modified surgical technique this has significantly reduced the risk of bearing dislocation with an improvement in range of movement.

---

**Summary**

UKA has many advantages over TKR and is the preferred treatment option for arthritis limited to a single compartment of the knee. The procedure can be performed using minimally invasive surgical technique. Long-term failure rates can be reduced by proper
patient selection, good surgical technique, and with the use of sophisticated instrumentation and optimal implant design.

Summary points

- Menisci have a complex load bearing function
- Loss leads to accelerated articular cartilage wear
- Injury is common but symptomatic relief straightforward with skilled arthroscopic surgery
- Peripheral tears have a blood supply and are potentially repairable.

Introduction

In the past, scant regard was paid to these collagenous structures, and almost any patient with a symptomatic knee, whatever their age, would have them totally removed through an arthrotomy with a Smillie knife.

Over time a more conservative surgical approach has evolved as surgeons have realized that menisci actually have an important role in knee function and that meniscectomized knees inevitably progress to accelerated osteoarthrosis. Arthroscopy has revolutionized the management of meniscal injury, allowing minimal resection or repair, with minimal morbidity and an extremely low complication rate.

Structure, function, and biomechanics

The menisci are semilunar in plan view, wedge-shaped in cross-section, and consist predominately of type 1 collagen, although types II, III, V, and VI are present in small amounts. Type II fibres are more prominent on the surface layers. They are attached circumferentially to the capsule and at either end to the tibial surface by strong ligaments (Figure 8.14.1). In addition, the posterior horn of the lateral meniscus has two ligaments (Wrisberg and Humphrey) which pass either side of the posterior cruciate ligament to the medial femoral condyle.

The predominant orientation of collagen bundles is circumferential, with a small number of radially orientated ‘tie’ fibres. When load is applied, the orientation of the fibres, with the meniscus fixed at either end, allows the generation of ‘hoop stresses’ and this in turn absorbs load across the joint. In the medial compartment the meniscus absorbs 40% of the load across the tibiofemoral joint and the lateral compartment 60% due to its higher relative surface area.

This becomes even more important when the anatomy of the tibial plateau on either side of the joint is taken into account. In the medial compartment the medial tibial plateau is concave and in the lateral compartment, convex. The consequences of loss of a meniscus are therefore much more severe on the lateral side of the joint, where without the meniscus there is almost point contact between the articular surfaces. The high contact stresses that this creates can lead to the rapid development of wear.

‘Dynamic’ magnetic resonance imaging (MRI) studies have shown that the medial meniscus is static during flexion and extension making the posterior horn vulnerable to tearing in extremes of flexion. The lateral meniscus, however, is extremely mobile during flexion and extension, virtually coming off the back of the lateral tibial plateau during full flexion.

The only common developmental variation is the discoid meniscus which almost exclusively occurs on the lateral side (Figure 8.14.2) and has a prevalence of approximately 5%. This can produce symptoms at a very young age.
History

In the younger patient the typical history of injury is of a weight-bearing, twisting injury. Pain is localized to the affected joint line. Swelling usually occurs slowly overnight and often settles in a few days.

In non-sporting situations, patients with occupations that involve working with the knees in full flexion such as electricians, plumbers, etc., are prone to tearing the posterior horn of the medial meniscus.

In the more chronic situation, there is recurrent pain localized to the affected joint line and intermittent swelling.

Examination

Chronic meniscal injuries usually produce a degree of quadriceps wasting. There may be subtle losses of either terminal extension or flexion. It is important to look for a small effusion as this may confirm intra-articular pathology. There may be joint line tenderness and a positive McMurray’s test.

Investigation

Plain x-rays (anteroposterior weight bearing, intercondylar and lateral) are useful, where early degenerative change may be identified and will exclude a number of other pathologies. Degenerative tears of the medial meniscus can produce narrowing of the posteromedial joint space on the intercondylar view.

MRI is only indicated where the diagnosis is in doubt after history, examination, and plain x-rays. MRI is neither 100% sensitive nor specific for either medial or lateral meniscal pathology and may completely miss a reduced peripheral bucket handle tear. It also has a false positive rate, especially in patients over the age of 40 where there is almost always a degenerate signal in the posterior horn of the medial meniscus which is difficult to distinguish from a degenerate tear.

MRI diagnosis should always be taken in conjunction with history and examination before subjecting the patient to surgery.

Differential diagnosis

Early compartment wear and small chondral lesions of the femoral or tibial surfaces can produce symptoms very similar to that of a meniscal tear and these may not be picked up on MRI scanning.

On the medial side of the joint, a medial plica and injury to the deep part of the medial collateral ligament (Figure 8.14.3) may also produce a clinical picture that is difficult to differentiate from a meniscal tear and these are also unlikely to be diagnosed on MRI.
Patterns of injury

Flap tears

Flap tears (Figure 8.14.4) tend to produce intermittent symptoms, with a feeling of catching and clicking. If in the middle third of the meniscus the patient may be able to feel something ‘pop out’ at the joint line. (If the lump always appears at the same site it will be a flap tear and not a loose body.)

Occasionally the flap will tuck itself underneath the rim of the meniscus—these tears often produce a fairly constant and quite significant pain. At arthroscopy there is a rounded appearance to the edge of the meniscus and the offending fragment can be retrieved into the joint with an arthroscopic probe, before resection.

Bucket handle tears

These tears may present with a locked knee or produce intermittent symptoms of true locking. A locked knee due to a torn meniscus presents with an inability to fully extend the knee with pain localized to the site of the pathology. Locking in full extension tends to be produced by patellofemoral pathology.

In the acute situation peripheral bucket handle tears may produce a haemarthrosis.

Once locked, the knee may spontaneously ‘clunk’ back into extension or, as patients learn how to unlock the knee, by hyperflexing and rotating the joint.

Horizontal cleavage tears

Horizontal cleavage tears (Figure 8.14.5) can act like flap valves allowing synovial fluid to be forced out of the joint during knee flexion and then not allowing it to return. This produces a meniscal cyst, classically seen on the lateral side. Meniscal cysts are not uncommon on the medial side but are less visible because of the broad medial collateral ligament.
Symptoms are of a chronic aching pain localized over the cyst, often worse at night. On the lateral side, a bony hard cyst may be found, localized to the joint line and, most pronounced at 45 degrees of flexion.

Almost invariably on the lateral side, there is a small radial tear at the junction of middle and anterior thirds with a horizontal cleavage behind it, leading into the cyst.

Degenerate tears

Degenerate type tears are usually complex with a combination of flap and horizontal cleavage patterns. Sometimes initial inspection may appear relatively normal but there may be an inferior partial thickness tear which then leads in to a horizontal cleavage component.

On the medial side with degenerate posterior horn tears, there may be limitation of flexion and difficulty with squatting. Patients often also complain of pain at night when sleeping on their side with the knees placed together.

Treatment

There are some tears that do not require treatment. Partial thickness or short (less than 5mm) full thickness split tears that are stable and small radial tears can safely be left, particularly if they are asymptomatic.

The majority of symptomatic meniscal tears are treated by arthroscopic resection of the damaged portion of the meniscus leaving as much normal tissue as possible. This results in a speedy resolution of symptoms with minimal morbidity.

Portal placement is critical in making resection technically easier. For a lateral meniscal tear an anterolateral portal for the arthroscope and a medial portal in the middle of the 'soft spot', with the knee in the 'figure 4' position, for the instruments, allows ready access to most of the meniscus. Slightly extending the knee makes surgery to the anterior horn easier.

On the medial side, an anterolateral portal and a low medial portal just over the anterior horn allows access to the posteromedial aspect of the joint. This is aided by a side post at mid-thigh and a strong assistant (or a leg holder) to open out the joint which can sometimes be very tight. Surgery to the anterior third may be aided by swapping the arthroscope to the medial portal and arthroscopic tools to the lateral.

A variety of sharp specialist tools with upbiters, sidebiters, and arthroscopic shavers are essential to provide speedy, low-morbidity surgery, without damage to the surrounding articular cartilage.

In degenerate tears of the posterior horn of the medial meniscus, where there is virtually always a horizontal cleavage component, it is important to remove the inferior leaf of the horizontal cleavage to prevent recurrence of symptoms.

In the absence of associated pathology, recovery to full activity takes on average 4–6 weeks on the medial and 6–8 weeks on the lateral side following resection of a meniscal tear.

Meniscal repair

It was King who first observed that menisci have a limited and peripheral blood supply and that meniscal tears could heal, but only when they involved the peripheral third of the meniscus. This work was expanded by Amoszky and Warren and their work led to the development of a variety of techniques for repairing appropriate meniscal tears rather than just excising them.

The current techniques of repair are either inside–outside (passing suture needles through the meniscus and out through a separate lateral or medial incision) if the tear involves the anterior two-thirds of the meniscus, or inside–inside with a ‘stapling’ device if the tear involves the posterior horn. Devices available include bioabsorbable darts, arrows, and screws as well as devices that use preknotted sutures. It is important to mix superior and inferior surface sutures to prevent the meniscus rucking up.

In an intact knee, a bucket handle tear involving the periphery of the meniscus with bleeding on both sides of the repair (‘red on red’), healing rates are in the region of 66% (Figure 8.14.6).
A red on red lateral meniscal bucket handle tear—an ideal indication for repair.

Rates of healing decrease if the tear is more than 4 weeks old, the peripheral rim width is greater than 4mm, or the patient is over 40 years of age. Rates of healing are better if the repair is done in conjunction with anterior cruciate ligament reconstruction.

Rehabilitation after repair is controversial with a range of protocols recommended from non-weight bearing and restricted range of motion, to full weight bearing with no restriction of range of movement or limitation of activity. Early full weight bearing and motion do not seem to be detrimental to healing rates, although limiting knee flexion to 90 degrees for 6 weeks and only returning to sport at 12 weeks seems a sensible approach.

The future

As the consequences of this common injury have become recognized, the challenge has been to find a solution that will prevent premature degenerative change occurring, lessen patients’ symptoms (predominantly pain), and improve function. This has largely been on two fronts.

Meniscal replacement

Clinical trials of the use of collagen scaffolds sutured into the meniscal defect with the aim of allowing healing to occur were carried out in the early 1990s. Despite promising initial and even medium-term results, this technique has not gained widespread acceptance.

Future developments may include implantation of patients’ fibrocytes into the synthetic collagen matrix, the use of growth factors, and tissue manipulation with gene therapy.

Meniscal transplant

Another key development has been the development of meniscal transplantation, where a suitably sized meniscal allograft is either sutured to a meniscal rim, or is transplanted with a bone bock and ligaments at either end and fixed into a suitably prepared bed.

The experience in both Europe and the USA has been encouraging with satisfactory early to medium-term results in reducing patient symptoms. Long-term results still remain uncertain, however, as does the best technique for preservation, sizing, and implantation.

Further reading

Summary points

- Hind foot arthritis is usually treated orthotically but may need surgical fusion
- Severe ankle arthritis requiring surgical intervention is uncommon
- Arthroscopic debridement of early ankle arthritis is effective
- End stage ankle arthritis can be treated by fusion or arthroplasty
- Ankle replacement has a higher failure rate than hip or knee arthroplasty
- Correct alignment of the hind foot and forefoot are essential for good results.

Introduction

The ankle, hindfoot, and midfoot function as a mobile unit, which provides shock absorption in the early stance phase of gait, and changes to a rigid unit in the late stance phase allowing transmission of power necessary for push off.

Within this complex, the ankle moves principally in dorsiflexion and plantarflexion, the subtalar joint in inversion/eversion, and the midfoot in rotation.

In early stance phase, the plantar fascia and interosseous ligaments are relaxed, the arch is low, and the joints of the hind- and midfoot are mobile, allowing shock absorption by the foot without damaging impacts being transmitted that could cause injury to the foot, the leg, and the trunk.

In later stance phase, the plantar fascia tightens and the arch is restored (by the windlass mechanism, Figure 9.1.1), and all the interosseous ligaments tighten, making the foot rigid. This allows power to be transmitted through the foot, and the weight of the body to be transferred forward without the foot collapsing.

The outcomes of all midfoot, hindfoot, and ankle procedures are often limited, achieving a 'second best' result of a stable pain-free foot, with the ability to walk and function domestically, but rarely restoring the levels of function required for running, and athletic or high demands.

The problems of the hind- and midfoot and the ankle will be considered separately for clarity, although deformity and pain often occur together in all.

Hindfoot and midfoot arthritis

Anatomy

The hindfoot comprises the talus, calcaneus, and navicular bones, as well as their articulations, which are responsible for most of
the inversion/eversion of the foot (subtalar joint) and rotation (talonavicular and calcaneocuboid joints).

In the midfoot the cuboid and cuneiform bones articulate to increase rotation of the foot, but the movements in the midfoot are less than those of the hindfoot.

Dorsiflexion of the foot complex is really limited to the ankle and metatarsophalangeal level.

Each of the joints of the hindfoot and midfoot allow some plantarflexion from their neutral position—contributing about 50% of the overall dorsiflexion/plantarflexion movement of the foot/ankle complex—but none of these joints allow any significant dorsiflexion.

The hindfoot and midfoot rely on a complex arrangement of ligaments between joints for stability, and on tendons which insert into or cross the region for movement.

The blood and nerve supplies of the region are rich, with abundant vessels and nerves which have to be respected by surgical approaches.

In contrast, the soft tissue envelope is thin, prone to injury, and gives little cover to underlying tissues or implanted metalwork.

Swelling of the soft tissues after surgery, especially with dependency during immobilization, makes the area prone to soft tissue break down. Furthermore, the bones of the hindfoot and midfoot generally (with the exception of the calcaneus) have few, if any, muscle attachments and therefore have relatively poor blood supplies. Hence the incidence of delayed or non-union after fusion is higher than in other areas of the body.

When arthritis and collapse occur, the pathological anatomy is changed, with complex deformities produced by unbalanced forces acting on bones and joints producing simultaneous subluxation, dislocation, and bone and joint deformity.

Correction of the deformities is difficult, and although it is tempting to plan simple angular corrections, careful consideration based on findings on clinical examination, biplanar radiographs, and, if necessary, scans often shows rotational and multilevel deformity. If function is to be restored, the deformities have to be corrected in all planes.

Thus, surgery in this area is fraught with potential problems due to geometric complexity and problems with healing. Surgeons undertaking this surgery need to understand these factors and also be able to manage the postoperative splintage, rehabilitation, and orthotic management of the patients.

For all these reasons, and at a time when experience of this type of surgery is waning—because of the virtual disappearance of polio and spina bifida within the United Kingdom—surgery to the mid- and hindfoot is now increasingly limited to specialist tertiary referral centres.

Presentation

Some degree of arthritis in the hind-/midfoot is extremely common with advancing age. Most commonly there is gradual collapse of the arch, leading to increasing stiffness and aching with pain on exertion, but rest pain is rare.

Although such arthritis is common, it is mostly self-treated by supportive footwear and restriction of activity, or in the community by orthotics provided by podiatrists.

Only the severe end of the spectrum, with increasing pain during and after exercise, is usually referred to an orthopaedic department.

There is a strong association between deformity and arthritis. Deformity causes abnormal and unequal loading, leading to arthritic wear and tear, and conversely arthritis often causes collapse of individual bones and abnormal alignment of joints affecting the stability of the longitudinal and transverse arches.

Aetiology

The causes fall into five groups (Box 9.1.1).

Box 9.1.1 Causes of hind- and midfoot arthritis

1) Post traumatic: especially major injuries and talar injuries
2) Systemic arthritis
3) Deformity
4) Coalition
5) Neuropathy.

Post-traumatic

A history of trauma is common in patients presenting to tertiary referral centres.

The hindfoot and midfoot are constantly exposed to low levels of trauma, being vulnerable with every trip and slip, and cumulative effects may account for the wear and tear changes commonly found with advancing age.
More major trauma has an association with arthritis, especially when joint integrity is affected. Injuries to the talus are associated with avascular necrosis due to its poor blood supply, especially after fractures of the neck of the talus, and dislocations. Peritalar arthritis affecting ankle, subtalar and/or talonavicular arthritis then often occur.

Complex calcaneal fractures also often lead to subtalar arthritis. However, even badly destroyed joints sometimes lead to more stiffness than pain, and this may give relatively little restriction.

The risk of developing painful arthritis is linked to the severity of the original injury. The method of early treatment is less well associated with outcome. So open treatment of calcaneal fractures may not decrease the risk of later pain, but anatomical reduction makes any later reconstructive surgery easier and more effective.

In the midfoot, arthritis may follow fracture dislocations including Lisfranc injuries.

Good reduction of the fractures and dislocations is important, because with a well-shaped foot, orthotic management can often control symptoms without resorting to reconstructive surgery.

Systemic arthropathy (Figure 9.1.2A)

All forms of arthritis present in the hind- and midfoot.

Seronegative arthropathies present with heel pain due to enthesopathy.

Generalized osteoarthritides presents with painful arch collapse, or localized arthritis - usually of the subtalar or talonavicular joints.

Rheumatoid arthritis commonly affects the region and may take one of two general forms. Proliferative synovitis can cause laxity, dislocation of the joints, and collapse of the arch, leading to planovalgus collapse with secondary arthritic changes.

In another group of patients—often with severely painful but less swollen joints—spontaneous ankylosis and eventually arthrodesis can occur. This is a common pattern in patients with rapidly progressive disease and in juvenile chronic arthritis.

Deformity

Deformity may occur due to weakness or imbalance. Two common patterns of deformity occur:

- Planovalgus deformity due to weakness of the tibialis posterior tendon (described in Chapter 9.5)

Fig. 9.1.2
Degenerative changes occurring as a result of (A) generalized arthritis (rheumatoid arthritis) and (B) neuropathic degeneration (Charcot disease).

- Equinocavovarus occurs secondary to muscle imbalance between weak dorsiflexors and evertors and relatively stronger invertors and plantarflexors and is common in neurological disease and after other foot deformities, including congenital clubfoot.

Secondary to restricted movement

Congenital coalitions of the hind- and midfoot lead to pain and degeneration. The commonest coalitions—calcaneo navicular, and subtalar—lead to pain and degeneration in the talonavicular and subtalar joints respectively. These often present later as pain in adult life, and by this time degeneration is often established and take down of the joints is rarely indicated.

Stiffness, including surgically induced stiffness, may also lead to secondary degeneration.

Neuropathic (Figure 9.1.2B)

Charcot’s joints are joints with severe degeneration—often with collapse and deformity—and occur in the presence of any sensory neuropathy. They are commonest in diabetes, usually in severe diabetes, and as such are dealt with in Chapter 9.3.

The careful clinician will always test for sensory loss when presented with a case of hind- and midfoot degeneration, using a tuning fork to test for vibration, and a Semmes-Weinstein filament to touch light sensation. A significant number of patients with early
diabetes and other causes, including reversible neuropathies, will be diagnosed by these simple means—supplemented by blood screening for neuropathy when abnormalities are found.

Clinical presentation

Arthritis of the hind- and midfoot leads to stiffness, pain, or, more commonly, a combination of both.

Stiffness is not usually a great problem except when single joints are affected in younger people who still participate in sporting activities, or in patients where spontaneous ankylosis of the whole complex occurs (usually in rheumatoid arthritis). In these situations, stiffness may impose extra demands on other joints in the foot, ankle, or elsewhere.

Pain, whether in single or multiple joints, tends to be present on standing and walking, and absent when sitting, lying, or asleep.

Pain which wakens the patient from sleep can occur as an end stage of joint destruction, but should alert the clinician to the risks of infection or tumour.

Examination (Figure 9.1.3)

Examination of pulses, perfusion, and sensation are essential parts of examination of any foot condition.

Clinical examination also involves observing the foot standing (Figure 9.1.3A,B) and on tip-toe standing (Figure 9.1.3C), measuring dorsiflexion/plantarflexion (Figure 9.1.3D,E) of the foot (including ankle movement, Figure 9.1.3F), inversion and eversion (Figure 9.1.3G,H) and rotation (9.1.3I,J), as well as simple examination of power of the muscle groups (Figures 9.1.3K–N).

Examination of the ankle, hind-, and midfoot. A,B,C) The foot is observed from in front and behind in standing and on toe raising—note position and increased arch on tip-toe raise. D,E,F) Maximum foot and ankle dorsiflexion (D) and plantarflexion (E) are compared with the normal side (F) to measure isolated ankle dorsiflexion/plantarflexion, the subtalar and midtarsal joints are immobilized by the examiner’s hand. G,H) Inversion and eversion are measured whilst immobilizing midtarsal rotation. This measures subtalar movement and any abnormal ankle movement present. I,J) The hindfoot is immobilized by the examiner’s left hand while the forefoot is rotated to measure midfoot movement. K,L,M,N) Pressure is exerted against the resistance of the examiner’s hand to test power of dorsiflexion (K), plantarflexion (L), inversion (M), and eversion (N).

Simple investigation is usually more helpful than complex scanning, which is reserved for a minority of cases.

Investigations
Blood tests may be indicated to investigate arthritis and accompanying neuropathy.

Plain x-rays taken non-weight bearing will show structure, but weight-bearing films will show loss of joint space and deformity which may occur only on standing (Figure 9.1.3A). Oblique views may be useful to show coalition and Cobey (skiers') views will show the relative contributions of the ankle and the subtalar joints to deformity of the hindfoot in standing (Figure 9.1.3B).

Magnetic resonance imaging (MRI) scans can be useful to isolate a single inflamed joint, and computed tomography (CT) scans to demonstrate structure in complex situations, but when surgical intervention is considered, selective diagnostic injection of affected joints is the most useful supplementary investigation. The reason for this is that the joints are difficult or impossible to differentiate clinically—even by the most experienced clinician. The worst affected joint on x-ray is not always the most painful joint.

Long-acting local anaesthesia is injected under image intensifier control along with x-ray contrast medium (Figure 9.1.4) to confirm that the correct joint has been injected, and that there are no connections into other joints (which occur commonly). The patient is instructed to undertake activity which would normally be painful and to complete a pain diary over the subsequent 12h to demonstrate whether the pain has been temporarily relieved. This can usually be performed by radiologists as an outpatient procedure, but when the joint is grossly destroyed this may require general anaesthesia. It may, on occasion, entail several injections to correctly identify which joint or combination of joints is symptomatic. This may seem tedious, but is preferable to the pain, inconvenience, frustration, and disability which arise if the wrong joints are fused.

Fig. 9.1.4
Selective injection of joints is used to ensure which joint is the source of the pain prior to fusion. Contrast medium is always used to prevent false positive effects of local anaesthetic flowing between joints, as communications are common.

Non-surgical management

Medical

Anti-inflammatories may be applied locally or administered systemically, and can be helpful as an adjunct to treatment by orthoses or surgery. They are rarely sufficient alone.

Blind or x-ray guided injections of depot steroids are more effective, but again are more usually combined with orthotic treatment, otherwise the pain inevitably recurs.

Orthotic management (Box 9.1.2)

Orthoses work by restoring anatomical alignment—reducing overload of affected joints by shock absorption and immobilization.

In general, orthoses will only be effective if deformity is corrected and deforming forces neutralized. Appropriate orthoses are described in Chapter 9.4 and may range from soft accommodative insoles, through to structural solutions such as ankle-foot orthoses (AFOs) or calipers.

Whatever type of orthotic appliance is used, it is important to remember to include adequate shock absorption in the system and consider footwear modification.

Box 9.1.2 Treatment of hind- and midfoot arthritis

- Diagnosis: x-ray, MRI scan, CT scan
- Orthotic treatment
- Localize symptomatic joints: selective injections
Surgical treatment (Box 9.1.3)

Surgical treatment of hind- and midfoot arthritis is almost entirely limited to arthrodesis to relieve pain and correct deformity. Arthroscopy of the subtalar joint is now performed in specialist centre but open surgery is still the norm. It is important that deformity is reduced, and that muscle power is balanced to prevent recurrence.

Arthrodesis

Arthrodesis can be difficult to achieve with the poor blood supply to the bones and fragile soft tissue envelope. The patient often has problems surviving the postoperative period, especially if they cannot bear weight through the leg and have generalized arthritis.

The principles of achieving successful arthrodesis are the same for all joints:

- Clearance of articular cartilage from the joint surface with minimal disruption to vascular supply
- Fixation of the arthrodesis (almost always by internal fixation)
- Protection of the limb from movement and/or weight bearing.

A bewildering range of screws of different metals and design, static and memory staples, and low profile and reconstruction plates are available to assist this surgery, but the commonest causes of failure remain poor tissue healing due to smoking or infection, inadequate surface preparation, or poor correction of deformity rather than inadequate fixation.

Box 9.1.3 Principles of surgical and orthotic treatment of foot and ankle deformity and arthritis

- Place the foot directly beneath the leg
- Place the foot square on the ground in all planes
- Balance (or neutralize) the muscle power to avoid recurrence.

Specific arthrodeses

Although any joint in the hind- or midfoot may be fused in isolation, the commonest fusions performed are of the talonavicular joint or subtalar joint in isolation and triple fusion (of the talonavicular, subtalar, and calcaneocuboid joints). Technique is briefly described because standard textbooks and operative guides tend to describe outmoded techniques.

Talonavicular joint fusion (Figure 9.1.5A)

This is most commonly performed for isolated single joint arthritis to relieve pain. Although a limited degree of rotational correction can be achieved when performed as part of a flat foot correction, it does not generally correct deformity well.

Preliminary examination and investigation is directed towards identifying predisposing factors, such as coalitions which may continue to generate pain if not addressed directly or by more extensive fusion.

In almost every case a preoperative, diagnostic injection arthrogram with local anaesthetic should be performed prior to surgery.
In almost every case a preoperative, diagnostic injection arthrogram with local anaesthetic should be performed prior to surgery.

**Procedure**

The joint is approached through a medial or dorsal approach. The articular cartilage is then removed from both joint surfaces.

The medial approach has the advantage of preserving cutaneous nerves, but in stiff joints it can be difficult to fully clear the lateral side of the joint. If it is not well cleared the remaining cartilage holds the joint open, and the risk of non-union is increased.

The dorsal approach gives easier clearance of the joint surfaces, but at the expense of producing numbness on the dorsum of the foot in about 50% of cases, after division of the medial branch of the superficial peroneal nerve.

Whichever approach is used, the arthrodesis should be rigidly fixed, usually by compression screws or staples.

**Postoperative care**

The foot is elevated and protected in a cast or splint until the wound is healed, and then mobilization allowed—retaining the splint for at least 6 more weeks. Usually the patient will remain non-weight bearing during this time, unless a decision is made that because of general disease and/or excellent fixation this can be over-riden.

After 8 weeks, radiographs are taken, and if union is seen to be proceeding, gradual weight bearing is allowed, usually in a lighter brace, followed by supportive insoles which are often retained in the long term.

The time to recovery is often prolonged, and we advise patients that it will take 6 months to return to the preoperative level of pain and function, and much longer to achieve their final result.

**Results**

Although some papers describe a high rate of non-union in isolated talonavicular fusion, this need not be the case with thorough joint clearance and rigid fixation, and in non-smokers rates of union around 95% should be expected.

The theoretical advantages of isolated fusion are less than might be expected, and mechanical studies of isolated talonavicular fusion show that it creates considerable stiffness throughout the hindfoot complex.

**Subtalar arthrodesis**

Subtalar arthrodesis may be performed for pain relief, for correction of deformity, for stabilization, or a combination of these.

**Surgical techniques**

The standard approach to the subtalar joints (posterior, middle, and anterior facets) is via a lateral approach, starting at the tip of the fibula and directed towards the base of the fourth toe. Older transverse incisions such as the Ollier incision unnecessarily destroy nerves and vessels and are of historical interest only. Medial approaches are useful for correction of severe valgus.

The lateral incision exposes the sinus tarsi, which is cleared to show the three facets of the joint. These are cleared using osteotomes or burs, using upward-cutting spinal bone cutters to clear the medial edges, to ensure safety of the posterior tibial nerve.

Once the surfaces are cleared and corrective cuts made, the joint is accurately reduced to place the hindfoot beneath the leg, checking that the midfoot and forefoot are well aligned. Bone graft may be inserted if large defects are present, but are not usually needed. Internal fixation is performed with compression screws, which may be inserted from above or below. Screws passed from below have the advantage of greater grip of the thread in the talus, and ease of passage, but may suffer sinkage into the calcaneum on compression, or cause screw prominence and damage to the heel pad.

Screws from above may give less reliable compression, and have a small increased risk of nerve damage, but are convenient when other surgery is performed at the same time as other procedures (such as ankle replacement). They minimize the risk of heel pad damage, and are easy to remove when needed if subsequent ankle arthroplasty is performed.

There are many modifications to technique and in some centres the procedure is performed arthroscopically.

**Postoperative management**

Postoperative management mirrors that of talonavicular fusion, but the threshold for allowing weight bearing may be lower due to the essentially horizontal configuration of the joint.

**Results**

Union is expected in over 90% of cases. Smoking, inflammatory arthritis, and infection predispose to non-union. Patients with longstanding pain and after calcaneal fractures may not achieve full pain relief.

**Triple fusion**

Triple fusion is performed to treat painful arthritis and correct deformity around the hind- and midfoot.

When correcting deformity, preoperative clinical assessment of the foot is critical to ensure that the necessary degree of correction is achieved, and also to ensure that any osteotomies, tendon transfers, etc. are performed at the same time. Triple fusion is often
combined with other procedures such as heel osteotomy, dorsiflexion osteotomy of the first ray, and tendon lengthening, augmentation, or transfer.

Technique

Triple fusion starts with the technique described earlier for subtalar fusion. The incision is extended distally to allow the extensor digitorum brevis muscle to be split, exposing the calcaneocuboid joint whose joint surfaces are prepared.

Talonavicular preparation is performed as for isolated talonavicular fusion, and then after corrective wedges etc. have been cut if needed, the joints are internally fixed—fixing the subtalar joint first, then the talonavicular and calcaneocuboid joints—carefully ensuring the exact position of the midfoot and forefoot, because the foot after triple fusion will be stiff to rotation and very intolerant of any overload, especially lateral overload of the midfoot.

Results

Union occurs in more than 90% of cases. Non-union is 16 times more common in smokers. Recovery is often very prolonged, especially with regards to swelling and start-up pain.

The foot after triple fusion is stiff and often needs a total contact insole within the shoe. Walking should be possible without a limp, but the patient will often limp when running, and be unable to participate in active sports.

Ankle arthritis (Box 9.1.4)

Incidence and aetiology

Arthritis affecting the ankle is surprisingly uncommon when one considers the large number of injuries which are sustained at the ankle.

The number of operations performed for ankle arthritis is much less than the number performed for hip and knee arthritis. Although this may reflect the relatively successful outcomes of the latter procedures compared with procedures for ankle arthritis, the size of the discrepancy is such that it seems the ankle is relatively protected from arthritis and its effects.

In many cases of ankle arthritis a predisposing cause can be identified. The causes fall mainly into three groups:

1) Post-traumatic
2) Associated with systemic arthropathy
3) As a consequence of bleeding and bleeding diatheses.

Post-traumatic

Many patients give a history of previous fracture, often many years previously. There is an association between severe fractures, incompletely reduced fractures, fracture dislocations, malunited fractures, and arthritis.

Minor undisplaced, or well-reduced fractures do not appear to convey significant risk of later deterioration, but fractures (including tibial shaft fractures) which lead to angular deformity at the ankle may.

From a medicolegal standpoint, it appears that the fractures which have a significant chance of causing arthritis in the medium and long term will start to cause symptoms early, and certainly within 2 years of injury. It is uncommon for there to be a long completely symptom-free latent period before the onset of arthritis.

Less certain is the association between soft tissue injury and arthritis. Single soft tissue injuries rarely lead to ongoing problems, but recurrent instability of the ankle may do. Patients presenting with arthritic ankles frequently give a history of recurrent giving way and instability, and arthroscopic studies of ankles with chronic instability have shown universal chondral or osteochondral damage.

Secondary to systemic arthropathy

Of the inflammatory causes of ankle arthritis, rheumatoid arthritis is by far the commonest, although the ankle is also frequently affected in juvenile chronic arthritis (often in association with the other peritalar joints).

About half the patients admitted for inpatient treatment of rheumatoid arthritis have been noted to have significant affectionation of the ankles. The ankle is also disproportionately involved in some other inflammatory arthritides.

Bleeding and bleeding disorders

Trauma to the ankle is a common occurrence for those with bleeding disorders, as in the general population. The ensuing haemorrhage causes arthritis. The number of patients affected is small, but the difficulties presented by their management and the requirement for resources can be great.

Damage due to repeated haemorrhage may also occur secondary to pigmented villonodular synovitis.
Anatomical considerations

For most purposes, the ankle may be considered as a simple, stable hinge joint, with stability provided by its bony shape and ligamentous restraints allowing controlled dorsiflexion and plantarflexion of the foot.

The tibial surface bears most of the load transmitted from the talus, and the curved surfaces of these two bones allows restricted dorsiflexion and plantarflexion to occur within the restraints of ligaments and capsule, with inherent lateral stability provided by the medial and lateral malleoli as well as the ligaments.

A deeper understanding of topographical and functional anatomy is necessary to understand pathological processes about the ankle, to plan surgical interventions, and to design prostheses for ankle replacement.

The ankle joint is in fact a composite joint, comprising the tibiotalar mortise joint and tibiofibular syndesmosis.

The fibula lies posteriorly as well as laterally. The fibula displaces and rotates during ankle movement. It also carries between 6 –16% of the axial load during stance.

In the sagittal plane the talus is slightly saddle-shaped with a depressed centre and lateral condylar projections. This matches reciprocal shaping of the tibia, and thereby imparts lateral stability to the joint, which increases on weight bearing, and is additional to the restraint of the malleoli.

Both talus and tibia have curved surfaces when viewed from the side, but the radius of curvature of the talus is shorter than that of the tibial surface, so they are incongruent (Figure 9.1.6). The movement of this complex system is one of rotation about a moving instant centre aligned obliquely across the joint.

Anatomical changes in the arthritic ankle

During the development of ankle arthritis, the tibia usually first develops an anterior osteophyte. The changes have been described by Scranton and Mc Dermott as four stages of osteophyte formation:

- Stage 1: osteophyte on tibia only, less than 3mm
- Stage 2: osteophyte on tibia only, greater than 3mm
- Stage 3: tibial osteophyte greater than 3mm ± fragmentation, talar response
- Stage 4: tibia osteophyte greater than 3mm, talar osteophyte, degenerative changes.

At the same time other changes occur, with loss of joint space and flattening of the talus, which lead to restriction of movement.

Clinical presentation
Early arthritic changes present with symptoms and signs of inflammatory or mechanical arthritis, or with a combination of both. Inflammatory changes cause swelling around the ankle, and stiffness after immobility. The ankle is painful to all movements, and the joint line is tender.

Mechanical symptoms and signs are more common. Early mechanical symptoms are typified by the symptoms of ‘footballer’s ankle’.

As osteophytes develop anteriorly, impingement occurs in dorsiflexion (late stance phase). This progresses to pain during and after exercise, worse in dorsiflexion, such as ascending slopes and stairs. Patients may report relief of pain when wearing high heels. Later, posterior pain may develop due to ‘hinge-opening’.

Later degeneration of the articular surface occurs. The gross changes observed arthroscopically usually affect the talus first. The region of the talus in contact with the osteophyte is often disproportionately affected, with longitudinal striations visible on the anterior surface of the talus.

Clinical signs

The anterior joint line should be palpated. Osteophytes are rarely palpable, but are often tender. Both feet should be examined and the range of dorsiflexion compared. Any restriction of dorsiflexion is significant. Osteophytes are always visible on radiographs, but oblique views may be needed to detect anteromedial or anterolateral osteophytes.

In moderate arthritis there will be pain on palpation of the joint line, and on joint movement, as well as swelling. The range of movement is restricted, often dramatically, with dorsiflexion lost first.

Deformity is not a constant feature in ankle arthritis, but may occur if degeneration occurs unequally across the joint. Once deformity begins, it increases abnormal loading and both the arthritis and the deformity often progress.

Non-surgical management

Medical

Oral non-steroidal anti-inflammatory drugs may be helpful in early arthritis. When symptoms occur during and after sport, they are most effective taken just prior to activity.

Injection of the joint may be useful for occasional overuse, for an exacerbation in a generalized arthropathy, for an isolated acute inflammatory episode, but has no place in the long-term management.

Orthotic management

In early arthritis, silicone heel inserts can impart relief by acting as shock absorbers. They also act to raise the heel slightly, reducing anterior impingement.

More often, an AFO is required. The orthosis should restore anatomical alignment, hold the joint rigidly, and provide shock absorption. Some mechanism should be incorporated to allow walk-through gait (for example, by adding a rocker to the shoe).

A well-tailored rigid AFO with a shock absorbing heel will be effective for many cases, but when major deformity needs to be corrected a caliper with strap may be more effective.

Surgical treatments (Box 9.1.5)

A wide range of surgical options are available to treat ankle arthritis:

Osteotomy

Takakura from Japan performed tibial osteotomy on 18 ankles (in 18 patients) with intermediate disease and tibial deformity and found improvements in pain, walking, and ability to perform activities of daily living over an average of nearly 7 years, although range of movement was not improved.

Osteotomy is reserved for cases occurring in young patients with deformity and preserved joints.

Distraction

Around the same time in Europe, Van Valburg described applying long-term joint distraction using an Ilizarov apparatus for 18–34 weeks. All showed an improvement in pain and range of movement with five gaining complete relief.

The length of treatment limits its use to cases in young patients.

Arthroscopy

Arthroscopy of the ankle can help in arthritis by synovectomy, anterior cholectomy, surgery to chondral and osteochondral lesions, or by more extensive surgery such as distraction/debridement or arthroscopic arthrodesis (which is described later in the arthrodesis section).
Anterior spurs or osteophytes presenting as ‘footballer’s ankle’ are dealt with as effectively arthroscopically as by open means, but with more rapid recovery—a return to preoperative activity is expected within 6–8 weeks.

Larger and more advanced (grade III/IV) osteophytes can also be removed arthroscopically, in isolation, or with general debridement of joint surfaces, although on occasions the increased range of movement is accompanied by increased pain.

Arthroscopic debridement can be combined with rigid intraoperative distraction (Figure 9.1.7). The method does not work for patients with significant deformity or instability, but may avoid or delay arthrodesis in about half the cases, and can be useful for young patients wanting to avoid fusion.

![Click to view larger](image)

Fig. 9.1.7
A lateral radiograph of a degenerate ankle with distraction applied by an external fixator, showing that considerable distraction (and hence ligamentotaxis) is achieved during isolated distraction treatment or distraction arthroscopy.

**Arthrodesis**

Arthrodesis of the ankle has for many years been the mainstay of surgical treatment for ankle arthritis, but it remains difficult surgery. Sir John Charnley highlighted this and wrote that ‘in the ankle it would appear that this joint does not possess the same natural potential for bony union as exists in the soft cancellous bone of the knee’ and stated that the operation had ‘a narrow latitude for technical error’.

**Techniques**

Almost every approach to the ankle has been described for arthrodesis. The methods of obtaining fusion are:

1) Open arthrodesis using internal fixation
2) Open arthrodesis using external fixation
3) Arthroscopic arthrodesis using internal fixation.

Compression arthrodesis is now favoured, using internal fixation when there is no infection and external fixation in the presence of infection.

Whichever method is used to obtain arthrodesis, the position of the foot after arthrodesis is important. The ankle should be held in neutral position with regard to both varus/valgus and plantar/dorsiflexion as well as in slight external rotation. The talus should be positioned directly beneath the tibia.

Gait analysis has shown that even small amounts of calcaneus (5 degrees) give a stiff gait with no push off (due to absence of third rocker) and equinus position imposes a vaulting gait.

Excessive varus is poorly tolerated by the subtalar joint and the foot, with painful callous forming on the outer side of the foot, and pain in the mid and forefoot occurring with only minor deformities. Excessive valgus may lead to painful fibula impingement or peroneal tendinitis, and both may lead to secondary pain in the knee.

If the foot is fused in neutral then the gross appearance of the gait is normal, but gait analysis shows that the walking speed is decreased, as are step length and single stance duration.

Preoperative conditions often dictate the risk of failure, with large deformities, previous ulceration or infection, and poor bone stock being bad prognostic factors. Rates of failure up to 20% occur in mixed series with large numbers of rheumatoid and elderly patients, and rates of 5% or less achieved in selected series with predominantly fit osteoarthritic patients. Cobb has shown that the rate of non-union is substantially increased by smoking.

Open arthrodesis using internal fixation
Medial, lateral, posterior, anteromedial, anterolateral, anterior, and combination approaches are all used and in specific instances each will be indicated. The posterior approach may be appropriate when friable skin or skin graft lies anteriorly, medial approaches may be used to excise bone and correct valgus deformity, and conversely lateral approaches allow easy correction of varus.

The lateral approach (excising the fibula) and the anterior approach are currently the most popular open approaches. Whichever approach is adopted, it must allow full exposure of tibial and talar plafonds, and lateral aspects of the joint, with small accessory portals made if necessary to allow adequate internal fixation and correction of deformity. Lateral impingement of bone or peroneal tendons can be problematic after some approaches, but is avoided by partial fibula excision.

Postoperative regimens vary, but require 8–12 weeks minimum of cast immobilization to obtain union, with a similar period of protection in an orthosis or splint whilst consolidation occurs. A rocker bottom to the shoe is then frequently helpful.

Patients should be warned that they will get bony pain for up to 4 months after coming out of plaster, and this may continue to improve for a long time after surgery as full bony remodelling occurs.

Arthrodesis using external fixation

Charnley popularized the use of external fixation for ankle arthrodesis. His method was originally mainly used for patients with polio and other neurological conditions and used a transverse incision (dividing extensor tendons as well as vessels and nerves), with through and through compression pins anteriorly through the tibia and calcaneum. It is no longer performed this way. Most surgeons now use triangulated frames or ring external fixators with fine wires reserving external fixation for the treatment of infected non-union, and for more complicated procedures performed with bone transport, skin transfer, etc.

Arthroscopic arthrodesis (Figure 9.1.8)

In cases of painful articular arthritis with minimal (less than 10 degrees) varus or valgus tilt, arthroscopic arthrodesis may be performed. The degree of deformity which can be corrected increases with experience.

It has advantages in terms of postoperative pain (allowing early mobilization and short inpatient stay), and in speed and rate of union. It is particularly appropriate in patients with poor vascular supply, with bleeding disorders, or with skin grafts around the ankle.

A distractor is applied to the ankle, and after synovial clearance, anterior cholectomy is performed to allow good visibility. The articular surfaces are then cleared down to cancellous bone using power burrs, and the lateral and medial gutters are similarly cleared of articular cartilage. Two cannulated screws are then passed (from the medial tibia down into the talus) under x-ray control.

A plaster is applied, and early weight bearing can be allowed within the bounds of pain.

The immediate postoperative radiographs almost always appear to have a substantial gap, but within a few weeks this fills in. Union may be observed as early as 4 weeks after surgery and is more rapid than after open surgery. External immobilization is usually maintained for 8 weeks, and then mobilization is encouraged from an appropriate brace. Although the initial and postoperative pain levels are much lower than after open surgery, it still often takes many months before all bone pain around the ankle subsides.

Ankle arthroplasty (Figure 9.1.9)

Historically, ankle arthroplasty has been unsuccessful, with high rates of early and late failure, often of 10% or more per annum.

Clinical development has been slowed because of these failures, and because ankle arthrodesis is an effective treatment to relieve pain in many cases. However, arthrodesis has several drawbacks. The restriction of movement always imparts some disability and in patients with bilateral disease, and those with generalized disease, this may be severe. Both bilateral disease and multiple lower limb joint disease are common in patients with rheumatoid arthritis, and development of ankle prostheses has continued mainly because of the requirements of these patients.

In addition, long-term reviews of ankle arthrodesis have shown arthritic changes in adjacent joints with time.
Fig. 9.1.9  
A) Two modern meniscal ankle replacements. B) Postoperative radiographs of a patient with a total ankle replacement.

Over more than 25 years a variety of designs have been tried, with hinge and non-constrained designs all described, but with high rates of failure.

**Box 9.1.5 Surgical treatment of ankle arthritis**

- Osteotomy: to correct deformity with minor degeneration  
- Joint distraction: to avoid fusion in young patients  
- Arthroscopy: for mild and moderate arthritis  
- Distraction arthroscopy: a quicker way to simulate distraction  
- Arthrodesis  
- Arthroplasty.

The main causes of failure were sepsis and aseptic loosening. Constrained implants failed at a rate of around 10% per annum, with semiconstrained failing generally above 5% per annum.

The most popular designs of ankle replacements in Europe have a planar tibial surface, a curved talar surface, and a semiconstrained meniscal component. Early results suggest pain relief is good, functional restoration is reasonable, and the revision rate is around 1.5% per annum (although the confidence intervals are large due to small numbers).

There is a role for using a semiconstrained meniscal ankle replacement in bilateral disease, in rheumatoid disease, and in other circumstances where other joints are affected (Box 9.1.6).

**Box 9.1.6 Which operation for who?**

**Fusion**

- Young  
- High demand  
- Good compensatory joints  
- Deformity  
- Avascular necrosis, infection.

**Arthroplasty**

- Elderly  
- Low demand  
- Adjacent fusion  
- No deformity  
- ? Bilateral.

**Conclusions**

Hindfoot and midfoot arthritis cause pain and deformity or instability. Most cases can be helped by orthotic management. When orthotic management is inadequate, surgical treatment usually comprises of fusion in an anatomical position.

Ankle arthritis is rarer than arthritis of the hip or knee. The mainstay of surgical treatment is arthrodesis, which gives good results.
When union can be obtained in good position, but has a failure rate of 3–10%. After arthrodesis, degeneration of surrounding joints may be accelerated.

As an alternative to arthrodesis, and for less severe cases, arthroscopic surgery may provide relief, and osteotomy may be considered to correct varus deformity.

Ankle arthroplasty has been unsuccessful in the past, but modern meniscal designs show better results, and may offer an alternative to arthrodesis in some circumstances such as bilateral disease, and multiple joint involvement.

Further reading

Summary points

- The aim of modern forefoot surgery is to refunction the first ray, and balance the lesser rays around it
- The indications for surgery in hallux valgus are of pain over the bunion, or of pain with subluxation or dislocation of the lesser rays as a result of first ray insufficiency
- Hallux valgus surgery aims to reposition the metatarsal head over the sesamoids whilst maintaining length. The osteotomy should be stable to allow early mobilization
- The mainstays of the surgical treatment of hallux rigidus are dorsal cheilectomy and fusion of the first MTPJ
- 96% excellent and good results in reconstruction of the rheumatoid forefoot have been reported with fusion of the first MTPJ and resection of the lesser metatarsal heads.

Introduction

Over the last decade there has been a change from treatment of individual forefoot complaints in isolation to directing treatment at producing a balanced forefoot.

This chapter deals with the common forefoot problems of hallux valgus, hallux rigidus, sesamoiditis, and lesser toe deformity individually, and then summarizes the principles of reconstructing the whole forefoot.

Hallux valgus

Introduction

A bunion is a swelling of the first metatarsophalangeal joint (MTPJ) and is derived from the Latin for turnip (bunio). It is an imprecise term. Hallux valgus is a more precise term which describes the posture of the toe. Over 130 operations are described as no procedure addresses all cases.

Aetiology

Extrinsic factors include constricting and high heel shoes. Heredity is important with up to 84% of patients with juvenile hallux valgus showing a familial tendency—usually transmitted from mother to daughter. Hypermobility and pes planus also contribute to onset and rate of deterioration.

The role of footwear is controversial, but high heels and tight pointed toe boxes increase the rate of progression of hallux valgus (Box 9.2.1).

Box 9.2.1 Hallux valgus: aetiology

- Aetiology: familial, high heels, hypermobility, pes planus
- Proximal phalanx moves into valgus resulting in metatarsus primus varus
- Hallux dorsiflexes and pronates
- The two sesamoids are the radiological markers of the longitudinal axis of the first ray
- Blood supply to first metatarsal head comes from plantar lateral aspect of metatarsal neck.

Anatomy

The first MTPJ is prone to deformity as a result of its anatomy. The normal joint moves mainly in plantarflexion and dorsiflexion, but lateral movement is also possible.

Under the MTPJ are two plantar sesamoids. They lie in the two tendon slips of the flexor hallucis brevis, on either side of the flexor hallucis longus tendon and are thus radiological markers of the longitudinal axis of the first ray musculature.

The blood supply of the first metatarsal head comes from the plantar lateral part of the metatarsal neck, and should be preserved to prevent avascular necrosis of the first metatarsal head.

Pathogenesis
The pathogenesis of hallux valgus has been well described by Stephens. The proximal phalanx of the great toe moves into valgus and the first metatarsal splay, leading to metatarsus primus varus.

A groove develops on the medial side of the metatarsal head articular cartilage as it atrophies from the lack of normal pressure and defines the prominence of the medial exostosis—over which a bursa develops.

Erosion of the metatarsal crista between the medial and lateral sesamoids occurs early, and as the medial soft tissues become further attenuated, the metatarsal head moves medially from over the sesamoids. The medial sesamoid comes to lie under the eroded crista, and the lateral sesamoid on the lateral side of the metatarsal head in the first intermetatarsal space.

The extensor hallucis longus and flexor hallucis longus tendons remain in position while the MTPJ migrates medially and they come to act as bowstrings and exacerbate the deformity.

The adductor hallucis and the lateral head of flexor hallucis brevis also contribute to the development of the deformity. With time they become contracted, as does the lateral joint capsule.

The abductor hallucis and medial head of flexor hallucis brevis lose their abduction moment. The resultant imbalance causes dorsiflexion and pronation of the first toe.

These events combine to lead to first ray insufficiency and lesser ray overload. As a result, the second toe claws and eventually the second MTPJ dislocates.

**Presentation**

Patients present with restriction in shoes (80%), pain over the bunion (70%), cosmetic concerns (60%), and pain underneath the second metatarsal head (40%). Lesser toe deformities, Morton’s neuroma, corns, and calluses also occur as a result of first ray insufficiency and overcrowding.

**Clinical assessment**

The patient is examined standing to emphasize the hallux valgus and associated deformities.

Signs of generalized ligamentous laxity should be recorded.

It is important to assess the hindfoot, as planovalgus deformities and gastrocnemius-soleus tightness exacerbate loading and pain around the first MTPJ.

The degree of hallux valgus deformity and whether it is correctable is noted, as is pronation of the great toe. The range of motion of the first MTPJ is documented.

The lesser toes are examined for deformities and callosities, and the intermetatarsal spaces palpated for neuroma. The plantar surface of the foot should be checked for callosities.

Finally, first tarsometatarsal instability is assessed. The examiner immobilizes the lesser metatarsals with the thumb and fingers of one hand, with the ankle in neutral. The thumb and index finger of the other hand grasp the first metatarsal and move it from a plantar-lateral to dorsomedial direction.

**Radiological assessment**

Weight bearing anteroposterior and lateral radiographs of the foot are mandatory.

The hallux valgus angle (HVA) (normally less than 15 degrees) and intermetatarsal angle (IMA) (normally less than 9 degrees) are measured (Figure 9.2.1). The congruency of the joint is assessed. The relationship of the first metatarsal head to the sesamoids and presence of degeneration should also be recorded.

**Box 9.2.2 Hallux valgus: clinical features**

- **Presentation:** shoe restriction, pain, cosmesis, transfer lesions, lesser toe synovitis/deformity, callosities, Morton’s neuroma
- **Clinical examination should be weight bearing and includes:**
  - **Forefoot:** degree of hallux valgus and pronation, correctibility of deformity, range of movements, lesser toe deformity, callosities
  - **Hindfoot:** planovalgus deformity, Achilles tightness
  - **Ligamentous laxity:** generalized and tarsometatarsal.
The distal metatarsal articular angle (DMAA) (normally less than 10 degrees) measures the angle between the articular surface of the first metatarsal head and the first metatarsal shaft (Figure 9.2.1)—this is sometimes called the proximal articular set angle (PASA). The DMAA is difficult to measure with high inter- and intraobserver variability.

The proximal phalangeal articular angle (PPAA) is the angle between the proximal phalanx and its proximal articular surface (normally less than 10 degrees). Hallux valgus interphalangeus deformity is present if this value is increased, or if there is significant angulation between the proximal and distal phalanges.

The severity of the hallux valgus deformity is thus defined to help formulate surgical treatment.

**Forefoot balance**

Maestro and colleagues used anteroposterior standing radiographs to define the ideal forefoot morphotype and described a method of preoperative planning for forefoot osteotomies. According to their criteria a radiographically ‘harmonious’ forefoot displays a progression of the lengths of the lesser metatarsals, to give equal weight bearing across the forefoot (Figure 9.2.2).

**Non-operative treatment**

Hallux valgus can be treated with accommodative shoes made of soft leather with an extra wide and deep toe box. In the elderly and those with neurological or vascular compromise this is the treatment of choice.

There is little evidence to substantiate the use of orthoses. A medial longitudinal arch support has been shown to reduce symptoms temporarily. There is no evidence that orthoses prevent the progression of hallux valgus.

**Surgical treatment**
The indication for surgery is pain over the bunion or in the second MTPJ as a result of first ray insufficiency.

The management of patient expectation is important. In the United Kingdom, 30% of orthopaedic litigation is as a result of foot surgery, of which 80% arises from forefoot surgery.

Only 60% of patients can expect to wear fashion shoes following surgery.

There are many surgical procedures; they can be broadly classified by the anatomical location of the procedure (Table 9.2.1).

MTPJ, metatarsophalangeal joint.

Principles of surgery

- The technique should be technically easy and reproducible
- Osteotomies should be stable, with or without internal fixation
- The aim of surgery is to correct deformity and balance muscle power by repositioning the metatarsal head over the sesamoid apparatus
- The length and elevation of the first metatarsal should be maintained to prevent transfer lesions
- The metatarsal blood supply should be preserved to avoid avascular necrosis
- There should be a low hallux valgus recurrence rate.

Keller’s procedure

This procedure involves resection of one-third of the proximal phalanx of the great toe. There is a high rate of recurrent deformity and the IMA is improved little. The procedure defunctions the first ray with loss of flexion power. Metatarsalgia from overload of the lesser metatarsal heads, cock-up deformity, and reduction of first MTPJ motion also commonly occur.

Salvage of failed Keller’s procedure is technically demanding. Fusion of the first MTPJ is often needed, made more difficult by the shortening and bone loss necessitating structural interposition bone graft to re-establish length. This is associated with a high rate of non-union and other complications.

Keller’s procedure should only be considered in an elderly household ambulator with low functional demands who would not tolerate a larger procedure or when infection is present.

Distal soft tissue procedures

Simple bunionectomy and medial capsular placation sounds attractive but does not address the pathology. At 5-year review the HVA and IMA are increased. Patients are dissatisfied in over 40% of cases.

McBride described lateral release and excision of the lateral sesamoid to correct hallux valgus, and a modified procedure, preserving the sesamoids, reduced the HVA by 14.8 degrees and the IMA by 5.2 degrees, but with an 11% incidence of hallux varus.

Modified McBride procedure is an important component of hallux valgus correction but is not sufficient in isolation in the majority of
First metatarsal osteotomies

First metatarsal osteotomies are divided into proximal and distal. Proximal osteotomies allow a greater correction of IMA. Distal osteotomies are used for mild to moderate deformities, as they require less extensive exposure, with quicker recovery.

In recent years a new, intermediate group of diaphyseal osteotomies have become popular.

Distal metatarsal osteotomies

Wilson’s osteotomy is an oblique metaphyseal osteotomy from distal medial to proximal lateral, which allows the metatarsal head to displace laterally and proximally. It corrects the IMA and HVA. Satisfactory results of bunion correction are described in 90% of patients but there is an average of 8.5mm shortening of the first metatarsal and 24% incidence of dorsal angulation. Metatarsalgia occurs in 35% of patients. Seventy-eight per cent of patients have callosities under the second metatarsal head. As a result of these shortcomings this osteotomy is not recommended.

Mitchell’s osteotomy involves a double cut osteotomy through the first metatarsal neck, leaving a step which is used to ‘hitch’ the metatarsal head. The capital fragment is displaced laterally and plantarwards. Again, good clinical results have been reported with this procedure with a 91% patient satisfaction rate, but shortening of the first metatarsal can occur with an associated dorsal malunion. Thus transfer metatarsalgia occurs in 10–30% of cases, although the incidence of complications can be reduced by internal fixation.

The distal chevron osteotomy is a proximally based, V-shaped osteotomy of the metatarsal neck with lateral displacement of the capital fragment. It causes minimal shortening and is intrinsically stable. It is indicated for mild to moderate deformities. Excellent clinical results have been reported with little or no metatarsalgia and correction of the IMA by 4–8 degrees and the HVA by 11–18 degrees. Loss of correction and recurrence can occur, especially if used for more severe deformities. This risk can be minimized by cutting the osteotomy with a long dorsal or plantar arm and internally fixing the osteotomy. Variations include taking a medially-based closing wedge to correct the DMAA.

Avascular necrosis of the first metatarsal head occurs in up 20% of patients. Thus many caution against undertaking a simultaneous chevron osteotomy and lateral release.

Diaphyseal osteotomies

Diaphyseal osteotomy has been recommended for IMAs between 14–20 degrees. After division of the diaphysis, either translation (Scarf) or rotation of the metatarsal (Ludloff) corrects the IMA (Figure 9.2.3). Lateral release and medial capsular plication are performed.

The Ludloff osteotomy is an oblique osteotomy, angled 30 degrees to the long axis of the metatarsal. The distal fragment is rotated and the metatarsal head turned plantarwards before internal fixation. Excellent clinical results are reported, with good correction and no metatarsalgia. There is minimal metatarsal shortening and the osteotomy is biomechanically more stable than the proximal chevron and proximal crescentic osteotomies.

The scarf osteotomy is a Z-shaped step-cut osteotomy. It is named after its woodworking equivalent. A stepped longitudinal cut is made along the length of the diaphysis (Figure 9.2.3) and is sloped plantarwards as it passes laterally. When the osteotomy is displaced, it leads to plantar displacement, and off-loads the lesser rays. The head and plantar cortical fragment are translated laterally and the osteotomy held with two screws. As the technique relies on translation of the metatarsal head rather than rotation, shortening and increasing the DMAA is avoided. By altering the cuts it is possible to shorten the metatarsal, or alter the DMAA. It is more biomechanically stable than the basal osteotomies.

Scarf osteotomy has traditionally been recommended for an IMA of up to 20 degrees, but with experience it can be used for more severe deformities.

The clinical outcomes compare favourably with basal osteotomies with an incidence of complications of 4–11%. It is a technically demanding procedure but once mastered it is a highly effective and versatile procedure.
Basal osteotomies

Opening wedge, closing wedge, crescentic, and basal chevron osteotomies have all been described, normally combined with a distal soft tissue procedure, bunionectomy, and capsular reefing. They correct splay due to their proximal location, but increase the DMAA, and are used for moderate and severe deformities. An increased DMAA can be corrected by adding a distal biplanar chevron (the double osteotomy), and Akin osteotomy to correct hallux valgus interphalangeus (triple osteotomy). There is 81% patient satisfaction rate but a 19% incidence of major complications with an average 5mm of metatarsal shortening.

Opening wedge osteotomies cause elongation and stretching of the medial soft tissues and require bone graft. They have greater potential for stiffness and non-union. Distraction plates address some of these issues. A closing wedge osteotomy is easier but leads to shortening of the metatarsal, and rates of dorsal malunion of up to 38%.

Proximal crescentic osteotomy is formed with a crescentic saw blade (concavity directed proximally) through a dorsal approach, and held with a screw. It leads to minimal shortening of the first metatarsal and excellent results are described with patient satisfaction rates of more than 90% and good correction of the IMA and HVA even in severe cases. It is technically difficult and instability leads to dorsal malunion in up to 17% of cases. The proximal chevron osteotomy is technically easier and intrinsically more stable to dorsiflexion than the crescentic osteotomy, and causes fewer transfer lesions.

Arthrodeses

First metatarsophalangeal joint arthrodesis

Fusion is used to treat hallux valgus in patients with rheumatoid arthritis, severe metatarsophalangeal osteoarthritis, severe or recurrent deformity particularly in the elderly patient, neuromuscular disease and salvage following failed surgery. The success rate of fusion is 90% with high levels of patient satisfaction. A concomitant basal procedure is not needed, as the increased IMA corrects spontaneously.

First tarsometatarsal joint arthrodesis (Lapidus)

First tarsometatarsal arthrodesis with excision of a laterally-based wedge is performed in combination with a distal soft tissue procedure, in patients with hypermobility of the first tarsometatarsal joint, or for degenerative changes of the first or second tarsometatarsal joint. It is contraindicated in the adolescent with an open physis at the base of the first metatarsal, patients with a short first metatarsal or degenerative changes in the first MTPJ. The procedure is technically demanding and has higher rates of complication than metatarsal osteotomies. Satisfaction rates vary from 75–90% with fusion rates of 90%.

Conclusion

Hallux valgus surgery is technically demanding but has a high success rate in appropriately selected patients. The treatment protocol we recommend always uses internal fixation and is shown in Table 9.2.2.

| Table 9.2.2 An algorithm for treating hallux valgus |
|---------------------------------|---------------------------------|
| **Mild hallux valgus (IMA up to 14°)** | **Normal DMAA** | Short scarf osteotomy with a distal soft tissue procedure or long inferior limb chevron |
| | Increased DMAA | A short scarf osteotomy with a distal soft tissue procedure with added rotation of the metatarsal head |
| **Moderate hallux valgus (IMA 14–20°)** | **Normal DMAA** | Scarf osteotomy with a distal soft tissue procedure. Varus osteotomy (Akin procedure) added if needed to correct angular and rotator deformity |
| | Increased DMAA | As normal DMAA, but increased corrective rotation of the scarf osteotomy |
| **Severe hallux valgus (IMA >20°)** | **Scarf osteotomy for most cases, but consider fusion instead** |
| **Hallux valgus with first tarsometatarsal hypermobility** | **A first tarsometatarsal fusion with distal soft tissue procedure** |
| **Hallux valgus with first MTPJ degeneration** | **First MTPJ arthrodesis** |
| **Hallux valgus interphalangeus** | **Akin osteotomy** |

IMA, intermetatarsal angle; MTPJ, metatarsophalangeal joint.
Special situations

Juvenile hallux valgus

Bunions presenting in the preteen or teen years are classified as juvenile hallux valgus. Juvenile hallux valgus is more likely to recur than its adult counterpart. The patients have a higher DMAA and more hallux valgus interphalangeus than their adult counterparts. Care must be taken not to damage the physis, which is proximal in both the first metatarsal and proximal phalanx. In boys foot growth ceases around the age of 16 years, and in girls foot growth ceases around 14 years.

Hallux varus

The commonest cause of hallux varus is overcorrection at the time of hallux valgus surgery. Other causes are inflammatory arthritis and trauma.

Hallux varus presents with deformity, pain, stiffness, instability, clawing of the great toe, weakness, and difficulty with shoe fitting. Some varus is acceptable and when easily correctible does not require treatment. However, the treatment of symptomatic hallux varus is difficult—by soft tissue procedures or bony procedures including reverse scarf osteotomy and MTPJ arthrodesis. Arthrodesis remains the most reliable treatment.

Disorders of the sesamoids

The sesamoid bones of the hallux cause symptoms by intrinsic pathology (sesamoiditis) and by plantar prominence leading to plantar keratosis and pain.

Anatomy

The sesamoids lie within the tendons of the flexor hallucis brevis. Most patients have two sesamoids although in one-third of cases the sesamoid may be bipartite. Sesamoiditis, presenting with pain and tenderness of the sesamoids, may be due to fracture, degeneration of the joint between the sesamoid and metatarsal head, or avascular necrosis.

Treatment

Non-operative

Both sesamoiditis and plantar keratosis are treated with pressure-relieving insoles. This is the commonest form of treatment.

Operative

Surgery for sesamoid disease is of two types.

In those cases with increased pressure the first metatarsal is often plantarflexed, and in this situation a dorsally-based wedge osteotomy of the first metatarsal is used to correct plantarflexion. In cases with ulceration or with no plantarflexion, the prominent plantar surface of the sesamoid is excised.

In pure ‘sesamoiditis’ Brodsky reported good or excellent results in 23 cases treated by excision of the sesamoid. If a sesamoid is removed, it is important to repair the tendon of the flexor hallucis brevis, to avoid the development of hallux deformity postoperatively. Early orthotic management is started, otherwise transfer pain to the other sesamoid is common.

Hallux rigidus

Introduction

Hallux rigidus describes stiffness of the great toe, and is most commonly caused by osteoarthritis of the first MTPJ. It affects one in 45 people over 50 years of age. There is a decrease in motion, especially dorsiflexion. Other terms that have been used include hallux limitus or dorsal bunion to describe the dorsal osteophyte.

Aetiology

Hallux rigidus may be caused by trauma or osteochondritis dissecans. It is associated with a long first metatarsal, hypermobility of the first ray, pronation, hallux valgus interphalangeus, hallux valgus, metatarsus adductus, and inflammatory or metabolic conditions such as gout, rheumatoid arthritis, and seronegative arthropathy.

Presentation

Hallux rigidus presents with pain and stiffness of the first MTPJ.

In the early stages the pain is dorsal and worsened by walking or wearing high heels. Later the pain is deeper and may include sesamoid pain. The dorsal cheilus may cause pressure on the dorsal cutaneous nerve resulting in dyseaesthesia and numbness along the medial border of the hallux.

Clinical assessment
The range of movement of the joint is restricted. Dorsiflexion is limited more than plantarflexion. Early in the disease, pain is only elicited at the extremes of dorsiflexion and plantar flexion, but in the later stages, crepitus and pain develops in the mid arc. The patient’s gait becomes increasingly antalgic as the MTPJ stiffens and then progressive transfer of weight to the lateral border of the foot occurs. The interphalangeal joint often hyperextends in chronic cases, a callosity may also occur on the plantar aspect of this joint.

Radiological assessment

Standing anteroposterior and lateral radiographs reveal a dorsal osteophyte on the head of the metatarsal early on, with joint space narrowing, subchondral cyst formation, and sclerosis later.

Hattrup and Johnson classified the radiographic findings in 1988:

- Grade I: mild to moderate osteophyte formation with preservation of the joint space
- Grade II: moderate osteophytes narrowing of the joint space and subchondral sclerosis
- Grade III: marked formation of osteophytes with loss of the joint space, with or without subchondral cysts.

Non-operative treatment

Orthoses and shoe modification reduce motion, impingement, and mechanical stress on the joint. An extra-depth toe box avoids pressure on the dorsal osteophyte. A shoe with a low heel, stiffened sole, and a rocker bottom limits dorsiflexion.

Operative treatment

Injection or manipulation under anaesthetic and steroid injection may lead to reduced symptoms in patients with grade I changes.

Dorsal cheilectomy

Cheilectomy of the dorsal osteophyte and the degenerate portion of the articular surface on the head of the metatarsal preserves or increases motion, maintains joint stability, has low morbidity, and permits revision surgery. The osteophyte recurs in one-third of cases, although this does not correlate with clinical failure.

Following cheilectomy 97% of patients with minimal joint space loss have an excellent or good self-assessment score and a mean increase in dorsiflexion from 14.5 to 38.4 degrees. Poor results may ensue after cheilectomy in the patients with advanced degeneration. Thus cheilectomy is recommended in patients with grade I and II hallux rigidus.

It is sometimes performed with a dorsal closing wedge osteotomy of the proximal phalanx to increase the arc of MTPJ motion—a Moberg osteotomy.

Keller’s resection arthroplasty

Keller’s procedure is only rarely used and then only in low-demand and elderly patients. Some authors advocate capsular interposition arthroplasty in more active patients.

Metatarsophalangeal joint replacement

Hemiarthroplasty of the proximal phalanx and total joint replacement using Silastic® (Dow Corning), ceramic arthroplasty, and unconstrained metallic implants have been tried for hallux rigidus. There is a high failure rate of joint replacement in hallux rigidus. Given these unfavourable results in multiple studies with different implants, joint replacement is usually reserved for unusual circumstances such as rheumatoid arthritis with stiff midfoot in low-demand patients.

Arthrodesis

Arthrodesis of the first MTPJ is the mainstay of treatment for grade 3 hallux rigidus. It eliminates painful motion and maintains stability of the first ray. Complications include non-union, progressive arthritis of the interphalangeal joint, and lateral transfer metatarsalgia. The great toe is fused in 5–10 degrees of valgus to allow the great toe to lie alongside the second toe without impingement. The condyles of the proximal phalanx of the hallux are positioned 3–4mm off the ground at surgery. This is judged preoperatively with simulated weight bearing, comparing the toe to a flat surface.

Arthrodesis has been compared with Keller’s procedure, hemiarthroplasty, and arthroplasty of the MTPJ. In all studies arthrodesis demonstrated superior results with fewer complications.

Lesser toes

Introduction

Deformities of the lesser toes should be considered in the context of the forefoot as a whole. For example, correcting a claw second toe with a dislocated MTPJ, without addressing an adjacent hallux valgus, usually fails. Firstly there is no space into which to reduce the toe, and secondly the deformity will recur if the underlying biomechanical cause of lesser toe overload is not addressed.

In this section the lesser toes will be addressed in isolation. The section on forefoot reconstruction addresses a more holistic
approach which is often needed.

**Box 9.2.3 Hallux rigidus**

- Affects 1:45 people over 50 years of age
- Characterized by stiffness: hallux rigidus
- Aetiology: idiopathic, trauma, osteochondritis dissecans, inflammatory arthritis
- Hattrup and Johnson radiological classification
- Non-operative treatment: extra-depth toe box with stiffened, rocker bottom sole
- Dorsal cheilectomy indicated for early hallux rigidus
- Arthrodesis is the mainstay for advanced disease.

**Definitions**

There are three principal deformities of the lesser toes. These are mallet, hammer, and claw (Figure 9.2.4). The deformities may be fixed or flexible.

**Mallet toe**

A mallet toe is flexed at the distal interphalangeal joint (DIPJ). Patients with mallet toes usually present with pain and callosities at the tip of the toe, where the sharp end of the distal phalanx impacts on the ground. Nail deformities are common.

**Hammer toe**

Hammer toes are flexed at the proximal interphalangeal joint (PIPJ), and usually at the DIPJ. Occasionally the DIPJ is extended—a boutonnière deformity.

**Claw toe**

Claw toes are the most complex and involve the same distal deformity as a hammer toe but with an extension deformity of the MTPJ. The most severe cases lead to subluxation or dislocation of the MTPJ.

**Anatomy**

The MTPJs are stabilized by two collateral ligaments and a plantar plate. The intrinsic and extrinsic musculature control movement of the toes (Figure 9.2.5). There are two extrinsic flexors and two extensors, none of which attach directly to the proximal phalanx. The short flexor inserts to the middle phalanx and the long flexor to the distal phalanx. The extensor mechanism is held centred over the MTPJ by the extensor hood. The extensor digitorum longus has a central slip that inserts into the middle phalanx but also has two slips connected to the distal phalanx—this is analogous with the anatomy seen in the hand.
The function of the extrinsic muscles is assisted by the intrinsic muscles. The interosseous and lumbrical muscles lie plantar to the MTPJ and act as flexors of this joint. They lie dorsal to the axis of the PIPJs and DIPJs and act as extensors of these.

**Aetiology**

Lesser toe deformities are common, occurring in 20% of individuals. Their incidence increases with age. They are commoner in women than men (4–5:1). The second toe is most commonly involved.

The most important aetiopathological factor in lesser toe deformity is probably shoes. Lesser toe deformity may also be a manifestation of neurological disease, compartment syndrome, and diabetes mellitus.

**Presentation**

Pressure produces callus, thus lesser toe deformity presents with deformity and painful callosities over the dorsal or plantar aspect of the foot.

The most severe and disabling symptoms are those in the MTPJ, where synovitis can progress on to subluxation and even dislocation of the joint.

**Clinical assessment**

The following points should be noted:

- The nature and type of the shoes worn
- Presence of systemic disease such as inflammatory arthropathy, diabetes mellitus, and peripheral vascular disease
- The exact location of pain
- Callosities
- Whether the deformity is correctable or uncorrectable.

**Radiographic examination**

Standing anteroposterior and lateral radiographs of the foot may help define subluxation or dislocation of the lesser MTPJs, Freiberg’s disease, and hallux valgus and rigidus.

**Non-operative treatment**

In many patients, simple measures provide adequate treatment—a shoe with a toe box which is deep and wide enough to accommodate the deformed toes. Protection with padding or silicone toe sleeves can help, as can toe props. Calluses should be removed by a podiatrist, or the patient.

Patients with metatarsalgia may be helped by insoles with a metatarsal dome, or bar.

**Operative treatment**

The principles of surgery are:

- Treat the toe from proximal to distal: MTPJ, PIPJ, DIPJ
- Address correctable deformity with soft tissue procedures
- Address fixed deformity with bony procedures.

**Mallet toes**

A flexible mallet toe rarely needs correction. If necessary, treatment consists of a tenotomy of the long flexor tendon through a plantar approach. A fixed deformity is treated with excision arthroplasty or fusion of the DIPJ, each with simultaneous tenotomy of the long flexor tendon through the DIPJ.

An alternative is terminalization of the toe.

**Hammer toes**

Correctable hammer toes rarely require surgery. When they do, a soft tissue procedure is performed, either a flexor to extensor tendon transfer (Girdlestone) or a long flexor tenotomy.

Fixed deformity is treated with a PIPJ fusion—usually with wire fixation—or excision arthroplasty where only the condyles of the middle phalanx are excised and a pseudoarthrosis is formed. This avoids the need for wires, but excessive resection can lead to a floppy toe. Excision arthroplasty is improved by interposition of retained redundant extensor tendon.

**Claw toes**

In claw toes there is an extension deformity of the MTPJ. Surgery to the MTPJ is incremental, until the deformity is corrected. A soft tissue release of the capsular structures including the collateral ligaments with tenotomy of the extensor digitorum brevis, and Z-lengthening of the extensor digitorum longus is performed.
If the MTPJ is subluxed or dislocated a bony procedure will be required which may be:

1) Du Vries arthroplasty: excising the distal 3–4mm of the metatarsal head, leading to arthrofibrosis (with about 50% reduced movement)

2) Weil osteotomy: the Weil osteotomy is an oblique osteotomy which translates the metatarsal head proximally, ideally without plantar displacement. This osteotomy is fixed with a small screw. The metatarsal head is translated sufficiently to allow the joint to reduce comfortably. The extensor tendons are left intact unless they remain tight at the end of the procedure, when they can be lengthened. It is difficult to cut the metatarsal parallel to the floor, especially in the second and third rays, with their steeper declination. Therefore a second cut excising a small segment is undertaken to prevent plantar displacement (Figure 9.2.6). Postoperatively the toe can be taped in 5–10 degrees of plantar flexion. Early mobilization is important to maintain mobility. The major complication of the Weil osteotomy is MTPJ stiffness as a result of impingement of the metalwork, prominent bone and arthrofibrosis.

3) Proximal phalangectomy (Stainsby): in this procedure a generous proximal phalangectomy is undertaken, the plantar plate is mobilized and reduced, and the extensor tendon is interposed into the joint. The toe is stabilized with a longitudinal Kirschner wire. Ninety-three per cent of patients report excellent result or good results after this procedure. It leads to a weak toe.

---

**Forefoot reconstruction**

In some feet it is possible to address a single issue, for example, a hallux valgus or claw toe. In other feet the whole forefoot needs addressing. In this section the principles of forefoot reconstruction will be addressed.

**First ray insufficiency**

If there is hallux valgus this must be corrected to stabilize the first ray. This leads to resolution of the transfer lesions in some patients, but in patients with subluxed or dislocated lesser toes or those with secondary valgus drift of the lesser toes, the MTPJ needs to be reduced.

Barouk has outlined a number of principles for treating these feet (Table 9.2.3) and introduced the concept of the metatarsal shortening (MS) point. The MS point is the point to which shortening is required to correct the deformity. A standing anteroposterior radiograph of the foot is taken, and the point of maximum bony deformity is marked. Usually this corresponds to the proximal phalanx of the first ray.
Table 9.2.3 Barouk’s principles of forefoot reconstruction, with modifications

<table>
<thead>
<tr>
<th>Barouk’s principles of forefoot reconstruction, with modifications</th>

</tr>
<tr>
<td>Balance the forefoot to establish a normal metatarsal parabola</td>
</tr>
<tr>
<td>If the surgery only affects a single ray, you only need to operate on this ray</td>
</tr>
<tr>
<td>A foot that fits a shoe, will function like a foot</td>
</tr>
</tbody>
</table>

Barouk proposes that this point is the point to which the metatarsal parabola should be shortened in the most affected ray. The other rays are then corrected such that their length is balanced according to Maestro’s criteria (see Figure 9.2.2). Thus, to correct the forefoot the hallux valgus is corrected, with or without shortening, and the lesser rays are shortened with Weil osteotomies.

Rheumatoid forefoot

Pathophysiology

Ninety-four per cent of patients with rheumatoid arthritis (RA) have symptoms from the foot and ankle, with hallux valgus in the majority. The typical deformities in the rheumatoid forefoot are hallux valgus and claw toes. Overload and synovial inflammation of the lesser MTPJs leads to disruption of the collateral ligaments and capsule, and dorsal subluxation and dislocation of the MTPJ occurs. The dorsally dislocated phalanx forces the corresponding metatarsal head into plantar flexion. At the same time, the plantar fat pad also moves distally from beneath the metatarsal head. These factors increase plantar pressure. Consequently large plantar callosities and bursae develop.

Non-operative treatment

This comprises pharmacological treatment, shoe modification, orthoses, and steroid injections. Total contact insoles and rocker bottomed shoes can diminish peak pressures and shear stresses under the forefoot.

Operative treatment

Hallux

Excision arthroplasty

Hallux valgus is the commonest deformity of the rheumatoid forefoot. Keller’s procedure and excision of the first metatarsal head (Mayo’s procedure) have both been used. Good initial patient satisfaction has been reported, but recurrent deformity, pain, and functional deterioration are common.

Arthrodesis

Arthrodesis of the first MTPJ offers the advantages of good correction, relief of pain, and predictable outcomes, with union rates of around 90%. Several studies have compared arthrodesis with resection arthroplasty and have shown fusion to be superior for pain relief, cosmetic appearance, shoe-fitting, maintenance of alignment, and restoration of weight bearing under the hallux.

Hallux metatarsophalangeal joint arthroplasty

Arthroplasty of the hallux MTPJ may be an alternative to resection arthroplasty or arthrodesis for the severely affected rheumatoid patient, usually with hinged double-stemmed silicone implants or ceramic or metallic arthroplasty. Moderate pain relief and patient satisfaction has been reported with the use of silicone implants but they may fracture or fragment, and cause synovitis in up to 29% of cases. Other complications include aseptic loosening of the implant, cock-up deformity, stiffness, and transfer metatarsalgia.

Box 9.2.4 Rheumatoid forefoot

♦ Typical deformities in the rheumatoid forefoot are hallux valgus and claw toes
♦ Non-operative treatment: pharmacological, total contact insoles, extra wide shoes with deep toe box
♦ Hallux MTPJ fusion
♦ Hoffman procedure (excision of lesser metatarsal heads) for the lesser toes
♦ Joint preservation can be considered in young patients with rheumatoid arthritis.
Lesser toe deformity

Excision procedures

Hoffman described resection of the lesser metatarsal heads to allow deformity correction and relief of metatarsalgia. This procedure and its many variations have become the commonest treatment.

A transverse plantar incision, two longitudinal dorsal incisions, and a single transverse dorsal incision have been used to approach the lesser MTPJs, all with good reported outcomes. The plantar incision allows direct access to the dislocated MTPJs and excision of excess plantar fat pad and skin; alternatively, the dorsal incisions are felt to provide good MTPJ access while avoiding a scar on the plantar surface in patients who have impaired wound healing.

The Stainsby procedure, with generous proximal phalangectomy is also widely used.

Coughlin reported 96% good to excellent results with an arthrodesis of the first MTPJ and resection of the lesser toe metatarsal heads in 58 feet.

MTPJ preserving procedures

Barouk and Barouk proposed joint-preserving surgery as an alternative approach to the rheumatoid forefoot. They reported excellent results using a scarf osteotomy for the first ray and Weil osteotomies of the lesser metatarsals. A recent study reported 88% excellent or good results following arthrodesis of the first MTPJ combined with multiple Weil metatarsal osteotomies of the lesser rays. Weil shortening can be difficult in dislocated MTPJs with joint destruction and soft bone.

Further reading

Summary points

- Diabetic foot problems are of major socioeconomic importance
- Aetiology is multifactorial, with a neuropathic, vascular, and immune component
- A multidisciplinary approach must be adopted, with education and prevention being key aims
- If ulceration develops, restoration/preservation of an intact soft tissue envelope and the creation of a plantigrade foot that can bear weight are the key treatment goals.

Introduction

Diabetes affects 5% of the world’s population. For diabetic patients, 30% of hospital admissions are for complications of the feet. With 20 million people worldwide suffering from Type 1 diabetes and up to twelve times that with Type 2 diabetes, their foot problems have a major social and economic importance.

Twenty per cent of diabetics develop clinically significant neuropathy after 10 years from diagnosis and 50% after 20 years. The longer the duration of the disease, the greater the risk of developing significant neuropathy.

Fifty per cent of diabetic foot problems and subsequent amputations can be eliminated by educating patients and physicians, and providing proper prevention and early treatment.

Aetiology

The aetiology of diabetic foot problems is multifactorial with a neuropathic, vascular, and immune component.

Neuropathic component

Neuropathy appears to be the most important factor in the aetiology of the diabetic foot and although not fully understood, involves the sensory, motor, and autonomic systems. Tight control of blood glucose levels reduces or prevents the development of neuropathy, but once developed it is irreversible.

Most patients complain of sensory changes in a glove and stocking distribution. Some have numbness and paraesthesia, others have hyperaesthesia or dysesthesia, presenting as a burning sensation, usually nocturnal. It is this lack of sensation and, therefore, basic protective mechanisms, that makes problems of the diabetic foot severe and difficult for both patients and doctors.

Motor neuropathy leads to muscle weakness and intrinsic muscle atrophy. The plantar fat pad shifts and there is possibly rupture of some of the slips of the plantar fascia. The cumulative effect of these changes is less plantar protection of the bony prominences leading to callus formation, pressure necrosis, and ulceration. Patients with motor neuropathy may develop bunions, claw toes, and hammer toe deformities as a result of muscle imbalances.

Isolated mononeuropathy also occurs in diabetics, with the common peroneal nerve most typically being involved. This is characterized by unilateral foot drop, which must be differentiated from spontaneous rupture of the tibialis anterior tendon that is also seen in diabetics.

Autonomic neuropathy leads to loss of autonomic function and hence changes in blood flow and sweating, resulting in thick, dry, scaly skin and nail deformities.

Charcot neuroarthropathy is a non-infective destructive process that manifests as dislocation, periarticular fracture, or both, in patients with peripheral neuropathy. Although the incidence of Charcot disease is very low (0.3% of diabetics), its impact on patients and treating surgeons is major and hence we have dedicated a section to Charcot disease at the end of this chapter.

Box 9.3.1 Key facts on diabetic foot

- 3–4% of diabetics have foot ulcers or deep infections
- 15% of diabetics develop foot ulcers during their lifetime
- 30% of hospital admissions in diabetics are for pathologic conditions of the feet
- Severity of complications correlates with diabetic control
- Diabetic foot ulcers (DFUs) precede 70% of non-traumatic lower extremity amputations
- The risk of amputation increases eightfold once an ulcer develops
- 5 years after lower-extremity amputation, nearly two-thirds of these patients have died.
Vascular component

Demonstrable peripheral vascular disease is present in 8% of adult diabetics at the time of diagnosis and increases to 45% after 20 years. The vascular deficiency in these patients is a mixture of large and small vessel disease and the presence of pulses does not necessarily mean the vascular supply is normal.

Immune component

Glycosylated immune proteins lose their efficiency in diabetics and granulocyte function is often impaired, especially if the patient is malnourished. These changes increase susceptibility to infection with organisms that would not normally affect a healthy host.

Clinical presentation

Diabetic patients can present to the orthopaedic surgeon with four broad groups of problems:

- Ulcerations
- Infections
- Charcot’s joints
- Skin and nail problems.

Clinical assessment

General assessment

In your history, establish the duration of the diabetes itself as well as any prior foot ulceration and whether or not any surgery has been performed. The duration of diabetes as well as the level of diabetic control correlates with the severity of vascular and neurologic change. It is also important to identify patients with ischaemic rest pain as opposed to those with dysaesthesia or insensitivity.

Foot assessment

Observe the patient’s gait, both with and without shoes. In standing posture assess the hindfoot alignment as well as the arches of the foot.

During supine or sitting examination, document the general condition of the skin and toenails and in particular the presence of corns, calluses, and ulcerations. Note areas of bony prominence as well as those areas lacking normal fat-pad protection.

Examine light touch, pinprick, vibration sense, and deep tendon reflexes. The threshold for diagnosis of peripheral neuropathy is the inability to perceive 10g of pressure applied to the skin using the Semmes–Weinstein monofilament (Figure 9.3.1). The 5.07 monofilament is estimated to apply just over 10g of pressure and with this benchmark in population screening, plantar insensitivity is present in approximately 25% of adult diabetics.

Vascular examination

Feel the dorsalis pedis and posterior tibial pulses. If present and the capillary refill is brisk then further assessment is not usually helpful. If pedal pulses are absent, the ankle–brachial pressure index (ABPI) should be carried out using a handheld Doppler probe and a sphygmomanometer.
The ABPI in normal patients is usually around 1.1. An ABPI of less than 0.9 is regarded as abnormal. Critical ischaemia is indicated by an ABPI of less than 0.5 or one that is unrecordable. In diabetics, the ABPI may be spuriously high because of calcification in the distal vessels which prevents them from being compressed by the sphygmomanometer cuff around the calf, and so if the ABPI is over 1.3 then it is deemed an unreliable test.

If the patient has absent pulses or an abnormal ABPI then referral to a vascular surgeon is recommended. They will tend to carry out an arterial Doppler ultrasound (duplex scan) in the first instance as this is cheap and non-invasive. The wave pattern on the duplex provides important information. A triphasic waveform is consistent with normal vessel elasticity whereas a monophasic waveform indicates a calcified vessel. The measurement of toe pressures is also useful and an absolute toe pressure of 45mmHg is more predictive of healing than the ABPI.

If further information is required then magnetic resonance imaging (MRI) angiography is usual, although the use of contrast may be contraindicated in those with renal impairment.

### Skin assessment

Skin breakdown is usually caused by shear forces. Plantar ulcers are due to weight-bearing pressure, whereas dorsal and side ulcers are, in the main, caused by shoe pressure.

The most widely used system to classify diabetic ulceration is the depth–ischaemia classification which looks at the size and depth of affected areas as well as the vascular status of the limb (see Table 9.3.1, Figure 9.3.2).

Blood tests include a full blood count (FBC), renal function (urea and electrolytes, U&Es), liver function tests (LFTs to look at albumin levels for nutritional deficiency), and haemoglobin A1c (HbA1c) to look at longer-term diabetic compliance. If osteomyelitis is suspected you should request an erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).

Plain radiographs of the foot and ankle are standard. Permeative radiolucencies, destructive changes, periostatis, and new bone formation without reparative response suggests osteomyelitis, but plain film changes may lag 2 weeks or more behind the onset of osteomyelitis.

Bone scans (technetium-99m, 99mTc) and MRI are more sensitive than plain radiographs in detecting early bone changes of osteomyelitis and Charcot’s joints. However, MRI is more sensitive and detects osteomyelitis earlier than a bone scan. Although MRI is useful in diagnosing occult abscess formation, especially if contrast is used, it is important to stress that no imaging techniques (plain radiographs, bone scans, or MRI) clearly distinguish neuroarthropathy from evolving deep bone infection and the diagnosis has to be made clinically.

Superficial swabs from ulcers will always grow mixed skin flora and are not helpful. If infection is suspected, deep biopsies should be obtained to direct antibiotic treatment.

**Prevention**

A multidisciplinary approach is used to manage the diabetic foot and the most important measures are education and prevention, in particular in stressing the importance of good accommodative footwear and diligent control of blood sugars (Box 9.3.2).

**Box 9.3.2 Prevention**

- Basic principles are education and prevention
- Good footwear
- Good glucose control.

In patients with neuropathy it is important to stress that they need to examine their feet on a daily basis in front of a mirror, as they will not be alert to the same warning signs as those with sensate feet. It is also important to instruct diabetic patients in proper nutrition and the harmful effects of tobacco use.

**Treatment**

There is no set treatment for the diabetic foot and each treatment plan has to be individualized to the patient. There are, however, some broad goals for treatment, listed in Box 9.3.3.

**Box 9.3.3 Treatment goals**

1) Restore or preserve an intact soft tissue envelope (get any ulceration to heal)
2) Create or preserve a plantigrade foot that can weight bear
3) Use bracing, orthotics, and appropriate footwear to maintain both of the above
4) Prevent amputation.

Treatment protocols correlate with the specific grades found in the depth–ischaemia system (Table 9.3.1) which require full assessment of the ulcer and also the vascularity of the feet.

Most wounds treated in the outpatient setting are grade 1. The focus of treatment for grade 0 or grade 1 lesions is to relieve pressure. Options to modify weight-bearing pressure include specialized footwear, total contact casts, prefabricated walking braces, or custom ankle–foot orthoses (AFOs). The choice depends on the lesion and the specific problems of each patient.

**Surgery on the diabetic foot**

Surgery in the diabetic foot is frequently based on failure of non-operative management.

The goals of surgery include: relief or redistribution of pressure to ensure closure of the soft tissue envelope; to create a plantigrade foot that can weight bear; and one in which bracing, if appropriate, is a viable option.

Contraindications to surgery include significant underlying medical disease, severe malnutrition, and patients unable to comply with the postoperative course.

If there is vascular insufficiency then an opinion of a vascular surgeon should be sought with a goal of limiting the extent of amputation, potentially through revascularization methods such as angioplasty (including subintimal angioplasty to get distal revascularization) or femorocrural or femorodistal bypass.
If amputation is necessary, transcutaneous oxygen assessment is useful to assist in delineating the amputation level as attempts are made to maximize residual limb length to improve postoperative function. As prosthetic management will be necessary, preoperative evaluation by a prosthetist and rehabilitation specialist is recommended.

There are a large number of surgical treatment options available to treat the diabetic foot, full details of which are beyond the scope of this textbook; however, for simplicity Table 9.3.2 outlines a number of common problems and their treatments. Tendoachilles (TA) contracture commonly occurs in these patients and TA lengthening should always be considered as part of the treatment.

Keller’s procedure  
Amputation of lesser toe  
1st MTJPJ fusion plus shortening/elevation of lesser toes (Weil osteotomies)  
1st MTJPJ fusion plus modified Hoffman procedure (resection arthroplasty of 2nd-5th MT heads) |
| Midfoot ulceration overlying bony prominence (rocker-bottom foot) | Aggressive exostectomy  
Realignment arthrodesis (tripple arthrodesis with or without wedge exostectomy. Note: tendoachilles lengthening is always required)  
Amputation |
| Ulceration secondary to ankle and hindfoot instability and deformity | Realignment arthrodesis (e.g. Tibiotalar-calcaneal arthrodesis)  
Amputation |
| Soft corns | Bony decompression via arthroplasty (excision or interposition) |
| Toenail disorders | Wedge excision of nail  
Zadik’s procedure (great toe nail ablation)  
In osteomyelitis, consider terminal amputation |

DIPJP, distal interphalangeal joint; IPJP, interphalangeal joint; MTJP, metatarsal; MTJPJP, metatarsophalangeal joint; PIPJP, proximal interphalangeal joint.

Treatment of infections

Grade 2 lesions involve deeper soft tissues and require more aggressive wound management, in addition to pressure-relieving devices. If probing a wound communicates to bone then there is a high probability (more than 80%) of osteomyelitis.

Whilst available evidence does not support treating clinically uninfected ulcers with antibiotics, deeply infected ulcers should be admitted and started on appropriate intravenous antibiotics, empirically at first and then culture specific. Because infections in the diabetic foot tend to be polymicrobial, consultation with an infectious diseases expert is recommended to assist with selection and duration of antibiotics.

Aerobic Gram-positive cocci (especially Staphylococcus aureus) are the predominant pathogens in diabetic foot infections. Patients with chronic wounds or those who have received recent antibiotics may also be infected with Gram-negative aerobic rods (e.g. Escherichia coli) and those with foot ischaemia may have obligate anaerobic pathogens (e.g. bacteroides).

If the patient fails to improve clinically after appropriate wound care and antibiotics, an MRI is recommended to rule out occult abscess. Abscesses require drainage and if there is wet gangrene this must be carried out as an emergency.
Charcot disease

A complication of neuropathy in the diabetic population is Charcot disease. This neuropathic osteoarthropathy results in fragmentation, destruction, and dislocations of the bones of the foot and ankle. It was originally described by a French physician, Jean-Martin Charcot, in 1868 in a patient with tertiary syphilis. It was only described in diabetes in the 1930s although diabetes is now the commonest cause.

There are two theories of pathogenesis for the development of Charcot disease: neurotraumatic and neurovascular. The former involves repetitive trauma sustained by a joint unable to sense pain, whereas the latter refers to a sympathetic dysfunction with persistent hyperaemia and active bone resorption. The incidence of Charcot osteoarthropathy occurring in the diabetic population is 0.1–0.5%, despite up to 25% of diabetics having a clinically detectable peripheral neuropathy. The average time interval between the onset of diabetes and that of Charcot change is 16 years.

Despite it being a rare complication, it is one of the most severe of the problems encountered by the orthopaedic surgeon and therefore has a much greater impact on the treating surgeon’s practice, than its frequency would suggest.

Charcot disease may be the first presentation of diabetes. In Charcot’s disease the foot can assume significant deformity with a red, hot, swollen foot that mimics infection but without the clinical signs of overt sepsis such as fever, leucocytosis, and abnormal diabetic control. The muscle imbalance across a Charcot foot, with contracture of the Achilles tendon creates a static and dynamic equinus deformity of the ankle in which there is a pathological bending moment through the midfoot, leading to collapse of the arch and the development of a rocker-bottom deformity.

Contrary to common belief, 50% of Charcot feet have some pain, usually a deep pain.

Classification of Charcot

Eichenholtz characterized the natural history of Charcot neuroarthropathy into three stages as described in Table 9.3.3.

<table>
<thead>
<tr>
<th>Eichenholz stage</th>
<th>Clinical</th>
<th>Radiography</th>
</tr>
</thead>
<tbody>
<tr>
<td>I: fragmentation</td>
<td>Acute inflammatory phase: erythema, warmth, and swelling</td>
<td>Either normal, or debris, fragmentation of subchondral bone, subluxation, and/or dislocation</td>
</tr>
<tr>
<td>II: coalescence</td>
<td>Reparative phase: reduction in erythema, warmth, and swelling</td>
<td>New bone formation, Coalescence of larger fragments, Sclerosis of bone ends</td>
</tr>
<tr>
<td>III: consolidation</td>
<td>Healing phase: resolution of erythema and swelling; residual deformity</td>
<td>Remodelling, rounding of bone, Decreased sclerosis</td>
</tr>
</tbody>
</table>

Anatomical classification of Charcot

Brodsky introduced an anatomical classification based on the regions of the foot most often affected by the Charcot process (Table 9.3.4). The most commonly affected areas are the midfoot, followed by the hindfoot, and lastly the ankle joint. The forefoot is involved only on rare occasions.

<table>
<thead>
<tr>
<th>Type</th>
<th>Location</th>
<th>Typical joints affected</th>

<td>Type 3A: ankle joint, Type 3B: involves a pathologic fracture of tubercle of calcaneus (very uncommon)</td>
</tr>
</tbody>
</table>

Treatment of the Charcot foot (Figure 9.3.3)

The Eichenholtz stage I foot often presents with swelling and erythema and it is often very difficult to distinguish it from infection, although the patients lack the clinical signs of sepsis.

Admission and elevation of the limb to the level of the heart will often bring rapid (overnight) improvement in the appearance in Charcot, compared with infection where the signs will persist and may get worse.

Immobilization in a total contact cast is the mainstay of treatment for Eichenholtz stage I neuroarthropathy. Because one of the functions of the cast is to reduce swelling, it will tend to loosen quickly and so an initial cast should be changed after 5–10 days. Subsequent casts should be changed at intervals of 2–4 weeks.

The Charcot arthropathy process may take up to 2 years to run its course. The Eichenholtz stage I foot should be immobilized until it has progressed beyond the fragmentation stage, which can be 16 weeks or more.

Some surgeons have advocated the use of operative management of deformity during stage I neuroarthropathy, with arthrodesis in situ or realignment procedures. There is no data comparing this form of treatment with casting and it is not yet mainstream practice.

As increased osteoclastic activity is one of the processes leading to bony destruction, the administration of bisphosphonates have been advocated in stage I neuroarthropathy. Randomized controlled trials have been carried out using parenteral pamidronate and alendronate demonstrating decreased markers of bone turnover, as well as reduced warmth in the limb over the period of the study. Whilst some groups are using bisphosphonates in the treatment of stage I neuroarthropathy, neither pamidronate nor alendronate are currently licensed for this use.

As the involved extremity passes through the Charcot stages, the focus of treatment turns to preventing limb-threatening complications. Surgery is used to correct deformity and reduce recurrent problems due to structural abnormalities (Figure 9.3.4). Accommodative orthoses should be prescribed to correct inequalities in pressure. Rocker-bottom shoes combined with an AFO or a Charcot restraint orthotic walker (CROW) may also be necessary to manage more severe deformities.

Conclusion

The diabetic foot is a major challenge. Neuropathy is the major factor leading to morbidity although neuropathy alone will not cause ulceration and must be combined with pressure and shear forces across the soft tissues as well as underlying vascular and immune components. A multidisciplinary approach must be used in treating this important group of patients. The basic principles in the treatment of diabetic foot problems are education and prevention. However, once ulceration has developed, restoration or preservation of an intact soft tissue envelope and the creation of a plantigrade foot that can weight bear are key treatment goals.

Orthoses of the foot and leg

Summary points
- Orthoses may be corrective or accommodative
- Orthoses are described according to their anatomical application
- A knowledge of material properties, anatomy, and function is essential to prescribe
- Patients will only tolerate effective orthoses.

Introduction (Box 9.4.1)
Orthotic management of foot and ankle disorders is a little understood but important subject. Ortho- is derived from the Greek orthos, meaning straight.

Orthoses are externally applied devices used to modify the structural and functional characteristics of the neuromuscular or skeletal system through the application of forces.

Orthoses work in several ways:
- To correct malalignment and maintain correction
- To control motion (assist, resist, and/or stop)
- To augment weakened muscles
- To redistribute weight and generate a more natural loading pattern
- To accommodate fixed deformity.

A holistic approach is necessary when prescribing any type of orthosis. The cause of the problem and biomechanical deficit should be identified; then a device can be prescribed which effectively addresses the biomechanical problem.

Often, however, a compromise on the ideal form of orthotic treatment has to be made. This could be due to the fact that by controlling movement about a joint in one plane you may inadvertently affect movement in another plane which is unaffected. Other factors include the ability of the patient to put on and take off the orthosis independently and whether the item is cosmetically acceptable to the patient.

The correct terminology for describing an orthosis is generally accepted to be an indication of the joints that a device encompasses, for example, ankle-foot orthosis (AFO) and foot orthosis (FO). However, they can also be named after people or places (which should be avoided as it can be confusing) or by the function which they provide such as 'hallux valgus orthoses' (see next paragraph).

In this chapter we deal with orthoses in order from distal to proximal.

Toe splints
Hallux valgus orthoses to correct bunions will straighten the hallux when in place, but do not produce longstanding correction. They are most commonly used at night. Daytime splints are available but are difficult to wear within footwear. They can be useful as part of a postoperative regimen.

A variety of devices may be used on the lesser toes, usually decreasing pressure and friction rather than correcting deformity. Hammer toe ‘crests’ (banana splints) positioned in the sulcus raise the tip of the toe to relieve terminal corns. Silicon gel tubes reduce rubbing of the dorsum of clawed or hammer toes against the shoe; silicon polymer devices can be moulded in the clinic to protect and support lesser toe deformities.

Foot orthoses
Simple inlays (Figure 9.4.1A)
These are non-moulded and provide minimal support. They consist of a flat base made of card, leather, or closed-cell foam and can have valgus and/or metatarsal pads incorporated to support the arches of the foot. The base material may be full length or trimmed proximal to the metatarsal heads (three-quarter length). Off-the-shelf/prefabricated types are also available.
Orthoses correct deformity, maintain position, augment power, or accommodate.

- Orthoses are off the shelf or made to measure (bespoke)
- Rigid materials correct and maintain position
- Soft materials cushion and accommodate
- Orthoses must fit the patient and their footwear.

Such an insole is often included within the shoe by the manufacturer, but the use of different materials, with increased cushioning by the use of foam or gel, allows improved shock absorption, and changes can be made to the surface of the insole to reduce shear forces.

**Moulded inlays (functional foot orthoses, Figures 9.4.1B–D)**

These are corrective, bespoke orthoses—manufactured by taking casts, impressions, or scanning the foot. They can be made of polypropylene/polyethylene, ethylene vinyl acetate (EVA) foam or composite materials and can be full, three-quarter length, or customized to suit the patient’s needs (Table 9.4.1). Wedging or ‘posting’ can be added to the shell of the orthosis to correct or accommodate hindfoot and/or forefoot malalignment. Other additions can be incorporated, such as cushioning top layers and metatarsal pads.

**Table 9.4.1 Materials commonly used in the production of moulded inlays**

</tr>
</tbody>
</table>

EVA functional foot orthoses (FFOs) generally provide less control than polypropylene or carbonfibre foot orthoses and take up more room in the shoe. They are, however, more easily tolerated than rigid devices.

**Heel cups (Figure 9.4.1E)**

Where greater control of the subtalar and midtarsal joints is required the depth of the orthosis is increased to provide cupping around the heel. Heel cups are made of polypropylene and are generally three-quarter length so as not to interfere with forefoot function.

All these foot orthoses (and all ankle orthoses) are prescribed and fitted to address the patient’s problem, but due regard must also be taken of the footwear needed to accommodate an orthosis.

Shoes may be open (slip on) or enclosed, and have laces, hook-and-loop fasteners (e.g. Velcro®), or elastic fitting. They can be made of soft or firm materials and have widely varying soles—both the materials (e.g. shock absorbing, rigid) used and their design (flexible, rocker profiles).

In general a lace-up or Velcro®-fastened shoe is preferable to accommodate and optimally secure an orthosis. It is not normally possible to accommodate a FFO within a slip-on shoe or sandal. In these circumstances, patient compliance may necessitate compromise or, as they take up less space in the shoe, a simple inlay may be used.

So shoe choice is important; but equally important is the fit of the orthosis within the shoe. Inability to fit the orthosis inside the shoe is a common reason that foot orthoses are not used. Patients can be advised to find shoes with a removable insole (put there by the manufacturer) so that this can be removed and replaced with the foot orthosis, as in common sports shoes/trainers.

**Orthopaedic footwear**

Orthopaedic footwear may also be considered as an orthosis in that it is capable of applying forces to the foot in a controlled manner as well as performing an accommodative role.
Two types of footwear are commonly prescribed:

1) Made-to-measure (bespoke)
2) Off-the-shelf (stock).

Footwear adaptations

External adaptations such as raises (to accommodate leg length discrepancy), rocker soles (to enable heel rise in late stance with conditions such as hallux rigidus/limitus or ankle stiffness/fusion), floats (to increase the width of the heel, increasing stability), and wedges can be added to the patient’s own footwear or to orthopaedic shoes.

Ankle orthoses (Figure 9.4.2A)

These are usually prefabricated braces used to stabilize the ankle (after injury or for chronic instability). They act solely on the ankle joint providing mediolateral control. These braces can also provide support in early arthritis or postoperatively.

Supramalleolar orthoses (Figures 9.4.2B)

Supramalleolar orthoses (SMOs) are custom-made devices which influence movements at the ankle joint and the foot. They can be designed as a heel cup with high medial and lateral wings, anchored with Velcro® extending proximally over the malleoli, or with more extensive dorsal trim lines encapsulating the foot and ankle.

They are usually manufactured from flexible or rigid plastic and less commonly from blocked leather.

This design can control deformities in the transverse and coronal planes; however, it has no effect on sagittal plane movements of dorsiflexion and plantar flexion.

Ankle–foot orthoses

The primary function of all ankle–foot orthoses (AFOs) is to control alignment and movements of the foot and ankle complex. A secondary effect may be to influence the hip and knee joints by influencing the ground reaction force.

Polypropylene AFOs are manufactured by taking a cast of the patient’s leg in the corrected position. The polypropylene is moulded over the modified plaster model, thus producing a close fit and precise control of pressure distribution. After moulding, the device is trimmed to the required shape. Varying degrees of mediolateral stability can be achieved depending on the anterior trim lines and rigidity of the design.

Posterior leaf spring (Figure 9.4.3A)

A posterior leaf spring (PLS) AFO is used to aid or give passive dorsiflexion where a flaccid foot drop occurs due to nerve damage (e.g. from a prolapsed disc) or in neurological disease.

The trim line is narrow between the calf and foot piece allowing dorsiflexion against resistance but returning the foot to a neutral
alignment once plantar flexion power is removed, thus compensating for weak or absent dorsiflexors.

The addition of helical straps to reduce varus/valgus tendency increases mediolateral stability, and is used, for instance, in hereditary motor sensory neuropathy when inversion can be associated with foot drop.

Prefabricated AFOs are available and are useful assessment tools; however, custom-made designs are usually more comfortable and effective for long-term use.

Rigid ankle–foot orthoses (Figure 9.4.3B)

Rigid or solid ankle AFOs maintain the foot and ankle in a predetermined position. They prevent plantar flexion and dorsiflexion and offer good mediolateral control. Due to the rigidity of the design a rocker sole may be required to aid tibial advancement and walking.

Hinged ankle–foot orthoses (Figure 9.4.3C)

AFOs can be manufactured to incorporate hinges which can allow free motion, or restrict dorsiflexion and/or plantar flexion with the use of adjustable ankle locks, or aid dorsiflexion with the use of concealed springs. This can provide good control and allow movement, but is often at the expense of decreased cosmesis and increased bulk making footwear fitting difficult.

Anterior ground reaction ankle–foot orthoses (AGR-AFOs)

Anterior ground reaction ankle–foot orthoses (AGR-AFOs) can be a one-piece or two-piece design incorporating a rigid AFO with a removable front shell. They aim to bring the ground reaction force anterior to the knee and are used when there is excessive dorsiflexion and knee flexion as with crouch gait. A full range of knee extension must be present to allow them to work effectively.

Conventional ankle–foot orthoses (previously callipers), (Figure 9.4.3D)

These usually consist of one or two metal uprights attached to a metal, leather-covered calf band. They attach distally via a spur into a stirrup in the sole of the shoe.

The socket within the shoe can allow free motion or limit motion with the use of front (dorsiflexion) or back (plantar flexion) stops. These can be used in conjunction with T/Y straps stitched to the shoe to aid valgus/varus instability.

Ankle joints can also be added to conventional calipers to:

- Stop/block motion
- Assist motion with the use of springs.

Conventional orthoses have largely been replaced by contemporary plastic designs. However, conventional orthoses offer an alternative when plastic orthoses are not tolerated.

Charcot restraint orthotic walker (Figure 9.4.3E)

The Charcot restraint orthotic walker (CROW) is a custom-moulded bivalved orthosis incorporating a total contact cradle inlay and a full EVA lining. It is used to immobilize the foot and ankle and to protect neuropathic feet during the early and intermediate stages of neuropathic Charcot disease, usually due to diabetes. On occasion it may be used long term as an alternative to amputation.
**Conclusion**

Orthoses are widely used in orthopaedic foot and ankle treatment either alone or as an adjuvant treatment and can help avoid, or delay, the need for surgery. Orthoses act to correct malalignment of body segments, control motion, accommodate deformity, and reduce pain and pressure. Patients rarely want to wear orthoses but patients who find that they can walk further, faster, or with less pain will often adapt their lifestyle and footwear to use these devices. It is often worth trying orthoses before proceeding to more invasive treatment.

**Further reading**

Summary points

- Treatment of tendon and ligament disorders of the foot depends on accurate clinical diagnosis, supported by investigation.
- The treatment of posterior tibial tendon dysfunction is guided by classification.
- Ankle ligament injuries only need surgical treatment if very severe or chronic.
- Achilles tendonitis is usually treated conservatively.
- Rupture of the Achilles tendon may be treated operatively or conservatively.

Posterior tibial tendon dysfunction

Introduction

Tibialis posterior dysfunction is the most common cause of acquired flat-foot deformity in the adult.

Anatomy

The tibialis posterior muscle lies in the deep posterior compartment of the calf and is innervated by the tibial nerve (L4, L5). The musculotendinous junction is 4cm above the medial malleolus and the tendon passes behind the medial malleolus in its own sheath. It attaches mainly to the tuberosity of the navicula by three bands: anterior, middle, and posterior. The anterior is the largest (65%) attaching to the navicular tuberosity and inferior medial cuneiform. The middle band extends to the more lateral cuneiforms, cuboid, and metatarsal bases of the second, third, and fourth rays. The posterior band contributes to the soft tissue components of the acetabulum pedis.

Function

The posterior tibial tendon plays an important role in function of the foot and ankle. During gait the foot fulfils two purposes. As the foot contacts the ground it is flexible and acts as a shock absorber. By the end of the stance phase, the foot has changed into a rigid lever to maximize push-off strength. As a flexible shock-absorbing foot, the transverse tarsal (talonavicular and calcaneocuboid) joints are parallel and move in concert. With activity of tibialis posterior the heel inverts, the orientation of the transverse tarsal joints changes and flexibility is abolished.

Where tibialis posterior is dysfunctional the transition from flexible shock absorber into rigid lever does not occur. This places excess strain upon the medial column of the foot (the spring ligament in particular) and eventually leads to planovalgus deformity.

Clinical features

Posterior tibial tendon dysfunction (PTTD) is a progressive disorder. Johnson and Strom proposed a staging system that was later modified by Myerson (Table 9.5.1).

Table 9.5.1 Stages of tibialis posterior insufficiency. (I–III Johnson and Strom; IV added by Myerson)

Most patients with early PTTD go unrecognized. It occurs mostly in people with pre-existing low arches. Posterosmedial ankle pain and swelling occur first, but it is the ‘collapse’ of the medial longitudinal arch that usually prompts referral.

Once deformity becomes marked, fibular impingement develops.

Examination: standing

Walking aids, orthotics, and shoes are inspected for wear.

The medial longitudinal arch and the inclination of the heel are observed from behind. The ‘too many toes’ sign is a marker of forefoot abduction but not pathognomonic of PTTD (Figure 9.5.1).
Fig. 9.5.1
Acquired flat foot—heel valgus, flat arch, and ‘too many toes’.

The patient is asked to rise onto tiptoes. Normally both heels will invert. Failure of inversion indicates PTTD (Figure 9.5.2) but subtalar joint stiffness may cause the same appearance.

Fig. 9.5.2
Failure of (right) heel to invert on tiptoe raise.

If double-stance heel rise is normal then single-stance heel rise is performed.

This may be: impossible; more difficult than on the unaffected side; or fatigue easily with repetition—according to the severity of the PTTD.

It is important to consider the more proximal parts of the lower limb.

The leg must be exposed to allow knee alignment to be assessed as valgus deformity of the knee may be associated with an acquired flat-foot deformity.

To assess contracture of the gastrocnemius, the patient is asked to stand on their heels only, with the toes clear off the ground (forefoot ground clearance).

**Examination: sitting**

The pulses and sensation are checked.

Ankle and triple joint flexibility is assessed, and joint line tenderness noted. Silfverskiöld’s test demonstrates the severity of an associated gastrocnemius contracture by assessing the difference in ankle equinus observed when the knee is flexed compared to when the knee is extended fully (Figure 9.5.3).

The forefoot to hindfoot alignment is observed after reducing and holding the heel into neutral position beneath the tibia, then observing the relative position of the sole of the forefoot to the heel.

Where the first ray is elevated in relation to the fifth ray, the deformity is known as forefoot varus (Figure 9.5.4).

**Differential diagnosis**

Acquired flat foot in adulthood is most commonly caused by PTTD. Tarsometatarsal osteoarthritis, spring ligament injury, and subtalar joint inflammatory arthropathy are important differential diagnoses.

**Clinical investigation**

Plain weight-bearing anteroposterior (AP) radiographs show dorsolateral peritalar subluxation. Bilateral films allow comparison of the degree of uncovering of the talar head. A weight-bearing lateral film may demonstrate alignment of first tarsometatarsal and naviculocuneiform joints (Figure 9.5.5). These films and an oblique view should be studied for evidence of degenerative joint disease.

**Click to view larger**

Fig. 9.5.5
A) Weight-bearing anteroposterior radiograph showing dorsolateral peritalar subluxation. B) Weightbearing radiograph with midfoot break.

In advanced PTTD, an AP weight-bearing radiograph of the ankle may show ankle arthritis.

Ultrasound of the posterior tibial tendon is a useful means of confirming tenosynovitis, thickening, or rupture of the tendon but is operator dependent so may be less useful to the treating surgeon than a magnetic resonance imaging (MRI) scan (Figure 9.5.6).
Treatment

Non-operative

Physiotherapy and orthotic management are the mainstays of treatment. Physiotherapy addresses the gastrocnemius contracture and strengthens the tibialis posterior tendon and toe flexors.

Orthotic management

Orthotics may be corrective or accommodative. Functional foot orthoses (FFOs) extend only across the foot. More extensive devices (e.g. ankle–foot orthosis, AFO) are reserved for advanced stages of PTTD.

Details of specific orthotics are contained in (chapter 9.4)

Operative

Surgery for PTTD should achieve a stable, painless, and plantigrade foot.

Corrective knee surgery must be undertaken before the foot and ankle are addressed.

The stage of PTTD is a useful guide to treatment (Box 9.5.1)

Box 9.5.1 Tibialis posterior insufficiency

- The common cause of flat-foot deformity in adults
- Classified according to tendon involvement and flexibility
- Management plan: try orthotics first
- Flexible feet: corrective orthotics vs. tendon transfer/osteotomy
- Fixed deformity: accommodative orthotic vs. corrective arthrodesis.

If non-operative treatments for stage 1 PTTD do not work, tenosynovectomy may prevent progression of the tendinopathy and relieve the pain and swelling in about three-quarters of patients. In selected cases this may now be performed arthroscopically.

In stage 2, joint-preserving surgery with tendon transfer and osteotomy is preferable to arthrodesis. It is most successful where the forefoot varus is correctable.

The most widely used tendon is the flexor digitorum longus (FDL). This fails in isolation, so it is combined with medializing calcaneal osteotomy. The osteotomy protects the tendon transfer by correcting heel valgus and medializing the insertion of the Achilles tendon. Plication of the spring ligament and short plantar ligaments are also performed to restore static restraint.

In patients with medial column joint laxity, midfoot osteoarthritis, or hallux valgus, appropriate midfoot fusions and/or correction of the hallux valgus may be required to restore structure.

Surgical correction of associated gastrocnemius contracture should be performed if tight.
Alternative techniques to FDL transfer and calcaneal osteotomy include lateral column lengthening.

Where the hindfoot is stiff or there is significant degenerative joint disease (stage 3), corrective fusion is preferred. Traditionally, triple arthrodesis has been used, but produces considerable hindfoot stiffness.

Subtalar fusion may be used if there is no fixed midfoot deformity, with cuneiform osteotomy, midfoot fusion, or talonavicular fusion also sometimes required to correct the forefoot–hindfoot relationship.

Where the talonavicular joint is unstable, isolated talonavicular fusion may be considered.

In severe cases, where there is ankle degenerative joint disease, pantalar fusion or corrective triple arthrodesis followed by an ankle replacement are considered (Figure 9.5.7).

**Prognosis**

Surgical treatment of stage 2 PTTD gives satisfaction rates of 90% after 2 or 3 months' cast immobilization. It takes another 6–9 months for swelling to resolve and strength to improve.

Selective or triple joint fusion for stage 3 PTTD also has good results, as long as plantigrade position is achieved.

**Disorders of the ligaments of the ankle**

**Introduction**

Ankle injuries make up 10% of attendances to Emergency Departments. The majority are inversion injuries resulting in localized pain, swelling, and bruising maximal over the anterolateral aspect of the ankle from damage to the anterior talofibular ligament (ATFL) and joint capsule.

Most are treated initially with rest, ice, compression, and elevation (RICE) followed by early weight bearing with an ankle brace. Physiotherapy concentrates on proprioceptive training and peroneal tendon strengthening.

Approximately 20–30% of patients suffer ongoing problems with their ankle. Table 9.5.2 shows the possible differential diagnoses.

Predisposing factors

Varus ankle, tarsal coalition, cavovarus foot posture (e.g. Charcot–Marie–Tooth), and generalized joint laxity predispose to ankle sprain.

Anatomy

There are three groups of ligaments each of which has three elements (Table 9.5.3).

Acute lateral ligament sprain

Ankle sprains most commonly injure the ATFL. The calcaneofibular ligament (CFL) is involved in more severe cases.

Examination

Examination aims to define which ligaments are torn and to exclude fracture. Watson Jones described passive inversion of the ankle to test for ligament insufficiency. Test the ATFL by inversion with the foot plantarflexed and the CFL with the foot dorsiflexion.

Treatment

Early functional treatment is recommended initially for all grades of injury.

There is no evidence for surgery after an uncomplicated acute injury. RICE is supplemented by early weight bearing, physiotherapy, and bracing. Return to sport is gradual.

Syndesmosis injury
The syndesmosis is injured in 18% of ankle sprains. The mechanism of injury is external rotation with a dorsiflexion component. These injuries cause more disability than isolated injury to the lateral ligament complex.

Clinical evaluation

Tenderness is maximal at the distal tibiofibular articulation. The ‘squeeze test’ compresses the tibia and fibula together thereby stressing the syndesmosis. If this provokes pain then the test is positive. External rotation of the foot with the ankle dorsiflexed will also stress the inferior tibiofibular articulation. If the patient twists their body while standing on the affected leg only (sometimes called the Jive test) discomfort is produced in cases of subtle syndesmosis injury.

Radiographs

Plain radiographs and axial computed tomography (CT) of both ankles allows asymmetry of the tibiofibular joint to be detected. MRI can demonstrate injury to the component ligaments of the joint complex. Fluoroscopic examination under anaesthesia may show instability.

Treatment

Stable injuries are treated symptomatically. A removable boot allows a graduated approach to rehabilitation. Recovery takes considerably longer for syndesmosis injuries than for sprain of the lateral ligament complex. There should be a low threshold for exposing the interior tibio-fibular joint through an anterolateral incision to ensure proper reduction.

An acute unstable syndesmosis injury should be treated surgically. The goals of surgery are anatomical reduction and stabilization.

When closed reduction is difficult, open or arthroscopic clearance of soft tissue from the medial side of the joint is performed. Stabilization of the tibiofibular joint is then performed with a diastasis screw. The screw is used as a position screw, and not in lag mode. More recently, suture devices passed across fibula and tibia have become popular.

Screw removal should be scheduled for no earlier than 12 weeks from surgery. Weight bearing may be permitted prior to screw removal, but screw breakage is a possibility, especially where the screw engages the far medial cortex of the tibia (four-cortex technique).

In chronic cases the medial side of the ankle and the distal tibiofibular joint should always be explored. The syndesmosis is debrided and the ligament repaired or reconstructed.

Chronic lateral ligament insufficiency

Recurrent giving way of the ankle may be due to mechanical instability or functional insecurity. Mechanical instability is where recurrent giving way of the ankle occurs in association with an abnormal displacement of the talus. It is usually due to ligamentous disruption, osteochondral injuries or loose bodies, and peroneal tendon pathology can all contribute. By contrast, functional insecurity is present when a patient complains of recurrent giving way, yet physical examination and radiological tests reveal a stable joint. Synovial impingement, peroneal muscle weakness, and poor proprioception are common causes of functional instability.

Synovial impingement

Synovial impingement may be caused by, or give rise to, recurrent painful episodes of giving way. Synovial impingement may occur with or without joint laxity. The synovial impingement sign is a useful physical sign. It relies upon the examiner’s thumb pushing inflamed hypertrophic synovium into the tibiotalar joint as the ankle is moved from plantar flexion into dorsiflexion, trapping the synovium and producing pain (Figure 9.5.8). The test is highly sensitive but not specific for isolated synovitis.
Patients with synovial impingement syndrome enjoy excellent results with examination under anaesthetic, arthroscopic assessment, and debridement of the joint.

Where clinical assessment reveals both synovitis and true ligamentous instability then the decision to simply debride the joint or to proceed to lateral ligament reconstruction at the same time is difficult.

Debridement of synovitis in isolation carries a quicker recovery time and requires no cast immobilization—advantages which must be weighed against the small chance of requiring a second procedure to reconstruct the ligament if addressing the synovial impingement alone provides insufficient improvement.

Osteochondral lesion of the talar dome (OLT)

Osteochondral lesion of the talar dome (OLT) is now the preferred term for this condition—although other terms such as osteochondral disease, osteochondral defect, and osteochondral fracture are also used.

A high index of suspicion is required for the diagnosis of OLT since symptoms may be vague and plain radiographs unrevealing. MRI scan is often required and will tend to underdiagnose the cartilage component and overdiagnose bony oedema.

Unstable cartilage on the dome of the talus may cause insecurity of the joint, an ill-defined ‘deep’ pain, acute pain, and clicking or just aching. OLT of the talus is treated by arthroscopic debridement of the unstable surface and underlying necrotic bone. In over 80% of patients the resultant fibrocartilagenous healing affords excellent symptom relief. For the 15% where debridement and microfracture fail repeating this procedure affords a further 80 percent success rate.

Occasionally, cases relapse and then treatment by cartilage graft, cartilage substitution, or, in the presence of major and/or increasing joint damage, even arthrodesis may be indicated.

Treatment of chronic instability

Non-surgical

Physiotherapy is important and focuses upon peroneal tendon strengthening and proprioception.

Activity modification, ankle support bracing, footwear modification, and orthotics are useful means of avoiding giving way.

Surgery

Surgical treatment is reserved for ankles that have failed non-operative management.

Lateral ligament reconstruction

In cases requiring surgical stabilization, anatomical repair is preferred to non-anatomic reconstructions. This is because of the high incidence of degenerative change seen in follow-up after non-anatomic reconstruction (up to 60%), due to altered biomechanics. Non-anatomic reconstruction also has a high incidence of sural nerve damage and lengthy recovery time. It is therefore reserved for recurrent cases or very heavy patients, and robust sports.

Brostrom, in 1966, described anatomic repair of the attenuated ligaments. The most popular modification is that described by Gould who advocated advancing the extensor retinaculum across the repair (Figures 9.5.9). As well as reinforcing the repair, this increases subtalar stability.
Fig. 9.5.9  

Non-anatomic reconstructions use peroneus brevis to stabilize the joint.

Where lateral ligament insufficiency is consequent upon a cavus foot, consideration must be given to a dorsiflexion first metatarsal osteotomy and peroneus longus to brevis transfer.

Aftercare for either requires 4–6 weeks’ immobilization in cast or brace, followed by rehabilitation with an emphasis on proprioceptive re-education.

Box 9.5.2 Ankle instability

- Ligamentous insufficiency is less common than synovial impingement
- Arthroscopic treatment for synovial impingement affords excellent results
- Conservative treatment with physiotherapy always precedes surgery
- Ligament reconstruction should usually be anatomic (modified Brostrom)
- Non-anatomic repair (e.g. Chrissman–Snook) for heavy people and revision surgery.

Lisfranc ligament injury

Introduction

Injury to the tarsometatarsal joint is frequently overlooked, especially as the patient often has multiple injures. It is a potent cause of late disability.

Purely ligamentous injuries to the tarsometatarsal joint complex result from more minor accidents and again often cause long-term symptoms.

Historical perspective

Lisfranc was one of Napoleon’s surgeons who observed injuries in cavalry officers falling from their mounts while one foot remained in a stirrup.

Anatomy

The anatomy of the midfoot is complex. Stability depends upon bony and ligamentous anatomy, as well as dynamic (musculotendinous) stabilizers.

The wedge-shaped cuneiforms and metatarsal bases form a transverse arch. The second metatarsal base is considered to form the ‘keystone’ of the tarsometatarsal joint as it is the apex of the transverse arch and is recessed between the medial and the lateral cuneiforms providing lateral stability. In addition there are three groups of ligaments: dorsal, interosseous, and plantar (Figure 9.5.10). Without these ligaments the tarsometatarsal joint complex is inherently unstable.
Clinical features

Severe fracture or dislocation of the tarsometatarsal joint will be obvious, with gross swelling and deformity. The plantar ecchymosis sign, with a bruise under the foot at tarsometatarsal joint level, is seen. Tenderness is maximal over the second tarsometatarsal joint.

In contrast, a seemingly innocuous injury to the foot that presents late, once swelling and bruising have improved, is easily missed and requires careful examination and a high index of suspicion.

Differential diagnosis

Most cases of tarsometatarsal joint injury are presumed to be a 'sprained foot'. It is safer to assume that 'there is no such thing as a sprain of the midfoot'.

Investigation

In severe injuries, fracture and/or dislocation are usually obvious.

In contrast, in pure ligamentous injury, they may show no abnormality, particularly if taken non-weight bearing.

Positive radiographic features are the 'fleck sign' (a small avulsion of bone from the base of the second metatarsal) and an increase in the gap between the bases of the first and second metatarsal. The medial edge of the base of the second metatarsal should be aligned with the medial edge of the intermediate cuneiform. This is best assessed on an AP radiograph of both feet taken with the patient bearing weight (Figure 9.5.11A). Where plain radiographs are normal CT, MRI, or bone scan can be helpful (Figure 9.5.11B).
Targeted joint injection of local anaesthetic may be useful to confirm that pain is from the second tarsometatarsal articulation in chronic cases.

**Treatment**

Untreated, the ligamentous Lisfranc injury often results in a chronically painful foot with planovalgus deformity and tarsometatarsal joint arthrosis from which late salvage surgery in the form of corrective midfoot fusion gives unpredictable results.

**Non-operative treatment**

Non-operative treatment is only successful when no displacement is present, so a normal CT scan is a prerequisite.

Treatment comprises cast immobilization for 12 weeks with no weight bearing for the first half of this time period. Physiotherapy is required afterwards, as is prolonged support with a rigid FFO.

**Operative treatment**

When displacement is present, open reduction is preferred to give accurate reduction. Historically, K-wire stabilization was recommended. Screws across the tarsometatarsal articulation provide more stability but damage an already disrupted joint, so bridging plates are preferred by many surgeons.

In selected cases, primary fusion may be considered (Figure 9.5.12) to avoid repeated surgery and a protracted recovery.

![Click to view larger](Fig. 9.5.12 Primary fusion for tarsometatarsal fracture dislocations.)

**Prognosis**

Trauma to the Lisfranc joint is a potentially devastating injury. Even with good treatment, pain, stiffness and swelling lead to difficulty with sporting activities and shoe fitting in many patients. Patients should be warned that the foot is unlikely to return to full function, and may require long-term orthotic support.

---

**Achilles tendon**

**Introduction**

The Achilles tendon is the largest tendon in the body. In orthopaedic foot and ankle surgery, disorders of the Achilles relate to pain and swelling with resultant disability or to rupture.

The microscopic appearances of tendons that have ruptured are similar to the findings in specimens sent from tendons with tendinopathy without rupture, suggesting a pre-existing abnormality, prior to acute tearing.

However, many patients who sustain an acute rupture have never had symptoms while patients who endure chronic pain and swelling of the tendon rarely rupture.

**Anatomy (Figure 9.5.13)**

The Achilles tendon is the combined tendon of the three components of the triceps surae muscle. The gastrocnemii pass across both the knee joint and the ankle joint. Soleus does not extend above the knee. This distinction is important when stretching programmes are considered as part of a treatment programme, as the gastrocnemius cannot be properly stretched unless the knee is held in full extension.
Box 9.5.3 Lisfranc ligament injury

- Obvious fracture-dislocation or subtle ligament injury
- High index of suspicion—no such thing as a midfoot sprain'
- Poor results but worse if missed
- Surgery open reduction and bridging plate fixation
- Consider primary fusion of tarsometatarsal 1–3.

The fibres of the Achilles tendon rotate through 90 degrees as they pass distally. The medial fibres proximally become the posterior fibres distally. Thus valgus collapse of the ankle tends to increase the twist and therefore tightness of the tendon.

The tendon inserts onto the middle one-third of the posterior surface of the tuberosity of the calcaneum. Structurally the insertion changes by way of transitional zone: fibrocartilage, mineralized fibrocartilage, and finally bone. This allows effective force dissipation.

The tendon immediately proximal to the site of insertion is related to the superior one-third of the posterior surface of the os calcis. This surface is covered by fibrocartilage and the tendon is protected by the retrocalcaneal bursa. Another bursa lies between the Achilles tendon and the skin.

Blood supply

The blood supply in the non-insertional region of the Achilles tendon is poor. This is important in the pathophysiology of tendinopathy and rupture.

Posterior heel pain

Posterior heel pain most commonly arises from the Achilles tendon. Pathology may arise from the insertion of the tendon or from the non-insertional region. This distinction is helpful.

Non-insertional Achilles tendon pathology is more common and is due to degenerative changes within the tendon, thickening of the paratenon, or a combination of the two.

Retrocalcaneal bursitis with insertional tendinopathy accounts for approximately 20% of all Achilles tendinopathies. Pure insertional tendinopathy makes up only 5%.

Terminology

Maffulli has clarified the nomenclature. The triad of pain, swelling, and impaired function should be referred to as Achilles tendinopathy.

Non-insertional tendinopathy

Achilles tendinopathy is common, but there are no reliable epidemiological data. An association with athletic training supports the theory that overuse is the principal cause, although it can trouble sedentary individuals as well. It is more common in older athletes.

Insertional tendinopathy

An enlarged posterosuperior border of the tuberosity of the os calcis is called the bursal projection (Haglund deformity), and may
Impinge against the tendon resulting in retrocalcaneal bursitis or degenerative change in the tendon. With retrocalcaneal bursitis, the heel is swollen and maximally tender posteromedially or, more commonly, posterolaterally. It may also cause the heel counter of shoes to rub. This results in local swelling and tenderness.

Insertional heel pain may also be due to changes within the transitional zone of the tendon, to retrocalcaneal bursitis, or to both.

Patients with insertional tendinopathy complain of posterior heel pain that is maximal in the midline and inferiorly, at the insertion of the tendon.

**Clinical assessment of posterior heel pain**

A careful history determines the relationship of symptoms to: activity; new training regimens; poor warm-up technique; or to specific shoes. Atypical features in the history, such as night pain, should prompt investigations for enthesopathy or rare neoplastic causes.

Examination will reveal the site of maximal tenderness. The tendon is tender and swollen in non-insertional tendinopathy. Midline tenderness suggests insertional tendinopathy whereas maximal tenderness to the lateral (or less commonly medial) side of the tendon is due to bursitis.

Increased calcaneal pitch with heel varus makes the bursal projection of the calcaneum excessively prominent. Heel valgus with a low medial longitudinal arch and forefoot varus causes overpronation of the foot, tightening of the tendon, and secondary Achilles tendinopathy.

If a systemic inflammatory cause is suspected, general examination is performed and supplemented with blood tests.

**Imaging**

Plain radiographs may show deformity, bony lumps, and ectopic calcification (Figure 9.5.14A).

![Fig. 9.5.14](https://via.placeholder.com/150)

**A)** Calcific tendinopathy. **B)** Insertional tendinopathy and bursitis.

Ultrasound scan and MRI both provide useful information. MRI provides a permanent image (Figure 9.5.14B), but ultrasound allows dynamic assessment.

**Treatment**

**Non-operative treatment**

Patients must be informed of the natural history of non-insertional tendinopathy because the majority of patients improve and are only left with a palpable non-tender lump in the Achilles tendon in the long term.

Stretching regimens for non-insertional tendinopathy are effective, with 90% of patients responding. The patient and physiotherapist must understand that the knee has to be fully extended during the stretch for the gastrocnemius contracture to be improved. If the hamstrings are tight then stretches for this muscle group should be added to the regimen.

Steroid injection should be avoided except in proven cases of pure paratendinitis or bursitis, because of the risk of rupture. Sclerosant injection therapy is successful in the treatment of non-insertional tendinopathy. Extracorporeal shock wave lithotripsy is under evaluation.

Patients with 'pump bumps' respond to education, modification of shoes, and occasionally an orthotic to lift the affected part, or a silicone lined sock. To avoid recurrence it is important that the patient understands that they must continue to be careful with shoes even after the symptoms resolve.
Retrocalcaneal bursitis can be managed in the same way. Corrective orthotics for planovalgus deformity can be helpful, but overcorrection is poorly tolerated, especially in running athletes. There may be some benefit from anti-inflammatory medication or gel, but steroid injection should only be considered if an MRI or ultrasound scan shows normal tendon.

Operative treatments

Open procedures

Non-operative treatments are successful in about 90% of cases, so surgery is rarely required—especially as recovery times are often very long.

Non-insertional tendinitis

Surgery is rarely required. Available procedures include decompression—performed open or percutaneously by multiple incisions and paratenon stripping. In severe cases, surgeons increasingly perform supplementary transfer of the flexor hallucis longus (FHL) tendon, to augment the Achilles tendon.

Haglund disease alone or in combination with retrocalcaneal bursitis

Excision of the bursal projection is performed through a medial incision for osteotomy of the posteromedial and/or lateral bony prominence, minimizing risk to the sural nerve. At least 50% of the attachment of the tendon can be released without the need for suture anchor repair and without cast immobilization.

Combined excision of bursa and bony prominence results in 50% of patients being symptom free and a further 20% improved. In patients operated on within a year, 92% are cured or improved.

In rare cases where surgery is required for isolated insertional tendinitis, a posterior midline tendon splitting approach is used (Figure 9.5.15). The tendon is debrided, and may be completely detached and reattached. The success rates for pain relief are good, but the eventual outcome is often limited and not all patients improve sufficiently to resume sports.

The success rates for pain relief are good, but the eventual outcome is often limited and not all patients improve sufficiently to resume sports.
Sudden pain is a constant feature of the presentation, often with an audible tearing or snapping sound, though the pain may not last long.

Sadly even patients with classical presentations are misdiagnosed as having a sprained ankle, pulled calf muscle, or ‘partial tear’ of the Achilles tendon.

Clinicians may be deceived by the patient’s ability to plantar-flex using the muscles of the deep posterior compartment of the calf. In the acute setting, soft tissue swelling and tenderness may mean that the gap between the tendon ends cannot be palpated. The only reliable way to diagnose rupture is to use the clinical test of Simmonds and Thompson. The patient lies on a couch or kneels on a chair with the feet and ankles hanging free. The examiner notes the resting posture of the ankles. The affected side will lie in a less plantar-flexed position, through loss of the pull of the gastrosoleus complex (Matle’s test). The examiner then squeezes the normal calf and this action shortens the gastrosoleus muscle causing the foot to plantar-flex. When the manoeuvre is repeated on the affected limb there is no such movement at the ankle because there is no continuity of the tendon. To avoid confusion, the test should not be referred to as positive or negative—which is ambiguous—but as normal or abnormal.

**Differential diagnosis**

Sudden onset of posterior heel pain should be assumed to be due to a (complete) rupture of the Achilles tendon, until proven otherwise.

**Investigation**

Imaging is seldom required. Ultrasound or MRI (Figure 9.5.16) may be useful as an adjunct to clinical assessment where the presentation has been delayed or where there is a suspicion that the rupture is high, at the musculocutaneous junction—but may be misleading if clot or scar fills the gap.

![Fig. 9.5.16](https://example.com/fig9.5.16.png)

**Click to view larger**

Rupture after steroid injection.

**Treatment**

Achilles tendon rupture may be managed non-operatively or by surgical repair.

The benefits of surgical repair include a lower incidence of re-rupture and the opportunity to achieve adequate tension in the tendon. Most surgeons specializing in foot and ankle surgery are proponents of repair. A review of the Cochrane database concluded that surgery is advantageous as long as complications can be avoided. Wound infection and/or breakdown, in an area with a thin soft tissue envelope, is the most important complication.

The decision to surgically repair a ruptured Achilles tendon is made after considering:

- Patient activity levels and expectation
- Timing of presentation after injury
- General health
- Local soft tissues.

At one extreme, the older patient who has poor skin, smokes, and presents immediately after an injury may be managed non-operatively—avoiding high risks of wound problems, but mindful of an increased rate of re-rupture.

A sportsman with a few days’ delay in presentation should undergo surgical repair, as this allows the haematoma between the
tendon ends to be evacuated and both length and tension of the tendon restored.

Conservative treatment

Conservative treatment should be active and is not ‘treatment by neglect’. Equinus cast or functional immobilization should be monitored by ultrasound scans to confirm apposition of tendon ends at intervals during healing. After immobilization or functional treatment for 6 weeks, a heel raise allows the patient to gradually stretch out the repaired tendon during rehabilitation.

Open versus percutaneous repair

Open surgery allows direct visualization and robust repair but at the expense of possible wound complications. In an effort to avoid this, percutaneous repair has evolved. The incidence of painful sural nerve injury has been problematic.

The Achillon® device (Figure 9.5.17) facilitates percutaneous repair and has a very low incidence of nerve injury. Functional results after percutaneous repair are equal to those after open repair, but for those not familiar with its use, open procedures are more applicable.

Rehabilitation

Whether the tendon is repaired or treated conservatively, the rehabilitation protocol should allow the patient to bear weight from an early stage. This has been shown to improve collagen remodelling. With rapid rehabilitation it is often possible for the patient to be to bearing weight almost immediately and free from support by 6 weeks from the injury.

Delayed presentation of Achilles rupture

When a patient presents with a delayed Achilles tendon rupture a variety of terms may be used. Neglected may mean that the patient did not seek medical attention at the time of injury; Missed implies that the doctor, physiotherapist, or nurse failed to make the diagnosis.

When the rupture is not treated the natural history is for the tendon to heal, but at a length that prevents proper function of the triceps surae.

Clinical features

The patient may give a clear history of acute tendoachilles rupture that was not treated or of a minor exacerbation of chronic symptoms that was not appreciated to be a rupture. In either case, the presenting complaints are weakness, poor balance, difficulty with stairs, or inability to stand on tiptoes, with swelling of the ankle and pain.

On examination the ankle can be passively dorsiflexed further than the normal side; single-stance heel-rise is weak or impossible; the tendon is often thin at the site of rupture, if elongated healing has occurred; or deficient with a palpable gap.

Imaging

Plain films (lateral weight bearing of the foot and ankle) may show alterations of the normal soft tissue shadows, and may show features of insertion tendinopathy (calcification, Haglund deformity) which raises the possibility of distal rupture.

Ultrasound and MRI may confirm the diagnosis but also give information about the level of the rupture, the extent of retraction of the proximal stump, and the length of intervening scar tissue (Figure 9.5.18), but both may be deceptive and fail to differentiate between clot, scar, and tendon.
Treatment

Non-operative

This may be chosen when the patient reports minimal symptoms or if surgery is contraindicated. Physiotherapy strengthens the calf muscles and minimizes symptoms. Improvement may continue for more than 2 years.

Operative (Table 9.5.4)

Surgical treatment aims to restore plantar-flexion power to the ankle. There is a wide range of surgical techniques from which to choose. The choice is made according to the gap between the proximal and distal stump after debridement of scar tissue.

Available techniques include direct repair and indirect methods, and the more controversial autograft, synthetic graft, or allograft reconstructions.

End-to-end repair is unlikely to be successful if treatment is delayed for more than a few weeks. Advancement of the proximal stump can be achieved by means of V–Y-plasty or a ‘turn-down’ procedure. This produces a bulky repair with risk of wound problems and is less popular since the introduction of tendon transfer techniques.

Tendon transfer techniques may use peroneus brevis, FDL or (most commonly) FHL.

FHL, flexor hallucis longus. Adapted from Myerson, with permission. Source: Foot and Ankle Disorders: Chapter 55 Disorders of the Achilles Tendon and Retrocalcaneal Region p1386–6.

Reports of FHL transfer are good to excellent with negligible weakness of hallux flexion.

Synthetic graft should only be used in exceptional circumstances.

Plantar heel pain

Plantar heel pain is common, disabling, and usually due to plantar fasciitis at the point of insertion onto the heel.

Patients are often middle aged or elderly and present with severe heel pain, especially start-up pain that is most troublesome upon rising in the morning and improves, only to deteriorate again with prolonged standing or walking.

Atypical presentation in younger patients may be associated with stress fractures, enthesopathy, arthritis, tarsal tunnel syndrome, or lumbar radiculopathy.

Assessment
Patients should be examined for signs of a calcaneal stress fracture (calcaneal squeeze test) and for tarsal tunnel syndrome (Tinel sign over tibial nerve; altered sensation in sole of foot). Plantar fasciitis is classically maximally tender over the medial calcaneal tuberosity (Figure 9.5.19).

![Click to view larger](image)

Fig. 9.5.19
A) Site of tenderness in plantar fasciitis. B) Magnetic resonance image of plantar fascia rupture following injection.

The majority of patients with plantar fasciitis have isolated shortening of the gastrocnemius, identified using Silfverskiold’s test (Figure 9.5.3).

**Treatment**

Conservative treatment includes orthotics, physiotherapy (including ultrasound and stretching), night splints and lithotripsy. Patients who present early recover more quickly than those presenting late with established symptoms. The majority of cases respond, but in refractory cases, injection (preferably ultrasound guided) can be helpful. Rupture of the fascia is, however, a potential and serious complication (Figure 9.5.19B).

Open or endoscopic release of the plantar fascia insertion is sometimes performed, but the risk of provoking prolonged severe pain in association with acute flat foot and nerve damage means that it has not been adopted widely in the United Kingdom.

**Peroneal tendons**

**Introduction**

The peroneus longus and brevis tendons cause ankle symptoms either because of acute injury or because of chronic tendinopathy.

**Box 9.5.4 Achilles tendon**

- Rupture is complete (not partial) until proven otherwise
- Conservative treatment associated with higher re-rupture rate
- Surgical repair predictable but risk of wound problems
- Percutaneous techniques minimize wound
- Early weight bearing for both operative and non-operative cases.

**Anatomy**

Peroneus brevis lies anterior to longus as they course behind the lateral malleolus. Both are supplied by the superficial peroneal nerve (L5, S1 roots).

Proximal to the malleolus the tendons are invested in a synovial sheath. This extends beneath the peroneal retinaculum. After rounding the tip of the lateral malleolus, the tendons diverge, passing either side of the peroneal tubercle on the lateral wall of the os calcis. They pass beneath the inferior extensor retinaculum before following different courses. The brevis tendon passes to the styloid process of the fifth metatarsal base. Peroneus longus passes beneath the cuboid and across the sole of the foot to insert on the plantar aspect of the base of the first metatarsal. At the point that the tendon changes direction it is strengthened by a sesamoid bone, the os perineum, which is often cartilaginous.

**Clinical features**

**Injuries**

**Acute inflammation**

Inversion injuries of the ankle may result in acute inflammation of the peroneal tendons leading to signs of: local tenderness; pain
on passive stretch; and pain on active resisted movement. Swelling behind the fibula is characteristic.

**Peroneal tendinopathy**

The position of peroneus brevis, between the longus tendon and the fibula, makes it vulnerable to injury. It may also be trapped beneath the fibula when there is valgus deformity of the heel.

**Imaging**

Plain radiographs will not show the tendons but in the case of peroneus longus rupture may show proximal migration of a fracture through the os peroneum.

Ultrasound or MRI is more useful to show the structure of the tendons.

**Box 9.5.5 Plantar heel pain**

- Most commonly plantar fasciitis
- Atypical symptoms—young, night pain, malaise, or arthritis
- Treated with gastrocnemius and plantar fascia stretches
- Steroid injections may be effective
- Surgery usually avoided because of risk of complications.

**Treatment**

Non-operative treatments include activity modification and orthotic provision to address any cavovarus deformity or valgus collapse. Corticosteroid injection should usually be avoided.

Synovectomy can be performed arthroscopically. Open surgical exploration, with tenosynovectomy and repair or tendon debulking with tubularization of split/thickened tendons is indicated in severe cases with tendinosis/chronic rupture.

**Peroneal tendon dislocation**

The peroneal tendons dislocate from behind the fibula as a result of a twisting injury. In the normal ankle the peroneal retinaculum prevents this.

At the time of injury the tendons strip the retinaculum away from the bone of the fibula—a 'Bankart' lesion of the ankle.

Only occasionally does an avulsion fracture from the fibula make the injury apparent on plain radiographs. Neither MRI nor ultrasound is 100% sensitive.

A high index of suspicion is required to make the diagnosis in the acute setting.

After the acute symptoms have resolved, recurrent snapping of the tendons over the malleolus may be demonstrated by the patient.

**Box 9.5.6 Peroneal tendons**

- Vulnerable to inversion injury
- Peroneus longus may rupture through an os peroneum
- Dislocation due to retinaculum injury is often missed
- Anatomical repair advised.

**Treatment of peroneal dislocation**

After an acute injury cast immobilization may allow satisfactory healing. Surgery aims to repair the 'Bankart' lesion anatomically.

In recurrent situations after failed surgery, various techniques have been described to augment the repair. The 'groove' behind the fibula can be deepened with an osteotomy or using a burr. A strip of tendon from the lateral portion of the Achilles tendon may be used to fashion a new retinaculum. Alternatively, the calcaneofibular ligament may be transposed into a position superficial to the tendons.

Results of repair are good, but 6–8 weeks of protection in a cast are required, and a lengthy rehabilitation period follows this.

**Further reading**

Summary points

- Classic metabolic bone diseases include osteoporosis, osteomalacia, Paget’s disease, and parathyroid bone disease
- Heritable disorders of the skeleton include numerous osteochondrodysplasias, Marfan syndrome, and Ehlers-Danlos syndrome
- Investigation of short stature is indicated for those below 0.4 percentile, with skeletal disproportion and/or progressive shortness
- Genetic mutations for most of these conditions have been identified but clinical/radiographic features are usually diagnostic.

Introduction

The human skeleton serves both as a supporting frame and as an accessible mineral store. Bone is metabolically active throughout life and metabolic disturbances may have wide ranging consequences that are not restricted to altering its mechanics.

Structure

Bone consists of cells and an extracellular mineralized matrix (35% organic and 65% inorganic). About 90% of the organic component is type 1 collagen. The remainder includes many non-collagen products of the osteoblast (e.g. osteocalcin, osteonectin, and proteoglycans). The mineral is present mainly as calcium hydroxyapatite. There are two anatomical types of bone, trabecular (cancellous) and cortical, the proportions of which differ from one bone to another; vertebral bodies are predominantly trabecular, while the shafts of the long bones are cortical, reflecting their disparate functions. Trabecular bone contains more metabolically active surfaces in a given volume than cortical bone and is therefore more susceptible to conditions such as osteoporosis.

Bone cells

Three types of bone cell are clearly identifiable (Figure 10.1.1):

- Osteoblasts responsible for synthesis of the bone matrix
- Osteoclasts, which occupy areas of resorption and classically have a multinucleate appearance

Bone

- Bone is a mineral store (1 kg. calcium)
- 90% is type 1 collagen
- In adults bone turnover is 25% cancellous but only 2–3% cortical bone/annum.
- Osteoblasts lay down bone after osteoclasts remove it.

- Osteocytes within lacunae in the mineralized bone, apparently in contact with other osteocytes through extensions in bone canaliculi.

Fig. 10.1.1
A multinucleated osteoclast (Oc) in a resorption lacuna and a row of osteoblasts (Ob) on opposite surfaces of a bone trabecula (A) and the bone relationships of the osteocytes (B).

In the adult, the annual turnover of old bone is approximately 25% in cancellous bone but only 2–3% in cortical bone. Imbalance
between bone formation and resorption underlies many pathological states. Osteoblasts are pluripotent stromal cells which can also give rise to fibroblasts, chondrocytes, myocytes, and adipocytes. Osteoblasts respond to various systemic and local factors (cytokines) and also to mechanical stress. They synthesize the organic bone matrix (mainly collagen) and non-collagen proteins, and control bone mineralization. They also direct the activity of osteoclasts. Osteocytes, derived from osteoblasts, occupy lacunae within the mineralized bone, communicating with each other through gap junctions via their processes in the bone canaliculi. They probably have an important function in the detection of mechanical forces and the resultant response of bone to them. Osteoclasts have different cellular origins from osteoblasts, being derived from the haemopoietic system. They attach themselves to bone via integrins (vitronectin receptor) and produce a very acid environment within this sealed zone. Osteoclasts also have receptors to calcitonin, which suppresses their activity, but they are activated by prostaglandins.

**Bone formation**

Bone formation is largely dependent on osteoblasts. The stromal precursors of osteoblasts are found in the periosteum and the endosteal surfaces of bone. The local remodelling stimulus for new bone formation probably comes from product(s) of bone resorption which may include growth factors, cytokines, transforming growth factor β (TGFβ), or bone morphogenetic proteins (BMPs) liberated from resorbed bone.

**Bone resorption**

Osteoclasts respond to systemic and local factors but not to mechanical stress. Calcitonin directly inhibits osteoclasts and also suppresses the generation of new osteoclasts, whereas bone resorption is increased by parathyroid hormone and 1,25(OH)2D. However, because osteoclasts actually lack receptors for either of these factors, their resorbing effects are mediated via the osteoblast. The number and activity of the osteoclasts are also increased by a variety of cytokines. Thus, in myeloma the malignant plasma cells release interleukin (IL)-1, IL-6, and TNF (tumour necrosis factor), all of which stimulate osteoclastic destruction of bone. The actions of the osteoclast are critically dependent on its ability to create an acidic resorption lacuna (Figure 10.1.2).

**Bone mass**

Peak bone mass is strongly genetically determined. In keeping with the mechanical functions of the skeleton, bone is laid down along its lines of stress. Osteoblasts respond to mechanical stress but the size and density of the skeleton is also related to nutritional intake, particularly of calcium, protein, and calories. The sex hormones (testosterone and oestrogen) encourage new bone formation. The complexity of these hormonal influences is emphasized in that oestrogen-deficient men get osteoporosis and the skeleton clearly depends on a full complement of sex steroids for its integrity. Growth hormone is an important anabolic skeletal agent during the early years of life, partly through the local production of somatomedins (insulin-like growth factors).

Collagen is the main product of the osteoblast, but there are also non-collagen proteins in bone. Osteonectin, the major non-collagen protein produced by human osteoblasts, binds strongly to calcium ions, hydroxyapatite, and native collagen.

It has been known for many years that demineralized bone matrix contains substances capable of inducing ectopic bone formation. Because they are present in such small amounts these BMPs have only recently been isolated.

**Box 10.1.2 Bone metabolism control**

- Calcitonin inhibits osteoclasts
Calcitonin inhibits osteoclasts

PTH and 1,25(OH)₂D stimulate bone resorption

Peak bone mass is strongly genetically controlled

Sex hormones encourage bone deposition

Demineralised bone matrix contains bone morphogenetic proteins

Alkaline phosphatase is a good marker of bone turnover.

Bone mineral and mineralization

In most mineralized tissues, calcifying vesicles derived from chondrocytes or osteoblasts provide a focus for mineralization on bone matrix collagen. The precipitation of calcium within these vesicles is controlled by the action of alkaline phosphatase. Deficiency of alkaline phosphatase activity results in defective mineralization and also accumulation of pyrophosphate in other tissues, where it results in ectopic calcification. Abnormal calcification or ossification may occur in many other pathological states and also as a consequence of ageing. Thus abnormal calcification of articular cartilage (chondrocalcinosis) may occur with increasing age.

Calcium and phosphorus balance (Box 10.1.3)

Total plasma calcium concentration is closely maintained at 2.25–2.60 mmol/L. Nearly half of this calcium is in the ionized form. The skeleton contains approximately 1 kg of calcium. Plasma calcium concentration is determined by a balance between intestinal absorption, renal excretion, and the exchange of mineral with the skeleton (Figure 10.1.3).

Parathyroid hormone and vitamin D (Figure 10.1.4)

Small changes in plasma calcium are detected in the parathyroid gland. Reduction in the plasma ionized-calcium concentration stimulates the release of parathyroid hormone (PTH), which increases calcium absorption through the gut, increases calcium reabsorption in the kidney, and increases bone resorption. The renal effect of PTH on calcium reabsorption is direct but, in contrast, the effect of PTH on increasing intestinal calcium absorption is indirect via its actions on vitamin D. 1,25(OH)₂D is the most important active metabolite of vitamin D. The action of PTH on increasing calcium absorption from the gut is therefore indirect through its effects on 1,25(OH)₂D production. PTH also encourages osteoclastic bone resorption indirectly by its effects on the osteoblast. Measurement of the plasma 25OHD concentration is a useful indicator of vitamin D status.

Box 10.1.3 Calcium control

- PTH increases plasma calcium by:
  - Modifying gut absorption
  - Decreasing renal excretion
  - Reducing bone deposition
  - Increasing bone resorption
- Calcitonin—reduces bone resorption by suppressing osteoclasts.
Calcitonin reduces bone resorption by the direct and reversible suppression of osteoclasts.

Excess corticosteroids (either therapeutic or in Cushing’s syndrome) suppress new bone formation but can also be associated with exuberant callus formation after fractures. Androgens and oestrogens promote and maintain skeletal mass. Thyroxine increases bone turnover and resorption, thereby leading to bone loss. Excess growth hormone leads to gigantism/acromegaly (according to the age of onset). In contrast, growth hormone deficiency causes proportionate short stature and where there is general pituitary failure the reduction in gonadotrophins will also induce bone loss.

Biochemical measures of bone turnover

Total plasma alkaline phosphatase (largely derived from osteoblasts) provides a crude but readily accessible index of bone formation: it is increased during periods of rapid growth, following fractures and in conditions where bone turnover is greatly increased, such as Paget’s disease.

The diagnosis of bone disease (Box 10.1.4)

Deformity, pain, and fracture are common features. To these may be added proximal myopathy (in osteomalacia and rickets) and the symptoms of any underlying systemic disease, such as renal failure, steatorrhoea, or myeloma. Other relevant factors are both family and menopausal history. Previous abdominal operations, including hysterectomy and oophorectomy, dietary history, and documentation of smoking, alcohol, and caffeine intake are all relevant to assessing the risk of osteoporosis.

Deformity and short stature

Short stature (defined as <0.4th centile) can be divided into proportionate and disproportionate forms, of which the most frequent is caused by short limbs. About three-quarters of children with short stature either have familial short stature or constitutional delay of growth and puberty; others have chronic disease (10%), syndromic short stature (6%), chromosomal abnormalities (5%), skeletal dysplasias (1%), or hormone deficiencies (1–2%).

Box 10.1.4 Diagnosis of bone disease

- Diet
- Family history
- Menstrual history
- Pain, and fractures
- Stature (proportionate vs disproportionate)
- Progressive deformity.

Progressive kyphosis and loss of height is the commonest acquired deformity of adult life and is strongly associated with osteoporosis and osteomalacia. Other deformities include knock knees, bowed legs, enlarged epiphyses, and bossing of the skull in rickets; thick, bowed limb bones and an enlarged skull in Paget’s disease; and very short, deformed limbs and trunk in severe osteogenesis imperfecta.

Bone pain and fracture
In osteomalacia, pain may be widespread and associated with tenderness on pressure. Osteoporosis is typically asymptomatic in the absence of fractures. Fissure fractures are characteristically found on the convexity of pagetic bone; Looser’s zones on the medial borders of osteomalacic bones; and multiple vertebral compression fractures may be seen in osteoporosis. Degenerative joint disease is actually the most common cause of pain suffered by individuals with rare disorders of the skeleton.

**Myopathy**

Proximal muscle weakness is common in osteomalacia and rickets. The symptoms include a waddling gait and difficulty in climbing stairs. Limbs may be described as stiff rather than weak.

**Physical signs**

Abnormalities in physical signs may not be confined to the musculoskeletal system. Blue sclera (in osteogenesis imperfecta), lens dislocation in Marfan syndrome and tooth enamel defects (in hypoparathyroidism) are all examples.

Abnormal body proportions may give valuable clues to underlying conditions. The fingers may be abnormally long and thin (Marfan syndrome) or excessively short and mobile (pseudochondrodysplasia). The spine is relatively short after vertebral collapse; scoliosis often dates from adolescence and is occasionally a clue to an inherited connective tissue disorder; a thoracolumbar gibbus is a particular (though not exclusive) feature of the mucopolysaccharidoses. Spinal deformity often produces secondary changes; thus a young patient with severe osteoporosis will develop a prominent sternum with ribs that impinge on the iliac crest and a transverse crease across the front of the abdomen.

**Investigations**

**Biochemistry**

**Plasma**

Fasting plasma calcium is normal in osteoporosis and also in Paget’s disease unless the patient has been immobilized. Hypercalcaemia occurs in primary hyperparathyroidism, various neoplasms (including hypercalcaemia of malignancy), in sarcoidosis, vitamin-D overdosage and, rarely, in thyrotoxicosis. Hypocalcaemia is typical of parathyroid insufficiency and may be apparent in osteomalacia. However, hypophosphataemia is actually a more sensitive indicator of osteomalacia since calcium levels may be restored towards normal by secondary hyperparathyroidism. Plasma phosphate is reduced in primary hyperparathyroidism, in the humoral hypercalcaemia of malignancy and also in inherited hypophosphataemic rickets.

Plasma alkaline phosphatase is increased in primary hyperparathyroidism, but only where there is demonstrable bone disease. Plasma alkaline phosphatase is particularly elevated in young patients with active Paget’s disease. It is variably increased in metastatic bone cancers and sometimes in active fibrous dysplasia of bone. Low levels are characteristic of hypophosphatasia.

**Radiology**

Magnetic resonance imaging (MRI) is very useful in the diagnosis and assessment of musculoskeletal disease because of the additional information it can provide about soft tissue and bone pathology. Bisphosphonate-labelled radioisotope scanning is useful in demonstrating the skeletal extent of Paget’s disease, and the presence of bony metastases. Isotope scanning is preferable to multiple radiographs when assessing the distribution of abnormal bone but it is increasingly being supplanted by MRI.

**Further investigations**

Plasma PTH is useful when investigating hyper- and hypocalcaemia, PTHrP is useful for suspected hypercalcaemia of malignancy, and 25OHD and 1,25(OH)2D levels are reduced in rickets and osteomalacia. Some guidance to the diagnosis can be gained from the age of the patient and frequency of the disorder (Table 10.1.1).

**Osteomalacia and rickets (Box 10.1.5)**

Osteomalacia usually results from a lack of vitamin D and in the growing skeleton it is referred to as rickets. Inherited hypophosphataemia and several other renal tubular disorders may also cause rickets.

Vitamin D synthesis in the skin is quantitatively more important than dietary intake. Asian immigrants and the elderly are most at risk from vitamin D deficiency.

**Pathophysiology**

Many patients have more than one cause for their osteomalacia; in the housebound elderly, vitamin D intake is often poor.
exposure to sunlight limited, and renal glomerular failure progressive. Reduced exposure to sunlight is an indirect consequence of physical immobility and may contribute to osteomalacia in rheumatoid arthritis and other chronic diseases. Histology reveals an excess of unmineralized osteoid (Figure 10.1.5).

Clinical features

The main effects of osteomalacia are bone pain and tenderness, skeletal deformity, and proximal muscle weakness. In severe osteomalacia all the bones are painful and tender, sometimes sufficiently to disturb sleep and this may be accentuated over Looser’s zones. In children growth rate is reduced, there is bowing of the long bones, enlargement of the costochondral junctions (rickety rosary), and bossing of the frontal and parietal bones. Later, osteomalacia may produce a triradiate pelvis, kyphosis, and chest deformities.

Investigations

Biochemistry

Classic vitamin D deficiency or malabsorption causes low plasma calcium and phosphate, low urine calcium and, eventually, an increase in the plasma alkaline phosphatase. The measurement of vitamin D metabolites is now routine; low plasma 25OHD level is a good indication of vitamin D deficiency.

Box 10.1.5 Osteomalacia

- Rickets in children leads to growth deformity
- On adults low 1,25(OH)2D because of
  - Poor diet
  - Lack of sunlight
  - Inability to metabolize vitamin D.

Fig. 10.1.5
Bone from a patient with osteomalacia. The birefringent osteoid is abnormally thick (up to 12 lamellae, arrows) and covers all bone surfaces. The bone preparation is undecalcified and viewed under polarized light (von Kossa stain; magnification ×300).

Radiology

In childhood rickets the main abnormalities are at the ends of the long bones, where the width of the growth plate is increased, and the metaphysis is widened, cupped, and ragged (Figure 10.1.6) but the radiological hallmark of active osteomalacia is the Looser’s zone (Figure 10.1.7). This is a ribbon-like area of defective mineralization, which is seen particularly in the long bones, pelvis, ribs, and the scapulae. Looser’s zones typically occur on the medial border of the femoral shaft or neck, contrasting with the multiple fissure fractures on the lateral convexity of the bone in Paget’s disease. The vertebral bodies are often biconcave (‘codfish spine’). Additionally, in renal glomerular osteodystrophy, the endplates may become relatively denser than the rest of the vertebral body, producing the so-called ‘rugger jersey’ spine.
The radiological appearance of rickets in a child with inherited hypophosphataemia. The growth plates are widened and the metaphyses cupped and ragged.

X-linked hypophosphataemia Looser’s zone, bowing and fissure fractures in the left tibia.

Treatment

Rickets and osteomalacia should respond rapidly to vitamin D (or one of its metabolites). Increased mobility due to increased muscle strength is the first clinical response, despite a temporary increase in bone pain.

Paget’s disease of bone (Box 10.1.6)

Paget’s disease of bone is the most common metabolic bone disease after osteoporosis in the United Kingdom. It is characterized by excessive and disorganized resorption and formation of bone. The introduction of bisphosphonates, which act primarily on the abnormally active osteoclasts characteristic of the condition, has revolutionized the management of Paget’s disease.

Box 10.1.6 Paget’s disease

- Major genetic component
- Affects 750,000 in United Kingdom
- Rapid bone turnover with deposition of disordered bone
- Raised alkaline phosphatase
- Responds well to new aminobisphosphonates
- Premalignant in some cases.

Pathophysiology

There is now overwhelming evidence of a genetic contribution to a significant proportion of patients with Paget’s disease.
Histology shows increased numbers of bone-resorbing multinucleate osteoclasts and active osteoblasts. The bone matrix is laid down in a haphazard fashion and loses its birefringence and strength; mineralization may be defective. Osteosarcoma, which occurs in Paget's disease, probably results from the excessive and prolonged activity of the bone cells. Pagetic bone is typically enlarged, vascular, deformed, and somewhat fragile. Fractures account for about 10% of all clinical presentations.

**Incidence**

Paget's disease affects about 750,000 people in Britain, of whom up to 40% may have an affected relative. It becomes more common with advancing years (approximately 3% of those over 40 years old) but only about 5% of affected individuals are symptomatic. In England there is a slightly increased prevalence in some northern regions and it is also more frequent in recent British migrants to Australia than in the indigenous population.

**Clinical features**

Most subjects with Paget's disease are asymptomatic but bone pain is the most common symptom in the rest. Pain may arise from the bone itself or from the neighbouring joints. In around 10%, pain due to fracture through pagetic bone may be the presenting complaint, while pain from fissure fractures (see Figure 10.1.8) or sarcomatous change are important but later complications. Clinically, the affected bones are enlarged, deformed, and warm. The enlargement is most clearly seen in bones such as the tibia and the skull: in the former the bone is typically bowed forwards; the latter shows a characteristic enlargement of the vault that is said to look like a 'tam-o'-shanter' hat, which appears to descend over the ears. Although any bone can be affected, including the maxilla and the phalanges, the most common sites for Paget's disease are the pelvis and the spine.

![Fig. 10.1.8](image)

Fissure fractures on the convexity of a femur affected by Paget's disease.

Deafness in Paget's disease is one of its most disabling symptoms; it has many causes, of which nerve compression is only one. Almost any nerve can be compressed by enlarging pagetic bone; the spinal cord is particularly at risk, due to the combined effects of increased bone size, vertebral collapse, and excessive vascularity. Paraplegia or cauda equina lesions may occur. Alterations in the shape of the skull may produce multiple cranial nerve palsies and brainstem lesions, with dysphagia, dysarthria, and ataxia.

**Investigations**

**Biochemistry**

There is variable elevation of plasma alkaline phosphatase that roughly correlates with the extent of clinical and radiological involvement with Paget's disease.

**Radiology**

The most characteristic appearance is an increase in size of the affected bones, which also appear sclerotic with abnormal trabecular architecture. Early in the disease a resorbing front may be seen in a long bone as a flame-shaped area (Figure 10.1.9). Excessive resorption is inevitably followed by disordered bone formation, causing thickening and deformity of the bone. Multiple partial fractures (microfractures, fissure fractures) are common on the deformed convex surface of long bones, particularly the femur and tibia (see Figure 10.1.8), contrasting with the Looser's zones of osteomalacia that predominantly affect the concavities.
Bone scintigraphy may be particularly informative in Paget's disease, demonstrating not only the extent and activity of the bone lesions but also the effects of treatment. MRI is particularly helpful in the demonstration of suspected fractures and in identifying sarcomatous change.

**Diagnosis**

In prostate carcinoma with osteoblastic bone secondaries, the dense bones are not enlarged (in contrast to Paget's disease), and the prostate-specific antigen levels will be elevated in prostate disease but normal in Paget's disease.

**Treatment**

The newer aminobisphosphonates are particularly effective and many times more potent than the early bisphosphonates, such as etidronate. They may produce almost complete and permanent suppression of Paget’s disease with few side effects. Calcitonin is useful to treat bone pain, for osteolytic Paget’s disease and for pre-operative treatment.

**Surgical treatment**

Fractures through pagetic bone require the usual surgical treatment but union may be delayed. When fracture occurs through a deformed bone the deformity should be corrected where possible. Elective osteotomy with intramedullary nailing or ilizarov correction may be considered for a severe long-bone deformity. Spinal cord compression not responding to medical treatment requires surgery.

---

**Hypercalcaemia**

Malignancy is one of the most important causes of hypercalcaemia.

Where hypocalcaemia is prolonged, as in renal glomerular failure or coeliac disease, the parathyroid glands respond by increasing both in size and activity. Occasionally hypercalcaemia develops in such patients despite correction of the underlying disease due to one of the hyperplastic parathyroid glands becoming autonomous (‘tertiary hyperparathyroidism’).

**Hypoparathyroidism**

Parathyroid insufficiency most commonly occurs after surgical removal of the parathyroids but also in idiopathic hypoparathyroidism.

**Osteogenesis imperfecta: the brittle bone syndrome**

Osteogenesis imperfecta (OI) affects about 1 in 20,000 births and is a leading cause of lethal short-limbed dwarfism.

**Pathophysiology**

OI is a genetic disorder of type 1 collagen and affects those tissues which contain it. These include particularly bone and dentine but also the sclerae, joints, tendons, heart valves, and skin.

In the so-called ‘mild’ type I OI there is a reduction in the amount of bone (and hence in measured bone mineral density). In the extraskeletal tissues, the sclerae are thin (often blue or grey in colour), there is a varying degree of ligamentous laxity, hyper extensibility of the skin (sometimes with atrophic scars), and, uncommonly, incompetence of the heart valves.
Clinical features

Type I OI (60% of all patients) is the most frequent and least serious form. Fractures do not typically occur in the perinatal period and may even be delayed until the early menopause.

Type II OI is nearly always lethal, but not all infants with fractures at birth succumb immediately. A few survive the perinatal period to later merging with the type III (severe, progressively deforming) form.

Patients with type III OI are likely to survive but present major management problems because their disability is severe and progressive. Although intramedullary rods may be tried in some cases such patients rarely walk, even after multiple operations, and have a very short stature (>4 standard deviations below the mean) (Figure 10.1.10).

Diagnosis

In the first few years of life non-accidental injury is the main differential diagnosis. Although this may be suggested by multiple fractures at different sites and of different ages there are no pathognomonic signs. Some fractures, such as metaphyseal ‘corner’ fractures and posterior rib fractures are more often seen in non-accidental injury, but any type of fracture can also occur in OI. The distinction between OI and non-accidental injury is legally important and can be difficult. In adult life, mild OI may go unrecognized.

Marfan syndrome

In Marfan syndrome the fundamental genetic defect lies in fibrillin, one of the key microfibrillar components of elastic tissues.

Clinical features

Marfan syndrome is dominantly inherited. Its main effects are on the skeleton, cardiovascular, and ocular systems. In the typical patient with Marfan syndrome, overall height is increased and the limbs are long relative to the trunk. Long, thin fingers (arachnodactyly) are common. Scoliosis is common, may be severe, and worsens with the preadolescent growth spurt. Anterior chest wall deformity (pectus carinatum/pectus excavatum) is often associated with scoliosis (Figure 10.1.11).
Dislocation of the lens is the main ocular feature of Marfan syndrome, but the most severe complication is dilatation of the ascending aorta leading to aortic incompetence and/or dissection.

**Treatment**

There is no specific treatment yet for the underlying defect but many of the clinical manifestations require attention. Scoliosis may be progressive and severe. Bracing is largely ineffective and operative stabilization, ideally in adolescence, may be necessary. Epiphysiodesis may be considered in either sex where predicted height is in excess of that deemed to be socially acceptable.

**Ehlers–Danlos syndrome**

This heterogeneous syndrome includes individuals with the common clinical features of abnormal velvety hyperelastic skin, easy bruising, hyperextensible joints, and lax ligaments.

**Alkaptonuria**

The most important effects of this disease are on the spine (Figure 10.1.12) and later on the larger joints. The intervertebral discs lose height and later calcify. The spine becomes rigid and short and the lumbar lordosis is lost. In the large joints, such as the knees, shoulders, and hips, there are effusions and loose bodies. Ochronotic ‘arthritis’ is described with episodes of acute inflammation, reflecting the underlying pyrophosphate arthropathy. No effective medical treatment for the condition exists.

**Hypophosphatasia**

This rare disorder has similarities with rickets and osteomalacia. It is due to alkaline phosphatase deficiency which leads to defective mineralization of bone and varying degrees of fracture risk.

**Clinical features**

In the adult form, progressive stiffness, pain in the bones, and apparent ‘stress’ fractures can occur (Figure 10.1.13). Approximately 50% of such patients have a childhood history of bone disease or premature loss of deciduous teeth. Recurrent poorly healing metatarsal fractures occur. Partial fractures of the long bones characteristically occur on the convex outer surface (in contrast to Looser’s zones in osteomalacia). Calcium pyrophosphate chondrocalcinosis is also common and may be associated with arthropathy (pseudogout).
Mucopolysaccharidoses

Failure of the normal lysosomal breakdown of complex carbohydrates or glycosaminoglycans leads to their accumulation in the tissues. Hurler’s syndrome, the Hunter’s syndrome, and Morquio’s syndrome are such examples.

Hurler’s syndrome

This is the most severe type of mucopolysaccharidosis and causes death at an early age.

The physical features include proportionate short stature, a typical facial appearance, a short neck with a lumbar gibbus and chest deformity, and a protuberant abdomen. Similar but less severe features are seen in the Hunter’s syndrome.

Morquio’s syndrome

In this disorder the orthopaedic manifestations are striking, but intelligence is normal. Characteristically the neck is short, the sternum is protuberant, and there may be a flexed stance with knock-knees. Importantly, the odontoid may be hypoplastic, leading to atlantoaxial instability, compression of the long spinal tracts, and paraplegia.

Gaucher’s disease

This is a rare lysosomal storage disorder in which glucocerebroside-containing macrophages accumulate in the bone marrow, spleen, liver, and other organs. The skeletal manifestations are often severe and disabling. They vary from a characteristic but clinically insignificant failure of remodelling in the lower femora (Erlenmeyer-flask appearance) to diffuse and localized bone loss and osteosclerotic and osteonecrotic lesions, which cause pain and pathological fracture, often requiring precocious joint replacement surgery.

Skeletal dysplasias

Many of them are due to mutations in collagens

Most patients with skeletal dysplasias have restricted growth, and most are short-limbed. Achondroplasia is the most typical. Radiographs are essential to determine whether the metaphyses of the long bones or the epiphyses are primarily affected.

In achondroplasia, there are abnormalities in the epiphyseal growth cartilage. Radiological features include metaphyseal irregularity and flaring in the long bones, irregular and late-appearing epiphyses, a narrow pelvis in its anteroposterior diameter, with short iliac wings and deep sacroiliac notches. The spine shows progressive caudal narrowing of the interpedicular distance which is commonly associated with significant spinal stenosis. Spinal surgery for decompression of stenosis is commonly required and may be required at several levels. Eventual height can vary from about 80–150cm. Significant increase in height can be achieved by limb lengthening procedures.

Spondyloepiphyseal dysplasias

This heterogeneous group of disorders exhibits prominent spinal involvement and the short stature is partly due to shortness of the trunk. Hypermobility is marked and early osteoarthritis is quite typical, particularly in the hips. Joint replacement is often required in early adult life (Figure 10.1.14).
Proportionate dwarfism

The height of patients with epiphyseal dysplasias is variable but may be only slightly reduced.

Hereditary multiple exostoses

In patients with multiple hereditary exostoses (often referred to as diaphyseal aclasis) there is a juxtaepiphyseal disorder of bone growth, limited to bones developed in cartilage, which gives rise to cartilage-capped exostoses that point away from the joint. Stature is commonly normal. There may be mechanical interference with the normal functioning of affected joints. After skeletal maturity is reached there is a significant risk of malignant change in these exostoses that has been estimated at around 1% (lifetime risk). Any increase in size should raise the suspicion of malignant change which can be most effectively screened using ultrasonography to measure the thickness of the cartilage cap on the exostosis.

Cleidocranial dysplasia

In this rare condition the clavicles are hypoplastic or absent, the fontanelles remain open, there are supernumerary teeth and wormian bones may be apparent on skull radiographs.

Osteopetrosis

Patients with osteopetrosis (Albers–Schönberg disease) have increased bone density but pathological fractures are an important consequence of the abnormal architecture of the bone due to defective osteoclast function.

The mild forms vary widely in severity. The bones are relatively fragile despite being dense since they lack the normal capacity for remodelling along lines of maximum stress (Figure 10.1.15).
Fibrous dysplasia

Fibrous dysplasia of bone is a condition in which areas of immature fibrous tissue are found within the skeleton.

Monostotic fibrous dysplasia

This disorder is relatively common in orthopaedic practice. The lesions may occur in any bone and the most frequent presenting symptom at any age is a fracture, often of the upper end of the femur (Figure 10.1.16). There is a smooth-walled translucent area within the bone, often with thinning of the cortex and sometimes with associated deformity. The differential diagnosis is from other causes of bone cysts, including Paget’s disease and hyperparathyroidism with osteitis fibrosa cystica. The large size of some of the defects in the shafts of the long bones may make conventional stabilization of fractures very difficult.

Polyostotic fibrous dysplasia

The bone lesions tend to increase in size and number but less rapidly after growth had ceased. The skeletal lesions may cause complications such as spinal cord compression, and may be associated with hypophosphataemic osteomalacia. Radiologically, the bones are deformed, the cortex may be difficult to detect, and the medullary bone takes on a ‘ground glass’ or ‘smoky’ appearance.

Ectopic mineralization

Deposition of calcium in the soft tissues (ectopic calcification) and on ectopic bone matrix (ossification) is often pathological, but the cause is frequently unknown.

Calcification can result from previous damage to soft tissues (dystrophic calcification) or from an increase in the circulating concentration of calcium or phosphate; (such metastatic calcification occurs in advanced renal osteodystrophy). Chondrocalcinosis is a particular example of ectopic mineralization which is common in the elderly but may also be pathological at a younger age. Dystrophic calcification occurs after infection, tumour, and trauma. In scleroderma, subcutaneous calcification in the fingers may be part of the CREST syndrome (calcinosis, Raynaud’s phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia). The calcification can be very extensive but can also disappear rapidly. There is no specific treatment.

Calcific tendonitis

This is a particularly common form of soft tissue calcification to which many factors contribute. It may follow trauma but there is often no obvious injury. Calcific tendonitis is associated with flares prompted by crystal shedding.

Chondrocalcinosis

In chondrocalcinosis, crystals of calcium pyrophosphate dihydrate (CPPD) are deposited in the fibrocartilage of the knees, the triangular cartilage of the wrists, the symphysis pubis, and elsewhere. CPPD may also form as linear deposits in the hyaline cartilage. It is most commonly age-related but may also reflect an underlying metabolic disturbance, such as haemochromatosis, hypophosphatasia, or hyperparathyroidism. One florid form of familial chondrocalcinosis causes early-onset polyarticular arthritis. It is useful to include examination of synovial fluid under polarized light microscopy in cases of acute monoarthritis to avoid missing pyrophosphate arthritis. However, the weakly positively birefringent crystals are smaller and less durable than the urate crystals causing gout. Intra-articular steroids help to settle acute episodes but there is no specific cure for the condition.
Ectopic ossification

Acquired ectopic ossification may occur at the site of local injury, such as after hip replacement or as a systemic response following paraplegia. It may occur in tumours and in a variety of other disorders, most notably infections, such as tuberculosis (Table 10.1.2).

Post-traumatic ossification

Local ossification can occur after total hip replacement but the incidence varies widely. It occurs more often in men than in women and is more likely to recur in certain individuals following surgery to the contralateral hip if ossification followed surgery to the first hip. The risk of such ossification may be significantly increased in patients with diffuse idiopathic skeletal hyperostosis (DISH, Forestier’s disease). The bone mainly forms in the hip abductors. There is little evidence to justify routine use of prophylaxis for heterotopic ossification in hip surgery. However, in high-risk patients a single dose of radiotherapy perioperatively is more effective than anti-inflammatory agents.

Ossification after neurological injury

Extensive myositis ossificans may occur after injuries to the head or spinal cord in muscles distant from the injury after a significant delay. Affected muscles become swollen, red, and warm, and the differential diagnosis may include cellulitis, arthritis, and thrombophlebitis. Radiological calcification is initially absent (appearing at about 6 weeks or more after the injury), but an isotope bone scan or MRI will show changes well before that. Eventually organized bone appears. Because the bone affects the major periarticular muscles, it leads to joint fixation, particularly of the hips. Surgical removal of ectopic bone is technically difficult and usually ineffective. The ectopic bone recurs, especially if it is removed too early. The prevention of further ectopic bone formation after its removal may be delayed by non-steroidal anti-inflammatory drugs or radiotherapy, which should be commenced as soon as possible. Bisphosphonates are ineffective in the long term.

Myositis ossificans can also occur in neurological diseases, such as poliomyelitis and meningitis, and also after prolonged coma. It is not known why ectopic ossification occurs after head injury but interestingly head injury is associated with an increased rate of fracture healing and excessive callus formation. Ossification of the posterior longitudinal ligament of the spine (OPLL) is particularly described in Japan where it is a leading cause of myelopathy.

Fibrodysplasia ossificans progressiva

Fibrodysplasia ossificans progressiva (FOP) is rare, with an incidence of 1–2 per million. It is caused by activating mutations in ACVR1, a receptor for bone morphogenetic protein. Diagnosis depends on the combination of developmental abnormalities of the skeleton and progressive widespread myositis, leading to ossification in the major skeletal muscles.

Initially there is oedema and cellular infiltration throughout the muscle, with myofibrillar breakdown. Later endochondral ossification leads to mature bone, within which is haemopoietic marrow. The upper paraspinal trunk is typically first affected, and the peripheral skeleton and associated soft tissues are often spared. Typically, the affected muscle and/or associated fascia becomes swollen and hard, sometimes following injury; after a week or two these features subside, but the apparent improvement may be followed by ossification within the muscle and progressive joint fixation. Myositis usually begins in the upper paraspinal muscles in early childhood. By late childhood or adolescence, ossification will have usually occurred widely in the trunk but also within the muscles around the shoulders, hips, and less commonly knees, to fix these joints and to complete the disability (Figure 10.1.17). The large, striated muscles are affected; ossification does not involve the small muscles of the hands and feet, the diaphragm, the cardiac or the smooth muscles. Ossification in the muscles around the jaw may fix it almost completely.
Fibrodysplasia ossificans progressiva with widespread ossification of the muscles around the chest. The diaphragm is unaffected.

The diagnostic skeletal abnormalities affect the big toes (Figure 10.1.18), to a lesser extent the thumbs and the cervical spine (Figure 10.1.19).

Management

There is no effective treatment to prevent or reverse the abnormal ossification. Surgical removal of ectopic bone is technically difficult and may ultimately worsen the disability.

Miscellaneous bone disorders

Vitamin C (ascorbic acid) deficiency (scurvy) is reflected in weakness of collagen-containing tissues, notably causing haemorrhage and fractures. Extensive subperiosteal haemorrhage leads to pain and immobility; the legs are held in a ‘frog-like’ position. Radiographs in infancy show a widened zone of provisional calcification in the metaphyses and failure of new bone formation.

Prolonged parenteral nutrition can produce a form of bone disease similar to osteomalacia. The main symptom is periarticular bone pain, particularly in the ankles. The radiographic appearances suggest osteoporosis.

Deposition of excess fluoride in the skeleton can result from an excess in the diet (endemic fluorosis), from industrial exposure (during the manufacture of aluminium, steel, and glass, and from exposure to the dust of fluoride-containing rock), and from the administration of sodium fluoride in treatment. There is a generalized increase in bone density (with loss of the normal corticomedullary junction), and the tendons, ligaments, and sometimes muscles may be mineralized. Compression of the spinal cord and its roots, with progressive neurological disability has been described.

The prolonged use of vitamin A (retinoids) for the treatment of skin disease, such as psoriasis and ichthyosis, leads particularly to calcification of the spinal ligaments, causing stiffness and reduced mobility. There is a resemblance to Forestier’s disease (diffuse idiopathic skeletal hyperostosis).

Chronic vitamin D overdosage leads to soft tissue calcification, especially in the arteries and kidneys. After several years, progressive stiffness in the spine, major joints, and feet lead to difficulty in walking. Radiographs show ligamentous calcification.

Further poisoning in the growing skeleton produces a radiologically dense line near the growth plate.

Rheumatoid arthritis

**Summary points**

- Rheumatoid arthritis (RA) is one of the most common disabling chronic diseases of the Western world.
- New biologic treatments have provided great benefit in the management of this condition, reducing morbidity and mortality.
- RA diagnosis requires careful clinical, biochemical, and radiological assessment
- Rheumatoid factor is not a reliable diagnostic test for rheumatoid arthritis (RA)
- The core of its management requires careful input from all members of the multidisciplinary team.

**Introduction**

RA is a chronic systemic inflammatory disorder predominately affecting synovial joints. It affects approximately 1% of the population in most developed countries. There is a female predominance but this is age dependent; at 30 years of age women are ten times more likely to develop RA than men but this diminishes to equality aged 60. There is a peak incidence between the ages of 35–55 years, although it can start at virtually any time of life. There is some evidence that RA is a relatively new disease in the West because historical writings and artistic depictions are uncommon until about 200 years ago in Europe. There is also some evidence that the incidence of RA may have diminished slightly in Europe in the past 20 years, which some authorities have attributed to protective effects of oral contraceptives. RA not only results in highly significant joint-related morbidity but also has a major effect on mortality; standardized mortality rates are increased two to threefold (mainly due to excess cardiovascular disease and infections). Its effects are not limited to the joints; extra-articular manifestations are common and systemic features, such as weight loss, malaise, and fever are prominent. There is no specific test for RA and its diagnosis depends on a combination of clinical, serological, and radiological findings.

**Underlying causes**

The cause of RA is unknown, but it is certainly associated with immunological abnormalities that place it in the realm of the ‘autoimmune disorders’. Indeed it shares certain genetic susceptibility factors (human leukocyte antigen (HLA) genes, CTLA4 and PTPN22) with other autoimmune diseases, such as systemic lupus erythematosus, autoimmune thyroiditis, and type 1 diabetes mellitus. These conditions also often cluster together in individuals affected by RA and their families, suggesting that there is an underlying autoimmune diathesis linking these diseases. The presence of autoantibodies to immunoglobulin (Ig) (rheumatoid factors) and cyclic citrullinated peptides (anti-CCP antibodies) is suggestive of disordered immune function. Likewise the chronic inflammatory infiltrate in the synovium and many other tissues; monocytes, macrophages, and T and B lymphocytes are all found in large numbers in the hypertrophied synovial pannus. The limited range of HLA-DRB1 specificities associated with RA hints at a specific antigenic trigger for the disease but to date there is no convincing data as to its identity. Animal models, such as collagen-induced arthritis, have given some important insights into the underlying immunopathology despite their limitations. Basic research on the abnormal cytokine milieu in such animal studies was of fundamental importance to the introduction of anti-tumour necrosis factor (TNF) therapies for RA by Feldman and Maini that so revolutionized its management during the 1990s.

In contrast to the insights that have come from immunology, the contribution from epidemiology towards understanding the aetiology of RA has been relatively disappointing. Despite the widely held belief that infections may be involved in triggering RA, evidence for this is lacking. There is some evidence, particularly comparing indigenous South African populations in rural and urban communities, that increasing urbanization is associated with an increase in RA. Certainly the disease is uncommon in much of rural sub-Saharan Africa. The risk of RA is increased by smoking and furthermore cessation from smoking is associated with improvements in disease activity.

**Genetics**

Identical co-twins of individuals with RA are three to four times more likely to be concordant for the disease than non-identical twins although overall concordance is still relatively low at around 15%. Non-twin siblings have a sixfold increased risk of RA compared to the general population and it has been estimated that heritability of RA is around 55%. Genetic susceptibility is complex and polygenic but major advances are now being made towards identifying the full component of genes involved by using genome-wide association scans. These are capable of identifying genes increasing the risk of RA by as little as 10–15%; good evidence exists for the HLA-DRB1 locus, PTPN22, CTLA4, STAT4, IL-2R, and at least one gene on chromosome 6q.

**Human leukocyte antigens**

The human leukocyte antigen HLA-DR4, encoded by the immune response gene HLA-DRB1*04, is strongly associated with RA in the majority of populations that have been studied. In the United Kingdom, about 70% of patients with RA are HLA-DR4 positive compared with 35% of the normal population (odds ratio 4–5). In addition to HLA-DR4, other HLA molecules that share a high degree of structural homology with it, including HLA-DR1 and DR10 are also associated with RA. These molecules play a central role in the presentation of extrinsic antigens to the immune system and are implicated in numerous autoimmune diseases, suggesting involvement of specific components of the adaptive immune system in the aetiology of RA and related disorders.
However, convincing evidence for this has yet to be presented in RA. The observation that individuals with RA, who do not carry HLA-DR4, are more likely to have mothers that possess HLA-DR4 as the non-inherited *HLA-DRB1* allele adds yet another intriguing layer of complexity to this ongoing immunogenetic mystery.

### Pathophysiology

The most striking pathological finding is hypertrophy of the soft tissues around the synovial joints with evidence of chronic mononuclear cell infiltration. Histology of the synovium shows thickening of the synovial lining. The lining layer contains both fibroblast- and macrophage-like cells with evidence of *in situ* proliferation and migration into the lining layer. There is also a defect in apoptosis in the synovium that further increases the numbers of these cells. Many of the macrophages have a transformed appearance, neovascularization is prominent, and the synovial pannus is invasive with articular destruction beginning at the pannus/cartilage junction. Thelper cells (CD4+) are prominent, particularly in the perivenular space of the synovium. Cytotoxic (CD8+) T cells are present in smaller numbers but B cells and plasma cells locally synthesizing rheumatoid factors are also prominent. Within the joint macrophage-derived cytokines, such as TNF and interleukin (IL)-1 are found in high concentrations and appear to play a central role in mediating the chronic inflammation. There is currently much interest in the nature of the T-cell subsets involved in RA synovitis; in particular, the T<sub>r</sub>17 subset of helper T cells that are thought to play a dominant role in establishing tissue non-specific inflammation. Insights into the pathology of RA have also come from the successful therapeutic targeting of disparate molecules on various cell types, including CD20 (B cells), TNF (macrophages), soluble IL-6 receptor, CD28 (T cells), and IL-1. RA is clearly the end result of several complex pathological pathways; while amelioration of the disease is possible by targeting specific components of these systems, the primary triggers for the aberrant immune mediated inflammation remain to be identified.

### Clinical features

RA typically presents as a symmetric peripheral polyarthritis (Figure 10.2.1) although virtually any synovial joint in the body may be affected. The onset of the disease is usually insidious, with gradual recruitment of an increasing number of joints. Pain and stiffness, typically affecting the small peripheral joints, gradually increases in severity and spreads more centrally to involve the elbows, wrists, shoulders, ankles, knees, and hips. Systemic features such as malaise, weight loss, and low-grade fever are common and soft tissue problems such as carpal tunnel syndrome and flexor tenosynovitis may be prominent (Box 10.2.1).

![Symmetrical synovitis affecting the proximal interphalangeal joints in early rheumatoid arthritis.](Fig. 10.2.1)

**Box 10.2.1 American College of Rheumatology 1987 criteria for rheumatoid arthritis**

- Morning stiffness (>1h; >6 weeks)
- Arthritis in at least three areas (>6 weeks)
- Arthritis of hands or wrists (>6 weeks)
- Symmetrical arthritis (>6 weeks)
- Rheumatoid nodules
- Positive rheumatoid factor
- Radiographic changes in wrists/hands.

*aFour criteria are required for the diagnosis.*

Soft tissue swelling with tenderness, restricted movement, synovial effusion, redness, and warmth of the joints occurs with pronounced diurnal variation of symptoms, worse in the early morning and returning towards evening. The prolonged morning stiffness (>30min in duration) contrasts with the minor stiffness of osteoarthritis (rarely >5min in duration). The condition must be distinguished from other inflammatory arthropathies, such as systemic lupus erythematosus, seronegative spondyloarthropathies.
(see Chapter 10.4), crystal arthropathies (see Chapter 10.3), and viral arthropathies (rubella, parvovirus, hepatitis B and C). Several distinct patterns of onset are recognized: insidious onset with gradual recruitment of an increasing number of joints over weeks or months is common (approximately 60%); palindromic rheumatism with short-lived episodes (<48h) of completely resolving synovitis (5%); episodic disease may relapse and remit in an unpredictable fashion but is quite uncommon; systemic onset disease particularly in middle-aged males may mimic malignancy or deep-seated infection; explosive onset disease (approximately 5%) is typically polyarticular but may resolve spontaneously after a variable time.

Physical signs

Synovial joint involvement usually predominates, typically in the periphery; soft tissue swelling, tenderness, stiffness, erythema, increased joint temperature; tenosynovitis, particularly in the flexor tendons of the fingers and the long flexors around the medial malleolus; carpal tunnel syndrome.

Synovial effusions may be present and a symmetric small-joint arthritis of the hands and feet with fusiform swelling of the fingers is common because of the prominent involvement of the proximal interphalangeal joints with sparing of the distal interphalangeal joints.

Swan-neck and boutonnière deformities of the fingers commonly develop and ulnar deviation together with volar and ulnar subluxation of the fingers at the metacarpophalangeal joints frequently occur (Figure 10.2.2). Deformities of the foot commonly lead to problems but are under-recognized; these include dorsal subluxation of the toes, spreading of the forefoot due to metatarsophalangeal joint synovitis, and collapse of the transverse arch of the forefoot (Figure 10.2.3).

Extra-articular features (Box 10.2.2)

These affect many patients with RA at some stage during the course of their disease but may be relatively mild and bear little temporal relationship to the joint activity. Many organs can be involved, and systemic disease contributes markedly to the adverse prognosis of RA. Men are particularly susceptible to rheumatoid vasculitis (lifetime incidence 1:9) which can be life threatening if it involves major organs. Cardiovascular disease is a major comorbidity in RA with chronic inflammation thought to be responsible for much of this. About half of the excess risk only can be attributed to traditional risk factors, such as hypertension, smoking, dyslipidaemia, etc. but these should be controlled aggressively along similar lines to the management of such risk factors in diabetes mellitus.)
♦ Haematology: normochromic normocytic anemia

♦ Respiratory:
  • Mild pulmonary fibrosis
  • Pneumonitis
  • Pulmonary nodulosis
  • Bronchiectasis

♦ Cardiovascular:
  • Pericardial effusion
  • Vasculitis

♦ Neurology:
  • Sensory peripheral neuropathy
  • Cervical myelopathy due to atlanto-axial or subaxial instability (Figure 10.2.4).
  • Entrapment neuropathies (carpal tunnel syndrome, ulnar neuropathy, tarsal tunnel syndrome)

♦ Bone: osteoporosis

♦ Eyes:
  • Superficial episcleritis
  • Scleritis
  • Sicca syndrome

♦ Felty’s syndrome: neutropenia, splenomegaly, and lymphadenopathy

♦ Other: rheumatoid nodules, vasculitic ulcers

---

**Investigation**

The diagnosis of RA is mainly clinical (see Box 10.2.1). Pronounced elevation of inflammatory markers is usual but not invariably let count is found in active disease. Anaemia may indicate anti-inflammatory drug-induced gastrointestinal blood loss, which may also induce thrombocythaemia. Rheumatoid factor is found in around 80 per cent of patients but may be absent at the outset. There is increasing use of antibodies to cyclic citrullinated peptides (anti-CCP antibodies) in diagnosis since these are far more specific for RA than rheumatoid factor. Like rheumatoid factor they occur in around 80 per cent of patients and frequently predate the onset of symptoms. Most patients with RA develop erosions; these may be evident at presentation (Figure 10.2.5). And those patients destined to develop erosions will do so within the first 2 years of disease.
Rheumatoid factor

Rheumatoid factor is an antibody directed against the Fc portion of an IgG molecule (antigen). The antibody can be of various isotypes, IgM, IgG, IgA, IgE. Rheumatoid factor is present in about 75% of patients at initial diagnosis of RA, but can also be found in 10% of the normal population, those with chronic infections, and in patients with chronic inflammatory conditions—Sjögren’s syndrome, systemic lupus erythematosus, hepatitis C.

Management

Curative treatment is not currently available and halting the progression of disease and maintaining function is therefore the cornerstone of medical management. The management of patients with persistent RA is best coordinated through a multidisciplinary team including medical, nursing, occupational therapy, physiotherapy, and surgical specialists amongst others.

Drugs

At present no medication can be guaranteed to settle the inflammation and pain of RA. Drugs have traditionally been divided into those that afford rapid onset symptom relief (first-line drugs; non-steroidal anti-inflammatory drugs (NSAIDs)) and those which act more slowly to suppress inflammation (second-line; methotrexate). Anti TNF biologic agents are now routinely used with good effect in those who fail to have an adequate response with second-line drugs.

Simple analgesics and NSAIDs

If symptom control is adequate these drugs should be used as first-line agents because of the low incidence of side effects. NSAIDs are effective in reducing inflammation, pain, and morning stiffness.

Second-line antirheumatic drugs

These include low-dose weekly methotrexate, sulfasalazine, and antimalarial drugs. Typically they reduce pain and inflammation over the course of several weeks or months and suppress erosive disease. The use of corticosteroids causes a rapid reduction in symptoms which can be very helpful while the second-line drugs begin to exert their influence.

Biological therapies

These include drugs such as anti-TNFα biologic agents, anti-CD20 monoclonal antibodies, (e.g. rituximab), and abatacept, a CTLA4/Ig fusion protein that interferes with T-cell signaling.

Physical treatments

The maintenance of muscle strength and joint mobility is crucial since both may be rapidly lost in the phase of active synovitis. Advice from experienced physiotherapists and occupational therapists on a range of physical activities, footwear, and joint protection is essential, and simple orthoses may have a major impact on the patient’s symptoms.

Surgery

Soft tissue surgery

It is unusual for nodules to require excision but this may be required if there is troublesome ulceration or pain over pressure points. Large skin ulcers may require plastic surgery to obtain adequate skin cover once underlying vasculitis has been controlled medically. Surgery for entrapment syndromes, flexor tenosynovitis, or rupture of the extensor tendon at the wrist are common indications.
Synovectomy

Considerable debate has arisen to the value of this procedure. Synovectomy of the knee is sometimes undertaken using radioactive yttrium.

Total joint replacement

Replacement of the hip and knee for end-stage RA is highly effective but operator dependent. Shoulder and elbow replacement is now commonly undertaken for pain relief and gives good results in carefully selected patients. At the shoulder it is probably appropriate to use hemiarthroplasty in those patients who have evidence of rotator cuff disruption. Pure ankle mortise joint disease is quite uncommon but may be an appropriate indication for joint replacement in carefully selected individuals. More commonly it occurs with widespread involvement of the hindfoot in which case arthrodesis may be more appropriate.

As a general principle, lower-limb problems should be tackled before those in the upper limb because of the requirement for walking aids which may place excessive demands on the replacement joints in the upper limbs. In the hand, more proximal joints should be dealt with first, thus stabilization of the wrist by arthrodesis should precede stabilization of the carpometacarpal and metacarpophalangeal joints of the thumb. Arthrodesis of the small joints of the fingers in a position of good function is often more effective than joint replacement. Silastic joint replacement of the metacarpophalangeal and posterior interphalangeal joints may be appropriate in certain circumstances but rarely maintains the range of movement and is best reserved for those who have significant pain at rest.

Neck

Patients with widespread erosive joint pathology may also exhibit neck pathology. This is important to recognize in the pre- and perioperative phase. Patients should be handled with care during anaesthesia. Patients with overt signs of cervical myelopathy with significant atlantoaxial or subaxial subluxation should be considered for spinal fusion with or without decompression as appropriate.

Crystal arthropathies

DOI: 10.1093/med/9780199550647.003.010003

Summary points

- Always exclude infection in acute hot joint
- Raised serum uric acid does not necessarily confirm a diagnosis of gout
- Aspiration and microscopy is essential for accurate diagnosis of crystal arthropathies
- Non-steroidal anti-inflammatory drugs and intra-articular steroids are the treatments of choice
- Wait 2 weeks for acute gout to settle before starting hypouricaemic therapy
- Aim for target urate of <300µmol/L.

Introduction

A number of crystals are associated with acute and chronic arthritis as well as periarticular syndromes and other soft tissue syndromes (Table 10.3.1). The most important of these are:

- Monosodium urate associated with gout
- Calcium pyrophosphate dihydrate associated with pyrophosphate arthropathies
- Calcium hydroxyapatite associated with calcific tendinitis.

**Gout**

Gout is one of the oldest known forms of arthritis but the link with hyperuricaemia was only established in the nineteenth century. The fact that gout occurs exclusively in humans can be traced back to defunctioning mutations in the uricase gene. In other animals the accumulation of uric acid, a natural breakdown product of purine metabolism, is prevented by the action of this enzyme. The acute episodes of joint inflammation that characterize gout are said to be the most excruciating form of arthritis known. Acute gout is triggered by activation of the innate immune system through mechanisms that include the NALP3 inflammasome, activation of interleukin (IL)-1 and toll-like receptors. High levels of IL-1 provoke fever and neutrophilia; activated macrophages produce large amounts of tumour necrosis factor (TNF), and there is massive infiltration of the synovial compartment by neutrophils. As the attack continues and ultimately resolves there is a change in the cytokines produced by the macrophage population to a more anti-inflammatory profile with transforming growth factor (TGF)β and IL-10 supplanting TNF. The clinical features of gout are highly variable and include:

- Acute inflammatory arthritis (synovitis, bursitis), including the classic ‘podagra’ of the great toe
- Tophi with deposits of amorphous monosodium urate in the soft tissues
- Gouty nephropathy
- Uric acid stones.

**Epidemiology**

Gout is the most common inflammatory arthritis in adult men. Genetic, hormonal, and environmental factors are involved and the prevalence rises with increasing age and serum urate levels. The annual incidence of gout is approximately 0.3 per 1000, and its prevalence in males in the United Kingdom is 3–6 per 1000 adults. The male/female ratio is 8:1 and gout is rare in prepubertal boys and premenopausal women.
In addition to male gender, other risk factors include obesity, alcohol consumption, hypertension, renal failure, diuretics, social class, high protein intake, and a family history of gout. All these risk factors act through increasing serum urate concentrations. Hyperuricaemia is arbitrarily defined as a serum uric acid level two standard deviations above the mean (above 420µmol/L in adult males and 360µmol/L in adult females). Serum urate levels in boys rise at puberty while in women the pubertal rise is smaller and the level only approaches male values after the menopause. There are variations in serum urate levels between ethnic groups.

Several inherited enzyme defects can lead to the overproduction of uric acid. These are inherited as distinct Mendelian traits: X-linked (hypoxanthine-guanine phosphoribosyltransferase deficiency and phosphoribosylpyrophosphate synthetase overactivity), autosomal recessive (glucose-6-phosphatase deficiency), and autosomal dominant (familial urate nephropathy) patterns are recognized. Gout occurring before puberty, in premenopausal females, or where there is strong family history should prompt suspicion of an underlying enzyme defect.

Hyperuricaemia

Only 10–30% of hyperuricaemic subjects develop gout. Uric acid is derived from the purines of nucleoproteins through the intermediate metabolites xanthine, hypoxanthine, and guanine predominantly in the liver by the action of xanthine oxidase. Purines themselves are derived either from the diet or by de novo synthesis. Two-thirds of uric acid is renally excreted while the rest is degraded in the gut by bacteria. Lack of functional uricase which oxidizes uric acid to the more soluble allantoin is critical to the human predisposition to gout but other influences are also involved, notably diet and renal handling.

Hyperuricaemia results from overproduction or underexcretion of uric acid (Table 10.3.2). The majority of patients (50%) with primary gout are underexcretors of uric acid with an inability to increase uric acid excretion in response to a purine load. Fewer than 10% are overproducers of uric acid. A minority have underlying disorders of cell proliferation, including malignancy.

HGPRT, hypoxanthine-guanine phosphoribosyltransferase; PRPP, phosphoribosylpyrophosphate synthetase
Clinical presentation

The first presentation of gout is usually acute monoarthritis although 10% of initial attacks are polyarticular. The first metatarsophalangeal joint is affected in 50% of initial attacks (podagra) and will be involved in 75% of goutyees at some stage (Figure 10.3.1). Lower-limb joint involvement predominates (toes, ankle, knee, small joints of the hands and feet, wrist, elbow, and acromioclavicular joints in order of diminishing frequency). During the asymptomatic hyperuricaemic phase, up to 20% of patients have a history of renal colic from uric acid stones. Gouty arthritis and tophi have a predilection for cooler sites, such as the lower extremities and ears, because this reduces the solubility of monosodium urate.

Typical attacks have a rapid onset, often overnight, with the joint becoming swollen, hot, red, shiny, and extremely painful within a few hours (Figure 10.3.2). Inflammation is at a peak by 24h and can be associated with fever and malaise. Untreated attacks typically take 1–2 weeks to resolve spontaneously. Acute attacks may be triggered by dietary or alcohol excess, starvation, trauma (including surgery), haemorrhage, physical exercise, and severe systemic illness. Acute episodes may also be precipitated by sudden falls in serum urate after starting allopurinol or uricosuric drugs.

![Fig. 10.3.1](image)

Large gouty tophus in a male treated with thiazide diuretics for hypertension for 15 years.

![Fig. 10.3.2](image)

Acute gout with tophus extruding through the skin.

The course of gout is highly variable; some patients only ever have a single attack while others may rapidly develop polyarticular disease. A gradual evolution through several stages of disease is recognized (acute, episodic, interval, and chronic tophaceous gout). Joint involvement is usually asymmetric and monarticular initially; discrete episodes of inflammation with complete resolution occur in ‘interval gout’ while in the ‘chronic gout’ phase resolution is incomplete and there is always ongoing inflammation at one or more sites, causing progressive cartilage and bone erosion. Tophi may be present at any stage of the disease but are more typical of the late chronic phase. However, some individuals (particularly elderly women treated with thiazide diuretics) may develop massive tophi in the absence of any joint disease. Early diagnosis is important if one is to prevent potentially irreversible destructive arthritis in goutyees destined for the more severe forms of the condition.

Investigations

Synovial fluid

Septic arthritis can present in a very similar fashion to gout and must be formally excluded. Ideally the diagnosis of gout should be established by aspiration of synovial fluid from the affected joint during an acute attack. It is confirmed by demonstrating intracellular ‘needle-shaped’ monosodium urate crystals that are negatively birefringent under compensated polarized light microscopy (Figure 10.3.3). Joint fluid for examination can be stored at 4°C overnight (or sometimes longer) since urate crystals are generally robust to storage. The fluid itself will be turbid from a high neutrophil count and will exhibit a negative 'string sign' characteristic of inflammatory synovitis due to the break down of high molecular weight aggrecan.
Hyperuricaemia (above 420µmol/L in adult males and 360µmol/L in adult females) is confirmed with serum uric acid levels, but raised levels alone do not confirm a diagnosis of gout. During acute attacks uric acid levels are often (approximately 15%) in the normal range, returning to the more typical steady state levels after 6 weeks or so. If the diagnosis of gout is seriously entertained it may be appropriate to obtain a series of measurements of morning (not fasting) serum urates once the acute episode has settled. During acute attacks there is often a neutrophil leucocytosis as high as 20–25 × 10^9/L. The sedimentation rate and C-reactive protein are typically markedly elevated.

Radiographs

Joint radiographs are rarely useful in establishing an early diagnosis of gout since they are usually normal until the disease becomes established. However, after repeated attacks erosions and secondary osteoarthritic changes may develop. Gouty erosions are classically seen as punched-out cortical lesions with sclerotic margins and overhanging hooks of bone, sometimes well away from the joint (Figure 10.3.4). Bone density is preserved. As uric acid crystals are radiolucent, tophi appear as eccentric soft tissue swellings with patchy calcification due to hydroxyapatite. Chondrocalcinosis may also occur.

Treatment

Acute attack

The aim of treatment is to relieve pain and reduce inflammation. High doses of short-acting non-steroidal anti-inflammatory drugs (NSAIDs) given early in the attacks are usually effective but cannot be tolerated by some patients. They are contraindicated in renal failure because they decrease the glomerular filtration rate by one-third, cause fluid retention, and can be nephrotoxic.

Oral colchicine is a useful, rapidly effective alternative where NSAIDs cannot be used. The traditional dose schedules employed (1mg immediately followed by 0.5mg every 2h until symptoms improve) were associated for many with unacceptable side effects, such as abdominal cramps, nausea, and diarrhoea. It is now recognized that lower-dose schedules (500µg 2–4 times daily) are very effective while reducing the incidence of side effects very significantly.

Joint aspiration may relieve pain by reducing intra-articular tension and intra-articular corticosteroid injection is very effective in the acute stage. Oral or systemic corticosteroids may be useful in some patients for short periods, particularly in those with polyarticular problems. They may also be useful in some patients with ulcer disease because they are less gastrotoxic than NSAIDs.
Prevention

Gout is a potentially curable disease but treatment may require an alteration of lifestyle as well as long-term medication. It is sensible to make dietary alterations to achieve gradual weight of possible loss and a reduction in purine intake, to reduce alcohol intake, and if possible to avoid drugs that inhibit renal clearance of urate (e.g. diuretics). Aspirin in standard analgesic doses (600 –2400mg/day) reduces renal urate clearance but doses used in cardiovascular prophylaxis (75–150mg daily) have no significant effect on urate levels. Such measures may be enough to prevent further attacks but more commonly hypouricaemic agents will be required.

Hypouricaemic drugs are effective in lowering plasma urate levels, reducing the frequency of acute attacks, and decreasing the size of tophi. They are indicated in patients with the following:

- Recurrent troublesome attacks of acute arthritis
- Tophi or evidence of chronic gouty arthritis
- Associated renal disease including uric acid stones
- Very high uric acid levels (>550µmol/L), particularly with acute overproduction of uric acid, such as acute tumour lysis syndrome (in these individuals the prevalence of renal stones is 50%).

Allopurinol

Allopurinol lowers uric acid levels by inhibiting xanthine oxidase and hence the final conversion of xanthine and hypoxanthine to uric acid. It should only be started once the acute attack of gout has settled for 2 weeks. Maintenance treatment with low-dose NSAIDs or colchicine (500mcg once or twice daily) should be used for the first 3 months of any hypouricaemic therapy because of increased risk of acute attacks of gout until lowered levels of urate are established. It should be used with care and in lower doses in the elderly, in patients with renal failure and those on azathioprine. Febuxostat is another xanthine oxidase inhibitor recently introduced for gout which may be useful in cases where allopurinol has been poorly tolerated.

Uricosuric drugs

These are useful particularly if allopurinol is not tolerated and in subjects who are under-excretors of urate. They prevent tubular resorption of uric acid, but are ineffective in renal failure (creatinine clearance <50mL/min). They are contraindicated if there is a history of renal stones. Sulfinpyrazone (50mg twice daily to 100mg four times daily) is commonly used. Benz bromarone (50 –200mg daily) can be used in patients with moderate renal impairment when other uricosuric drugs are ineffective.

As with allopurinol, the aim of hypouricaemic drugs is to maintain the serum urate level below 300µmol/L. High fluid intake is recommended in the early weeks of treatment to prevent uric acid deposition within the kidney and the formation of uric acid stones.

Recombinant uricase

Human recombinant uricase is now available but has relatively limited applicability to the general treatment of gout. It is expensive, has a relatively short half-life, and requires weekly parenteral administration. It is occasionally used in the management of difficult cases or in the management of tumour lysis syndrome.

Calcium pyrophosphate arthropathy

The deposition of the calcium pyrophosphate dihydrate (CPPD) in cartilage is often an age-related phenomenon that does not necessarily imply any significant underlying joint problem. It may occur in normal cartilage or in cartilage already damaged by osteoarthritis. CPPD deposition within a joint can result in an acute arthritis.

Incidence

Chondrocalcinosis is uncommon in adults younger than 50 years old but occurs in up to 10% of the population over 65, increasing to 30% of those older than 85 years. Calcium pyrophosphate disease is more common in women and acute pyrophosphate arthropathy (‘pseudogout’) is the commonest cause of monoarthritis in the elderly (Box 10.3.1). An underlying metabolic abnormality is present in fewer than 10% of patients but should be sought in patients with younger onset disease.

Box 10.3.1 Classification of calcium pyrophosphate deposition disease

- Sporadic/idiopathic: associated with aging and joint disease
- Metabolic disease:
  - Hyperparathyroidism
  - Haemochromatosis
  - Gout
  - Hypophosphatasia
  - Hypomagnesaemia
Clinical features

The clinical features can mimic many different forms of arthritis; these include gout or septic arthritis, rheumatoid arthritis, osteoarthritis, Charcot joint, or even ankylosing spondylitis. Attacks of pseudogout often take longer to reach peak intensity than gout but may run a more protracted course. Larger joints, including the knees and wrists, are more frequently affected but virtually any joint may be affected. Chronic forms of pyrophosphate arthropathy have a variable pattern of joint involvement but should be particularly remembered in patients who have an unusual pattern of arthritis (e.g. ankle arthritis in the absence of injury, apparently degenerative arthritis of the metacarpophalangeal joints, or unexplained early onset arthritis).

Investigation

Synovial fluid

Acute pseudogout is diagnosed by microscopic examination of synovial fluid under polarized light. Calcium pyrophosphate crystals are rhomboid shaped and weakly positively birefringent. Both septic arthritis and gout can coexist with pseudogout, so the presence of crystals does not rule out these other conditions and fluid should also be sent for Gram stain and culture to rule out infection. Repeated joint aspiration and synovial fluid examination may be necessary to confirm the diagnosis since these crystals are harder to identify than urate crystals and are also less robust if left standing prior to examination.

Radiographs

Radiographs often show chondrocalcinosis as fine linear calcification parallel to the subchondral bone in articular hyaline cartilage (Figure 10.3.5). In fibrocartilage, ligaments, and joint capsules, calcifications appear as diffuse punctate linear densities. However, no more than 50% of individuals with pyrophosphate arthritis exhibit chondrocalcinosis so its absence does not exclude the diagnosis.

Blood tests

An atypical arthropathy may be the first clue to an underlying metabolic disease. In patients younger than 55 years a metabolic cause should be excluded. As a minimum screen the following tests are recommended: plasma calcium (hyperparathyroidism), ferritin and iron (haemochromatosis), magnesium (hypermagnesaemia) and alkaline phosphatase (hypophosphatasia).
Management

The principles of treatment are similar to gout; aspiration of the affected joint with injection of corticosteroids is the treatment of choice. NSAIDs at full dose, started at the onset of symptoms, are generally effective. Colchicine can also be tried but there is no effective long-term suppressive treatment known. Unfortunately, in cases where the pyrophosphate arthritis is secondary to another metabolic disorder, such as haemochromatosis, correction of the underlying metabolic disturbance (viz venesection to correct iron overload) will not prevent further progression of the arthropathy.

Basic calcium phosphate (hydroxyapatite) crystal deposition

Basic calcium phosphate, hydroxyapatite, is the calcium-containing mineral laid down in bone, dentine, and enamel. Hydroxyapatite and several other calcium-containing minerals may be found in soft tissues, tendon calcifications, and other forms of arthritis. Collectively, these minerals are referred to as basic calcium phosphate which is associated with the following joint disorders: calcific tendinitis, acute calcific periarthritis, and apatite-associated destructive arthropathy (Figure 10.3.6).

Other crystals

Calcium oxalate crystals have a characteristic bipyramidal appearance and occur in effusions from patients with primary oxalosis, a rare recessive disorder, or end-stage renal failure.

**Summary points**

- Spondyloarthropathies are related conditions typically associated with axial skeletal involvement, absence of rheumatoid factor, familial clustering, and a variable positive association with HLA-B27
- Ankylosing spondylitis is the prototype with sacroiliac joint involvement being a prerequisite for diagnosis
- Diagnosis is frequently delayed for several years but the use of magnetic resonance imaging to detect sacroiliitis greatly facilitates the establishment of an early diagnosis
- Psoriatic arthritis, reactive arthritis, and entero-pathic arthritis have prominent peripheral joint involvement with variable degrees of spinal involvement
- Non-steroidal anti-inflammatory drugs and physical therapy are the cornerstones of management but slow-acting disease-modifying antirheumatic drugs only have a role in peripheral arthritis
- Anti-tumour necrosis factor biologic agents have revolutionized the treatment of the spondyloarthropathies.

**Introduction**

The spondyloarthropathies are a cluster of chronic inflammatory rheumatic diseases characterized by association with the genetic marker HLA-B27, and a variable predilection for spinal involvement. They include ankylosing spondylitis (AS), psoriatic arthritis, reactive arthritis (ReA), and arthropathies associated with inflammatory bowel disease. At the pathological level their major distinctive histological feature is extrasynovial inflammation at sites of mechanical stress known as entheses. These include the insertion of the joint capsule, tendon attachments, and chondro-osseous junctions. The cardinal features of the spondyloarthropathies are given in Box 10.4.1.

**Box 10.4.1 Features of spondyloarthropathies**

- Axial skeletal involvement
- Negative rheumatoid factor
- Variable association with HLA-B27
- Familial clustering
- Tendency to acute anterior uveitis.

**Ankylosing spondylitis**

AS is the prototypic spondyloarthropathy. It affects up to 5 per 1000 of the Caucasian population although only a minority of these (perhaps 20%) will develop severe symptoms. It is two to three times more common in men and has a peak onset around the third decade of life. Typical sites of enthesitis include fibrocartilaginous joints, such as the sacroiliac joints (pathognomonic of AS), costochondral junctions, and ligament and tendon attachments to bone (e.g. plantar fascia). The initial inflammatory phase is typically followed by fibrosis, ossification, and ankylosis. Synovitis of joints may also occur. Involvement of tendons by tenosynovitis is relatively common, particularly in the lower extremities. The net effects are persistent pain, stiffness, and cumulative deformity of the spine over the course of many years.

Axial skeletal disease predominates in AS and demonstrable sacroiliitis on imaging is mandatory for its diagnosis. The modified New York criteria for the diagnosis of AS are listed in Table 10.4.1. However, it should be noted that these rely on the presence of radiographic evidence of sacroiliitis, which may take many years to develop. Because of their lack of sensitivity, x-rays are now considered to be much less effective than magnetic resonance imaging (MRI) of the sacroiliac joints in the early diagnosis of AS but formal diagnostic criteria to take account of this are still in development.
Table 10.4.1 New York criteria for ankylosing spondylitis (1966)

1. Pain at dorsolumbar junction or lumbar spine
2. Limitation of motion in anterior flexion, lateral flexion, and extension
3. Chest expansion less than or equal to 2.5cm at fourth intercostal space

Diagnostic requirements

Either
- grade 3 to 4 bilateral sacroiliitis with one or more clinical criteria

Or
- grade 3 to 4 unilateral or grade 2 bilateral sacroiliitis with clinical criterion 2

Or
- grade 3 to 4 unilateral or grade 2 bilateral sacroiliitis with criteria 1 and 3

AS is strongly familial (sibling recurrence risk is approximately 7%), reflecting the influence of several genes on susceptibility. The best known of these is the immune response gene, HLA-B27, found in more than 90% of patients with AS. More recently at least two other genes, IL-23R (interleukin 23 receptor) and ERAP1 (endoplasmic reticulum aminopeptidase 1) have also been implicated. IL-23R is particularly interesting because it is also implicated in psoriasis and inflammatory bowel disease, two disorders that are commonly associated with AS. The ERAP1 association is fascinating not only because of its potential role in the antigen presentation pathway that involves HLA-B27 but also because it may also be involved in the shedding of cytokine receptors (including the tumour necrosis factor (TNF) and interleukin (IL)-1, and IL-6 receptors) that are heavily implicated in inflammation.

Clinical features

Most patients present with AS in early adult life; it is rare for the diagnosis to be made after the age of 40 years. Typical features include pain at the thoracolumbar junction, around the rib cage and alternating buttck pain. The inflammatory, rather than mechanical, nature of the pain is revealed by its response to moderate activity and anti-inflammatory analgesics, the presence of prolonged morning stiffness (>30min) and back pain during the second half of the night often waking the patient from sleep. The pain typically radiates into the buttock as far as the posterior mid-thigh but not below the knee, in contrast to the pain from lumbosacral nerve root entrapment.

Reduced lumbar spine movements in all planes occurs relatively early in the disease in contrast to the neck which typically occurs later. Rib-cage pain and loss of movement resulting from involvement of the costovertebral joints and/or the costochondral junctions may eventually cause a fixed chest with purely diaphragmatic breathing. The combination of loss of lumbar lordosis, progressive thoracic kyphosis, and the development of flexion contractures at the hips causes the classic question mark posture over a period of time (Figure 10.4.1). Osteoporosis may be present from an early stage but may be missed on bone density scans due to the spurious effects of new bone growth (syndesmophyte) around the vertebrae. Reduced bone density not only increases the risk of fractures but also exacerbates the tendency to thoracic kyphosis due to spinal wedging. Ankylosis of the cervical spine is also a major risk factor for cervical fracture in road traffic accidents.

Fig. 10.4.1
Classic ‘question mark’ posture in ankylosing spondylitis with pronounced thoracolumbar kyphosis and flexion deformities of the hips.

The Achilles tendon and plantar fascia are commonly involved, often with pronounced local osteitis demonstrable on MRI. Peripheral joint involvement, particularly of the hips, knees, and shoulders, affects around 20% of patients. A coexistent history of inflammatory bowel disease and/or psoriasis occurs in about 15% of patients.
Around 40% of patients sustain episodes of acute anterior uveitis which may be recurrent and sight-threatening; all patients with AS should be warned of this potential complication and advised to seek prompt specialist ophthalmic treatment with mydriatics and steroid eye-drops if they develop symptoms (typically a unilateral, painful red eye). Diaphragmatic breathing is clinically obvious in those with a fixed rib cage due to costovertebral joint involvement and lung function may be somewhat restricted. Apical pulmonary fibrosis and cavitation mimicking tuberculosis radiographically is recognized but rare (in approximately 1%); colonization with bacteria, fungi, or *Aspergillus* species is an exceptional complication.

Aortitis causing incompetence of the aortic valve is an uncommon (approximately 1%) cardiovascular complication. Of far more clinical relevance in AS is the pronounced excess cardiovascular mortality from atheroma, similar to that for other chronic inflammatory diseases, such as rheumatoid arthritis and systemic lupus erythematosus. Accordingly any other cardiac risk factors, including hypertension, smoking, and hyperlipidaemia should be tackled aggressively.

**Investigation**

One of the most important challenges in AS for rheumatologists (and orthopaedic surgeons) lies in achieving early diagnosis. Too often the condition remains undiagnosed for several years or may be inappropriately treated with spinal immobilization or even surgery. Radiographic involvement of the sacroiliac joints is usually not evident early in the disease and a high index of suspicion is required in those with a history suggestive of inflammatory back pain. HLA-B27 testing, coupled with a careful assessment of the clinical history is useful in identifying those likely to be affected. However, because B27 is relatively common in the general population (approximately 10%) it is not a useful primary screening tool for back pain in the general community because of its lack of specificity. In contrast, when positive in an individual with inflammatory features (as outlined earlier) it is much more specific for AS. Further investigation of such B27-positive individuals by MRI can then be used to confirm the diagnosis beyond doubt. MRI of the sacroiliac joints using fat suppression techniques is highly sensitive at detecting early changes of osteitis. Although inflammatory changes may be seen widely in the axial skeleton, sacroiliitis is invariably present as the earliest sign of AS on MRI (Figure 10.4.2). Radiographic changes take longer to develop and are less useful in modern clinical practice. The earliest radiographic signs include sclerosis of both margins of the joint (often more pronounced on the iliac side) followed by erosion and widening of the joint. Ultimately ankylosis of the joint may occur (Figure 10.4.3).

---

**Fig. 10.4.2**
A) Early radiographical evidence of sacroiliitis with slight marginal sclerosis and widening particularly evident in the right sacroiliac joint. B) High signal on fat-suppressed MRI sequences of the same patient indicating marrow oedema adjacent to the right sacroiliac joint confirming asymmetric sacroiliitis.

---

**Fig. 10.4.3**
Ankylosis of the sacroiliac joints and extensive ossification of the paraspinal ligaments in late-stage ankylosing spondylitis.

Serum measures of inflammation, such as C-reactive protein, are frequently normal even in active AS although they can be
markedly elevated in some individuals with pronounced systemic disease.

**Management**

Successful management is dependent on early accurate diagnosis and patient education. Physical treatment, combining postural and stretching exercises, is highly beneficial. Patient education and instruction in a regular domiciliary physical exercise programme is fundamental to a successful outcome. This can be supplemented as necessary by intensive courses of treatment (including hydrotherapy) during exacerbations of AS. The worst outcomes in AS are often associated with failure to recognize the condition, resulting in inappropriate immobilization or failure to implement an active physical mobilizing regimen. NSAIDs typically provide good relief from pain and stiffness in the majority of patients. However, conventional disease-modifying anti-rheumatic drugs (DMARDs), like sulphasalazine and methotrexate, are ineffective for axial skeletal disease. In contrast they may be helpful for the minority of patients with significant peripheral joint arthritis. Fatigue is a major problem for many patients with AS, particularly when sleep disturbance is prominent. Low doses of tricyclic antidepressants have a potential role in such patients in improving the quality of sleep and pain. However, the introduction of the anti-TNF biologic agents in recent years has revolutionized the treatment of AS and related disorders. For those who still have significant symptoms despite an adequate trial of non-steroidal anti-inflammatory drugs (NSAIDs) and physical therapy, anti-TNF drugs (monoclonal antibodies or recombinant soluble TNF receptor/IgG fusion protein) have the potential to suppress both axial and peripheral joint symptoms and improve the quality of life dramatically. However, the relatively high cost of these drugs and concerns about potential serious side effects (infection and malignancy) necessarily restricts their use to patients with more severe disease. Most patients treated with anti-TNF drugs show at least some improvement and around half demonstrate a 50% improvement. It remains to be seen whether these agents actually suppress the abnormal ossification of the spine that characterizes the condition in the long term.

The rigid fixed cervical spine and immobile chest may cause peri/postoperative difficulties when surgical intervention is required. Prolonged recumbency and postoperative chest infections are detrimental to the long term outcome of these patients. There is no convincing evidence that patients with AS are more prone to heterotopic ossification following joint replacement surgery than the general population.

**Psoriatic arthritis**

Approximately 10% of patients with skin psoriasis develop inflammatory arthritis but this is highly variable in its presentation. Skin involvement often pre-dates the arthritis by many years but arthritis can be synchronous with or precede the skin disease. Nail involvement is evident in 70% of those who develop arthritis and the diagnosis can also be aided by a positive family history of psoriasis or psoriatic arthritis. The incidence of psoriatic arthritis is similar between the sexes.

Peripheral joint arthropathy (Figure 10.4.4) is more common than axial disease but is quite variable in extent (see later). Joint involvement in psoriasis is frequently coupled with nail changes, including nail pitting, discoloration, ridging, and onycholysis. Involvement of the distal and proximal interphalangeal joints of a single finger causes the appearance of a ‘sausage finger’, such dactylitis is highly characteristic of psoriatic arthritis. Tenosynovitis contributes to dactylitis but overall this type of pathology can best be regarded as a particular form of enthesitis (see earlier) and is strongly correlated with destructive arthritis and a tendency to axial disease.

**Box 10.4.2 The Moll and Wright classification of psoriatic arthritis**

- Arthritis with distal interphalangeal joint involvement predominant
Arthritis mutilans—a destructive erosive arthropathy
Symmetrical polyarthritis—indistinguishable from rheumatoid arthritis (but rheumatoid factor and nodules absent)
Asymmetric oligoarticular arthritis
Predominant spondylitis.

Although many cases of psoriatic arthritis are relatively mild symptomatically and appear to have a relatively good prognosis, there is a strong tendency for increasingly polyarticular involvement over time. Early management of single swollen joints with intra-articular steroid injection and splintage should be effected and NSAIDs offered for symptomatic relief. Persistent synovitis, particularly polyarticular, erosive disease warrants DMARD therapy. Methotrexate, leflunomide, and sulfasalazine are all of some benefit but consideration should be given to biological therapies with anti-TNF drugs in patients who do not respond adequately. Patients with psoriatic spondylitis should be managed in the same manner as AS. Anti-TNF drugs provide rapid symptomatic relief for most patients and prevent progressive peripheral joint destruction in psoriatic arthritis. These agents are also extremely effective for the cutaneous manifestations of psoriasis that are such a major source of distress for many patients with the disease.

Reactive arthritis

ReA refers to an episode of aseptic peripheral arthritis occurring within 1 month (typically 2–3 weeks) of a primary infection in another part of the body. The most common sites of infection are the gut or genital tract; Shigella, Salmonella, Campylobacter, or Yersinia species are implicated in postenteric ReA and Chlamydia trachomatis in the sexually acquired form. The precipitating infection is often not clinically apparent and a reasonably high index of suspicion may be required to make the diagnosis. The classic triad of urethritis, conjunctivitis, and arthritis was first described in association with endemic dysentery in the trenches during the First World War.

However, most cases of reactive arthritis currently present with joint symptoms alone. Between 60 and 80% of patients with typical ReA are HLA-B27 positive and this is associated with a more adverse prognosis. ReA is usually self-limiting but, particularly in the more severe HLA-B27 positive cases, persistent or recurrent joint symptoms occur (40% of patients at 15 year follow up). At prolonged follow up to 20% of patients with ReA may be found to have developed AS.

Clinical features

ReA typically presents as an acute asymmetric oligoarthropathy of the lower limb, with prominent knee and/or ankle synovitis. Rarely, it may present with more widespread synovitis including upper limb joints. An association with ocular inflammation (typically conjunctivitis and, rarely, anterior uveitis); enthesitis (Achilles tendinitis and plantar fasciitis) and dactylitis is common (the classic ‘sausage toe’ or dactylitis is illustrated in Figure 10.4.5). A minority of individuals exhibit mucocutaneous features including keratoderma blennorrhagica, circinate balanitis, painless ulceration of the hard palate, and nail dystrophy resembling that seen in psoriasis.

Joint symptoms are typically self-limiting, varying in duration from a few days to several months. Spondylitis or isolated sacroiliitis is more likely to occur in the 15–40% of patients that develop chronic or recurrent arthritis: many of these patients have a family history of spondyloarthropathy or are HLA-B27 positive. Aortic regurgitation and cardiac conduction defects occasionally occur.

Diagnosis

The diagnosis usually rests on the clinical history (Box 10.4.3). About half of those presenting with ReA have an obvious history of relevant infection although in the case of postenteric disease the causative organism is frequently not cultured because the infection has already cleared. ELISA (Enzyme-linked immunosorbent assay) for C. trachomatis will detect 50% of those with genital tract infection. Serology may demonstrate rising titres of antibodies to culprit organisms. Testing for rheumatoid factor or anti-COP (cyclic citrullinated peptide) antibodies may help to exclude the alternative diagnosis of rheumatoid arthritis which has some prognostic value. HLA-B27 testing is not routinely required but may sometimes be useful when the diagnosis is unclear. Joint radiographs contribute little to diagnosis in the acute episode, but the presence of sacroiliitis may be of diagnostic and prognostic value. The sedimentation rate or C-reactive protein can be useful for monitoring disease activity during treatment.
Box 10.4.3 Diagnostic criteria for reactive arthritis

♦ Predominantly lower-limb asymmetric oligoarthritis
♦ Evidence of infection such as diarrhea or urethritis in the preceding month or laboratory confirmation of infection
♦ The presence of extraarticular manifestations (e.g. conjunctivitis, iritis, mucocutaneous manifestation).

Management

Rest, aspiration, injection of inflamed joints with corticosteroids, and regular use of NSAIDs will usually be sufficient to settle the synovitis and prevent irreversible joint damage. Most cases settle relatively quickly treated conservatively in this way but persistent synovitis may require DMARDs like sulphasalazine or methotrexate. Recurrent disease is not uncommon and is treated in the same way as acute disease. For resistant cases anti-TNF therapy is also effective. The role of antibiotic therapy in influencing ReA arthritis is controversial. However, it is standard practice to treat sexually acquired disease with tetracycline. It is also prudent to investigate for other possible venereal infections and to initiate contact tracing and treatment where appropriate.

Arthritis complicating inflammatory bowel disease

Seronegative arthropathy occurs in 5–10% of individuals with inflammatory bowel disease. It is twice as common in Crohn’s disease as in ulcerative colitis. Spondylitis is well recognized, but the association with HLA-B27 is generally somewhat lower (60–80%) than in uncomplicated AS. Two forms of peripheral arthropathy are described, each with distinct clinical patterns and immunogenetic associations (Box 10.4.4). Neither form is erosive, although joint deformities may occur with type 2 disease.

Box 10.4.4 Classification of enteropathic peripheral arthropathy

♦ Type 1 (pauciarticular):
  • <5 joints
  • Acute self-limiting attacks (<10 weeks)
  • Often coincides with relapses of inflammatory bowel disease (IBD)
  • Strongly associated with extraintestinal manifestations of IBD
  • Associated with HLA-B*27 and HLA-DRB1*0103

♦ Type 2 (polyarticular):
  • 5 or more joints
  • Symptoms usually persist from months to years
  • Runs a course independent of IBD
  • Associated with uveitis but not with other extraintestinal manifestations
  • Associated with HLA-B*44 but not HLA-B*27.

Management focuses on good control of the inflammatory bowel disease. NSAIDs are effective in treatment of joint pains but can exacerbate bowel inflammation. Consequently, simple analgesics and intra-articular steroids should be used wherever possible. Sulfasalazine and methotrexate are both effective for the arthritis and bowel disease. When systemic corticosteroids are indicated for the bowel they will help the joint symptoms. Recent experience with anti-TNF drugs shows favourable results in resistant cases and is highly effective for the underlying bowel disease.

Inflammatory connective tissue disease

Chapter: Inflammatory connective tissue disease

Author(s): Catherine Swales

DOI: 10.1093/med/978019850047.003.010005

Summary points

- Systemic lupus erythematosus (SLE) is the commonest multisystem connective tissue disease
- All patients with SLE are antinuclear antibody (ANA) positive, but not all ANA-positive patients have SLE
- Renal lupus carries a high mortality and requires aggressive immunosuppression
- Dermatomyositis may be associated with malignancy in the elderly
- The vasculitides are classified according to vessel size and ANCA (antineutrophil cytoplasmic antibody) profile
- Therapy for vasculitis includes corticosteroids, steroid-sparing agents, and cytotoxics.

Connective tissue disease

The inflammatory connective tissue diseases and systemic vasculitides are multisystem disorders which are often associated with abnormal immune responses towards self-antigens. The commonest connective tissue disease is systemic lupus erythematosus (SLE), which is characterized by antibodies directed against nuclear components.

Systemic lupus erythematosus

SLE is a multisystem disease with prominent involvement of small and medium vessels and serosal surfaces. Women are more commonly affected than men (7:1) and the lifetime incidence in the United Kingdom is up to 1 in 1000.

Clinical features

SLE characteristically presents with vague constitutional symptoms, a photosensitive skin rash (Figure 10.5.1), arthralgia, oral ulcers, and Raynaud’s phenomenon. Raynaud’s phenomenon results from intermittent vasospasm of the digital vessels, usually in the cold. Digital pain is associated with the classic colour changes of pallor, cyanosis, and subsequently hyperaemia. Although involvement of virtually any organ system may occur in SLE, disease affecting the heart, lungs, kidneys, and nervous system is common.

Skin disease is frequently precipitated or exacerbated by exposure to sunlight and may be associated with an increase in the activity of systemic disease. Small-joint arthropathy affects up to 90% of patients, but clinically evident severe synovitis or joint effusions are relatively uncommon. Only 10–15% of patients develop progressive joint deformity (Jaccoud’s arthropathy) and erosive disease is exceptionally rare. Serosal involvement is common, leading to development of pleurisy and pericarditis, occasionally causing significant effusions. Haematological abnormalities are common and an autoimmune thrombocytopenia, leucopenia, or haemolytic anaemia may be present. A normochromic normocytic anaemia is typical and lymphadenopathy is common. Renal involvement occurs in about half of those with SLE with the development of a glomerulonephritis. In many cases renal involvement may be entirely subclinical, manifesting only as asymptomatic proteinuria or microscopic haematuria, but progressive renal failure may develop. Neuropsychiatric features include headaches and mild depressive or behavioural problems. Seizures, strokes (particularly in the presence of the antiphospholipid syndrome, see later), and psychotic episodes may also occur.

Diagnosis

The diagnosis rests on a combination of laboratory and clinical criteria (see Table 10.5.1). Using current techniques, antinuclear antibodies are present in virtually all patients with SLE but are also detectable in about 30% of patients with rheumatoid arthritis and other connective tissue diseases. The presence of antibodies to double-stranded DNA (dsDNA) is much more specific for SLE (~90%). In addition antibodies to the ‘extractable nuclear antigens’ Ro, La, and Sm, and ribonucleoprotein (RNP) also occur in...
In addition, antibodies to the 'extractable nuclear antigens' Ro, La, and Sm, and ribonucleoprotein (RNP) also occur in SLE.

Four of the 11 criteria need to be met (serially or simultaneously) in order to make a diagnosis of systemic lupus erythematosus.

Management

Raynaud’s phenomenon is best managed by keeping the hands warm but calcium channel blockers, such as nifedipine, may be of additional benefit. Avoidance of direct sunlight and the use of high sun protection factor sunscreens may be all that is required to suppress the skin manifestations and arthralgia responds well to non-steroidal anti-inflammatory drugs and/or hydroxychloroquine.

Corticosteroids and steroid-sparing agents such as azathioprine should be reserved for patients who either do not respond to these measures or who have evidence of more severe systemic features. Treatment with high-dose corticosteroids and agents such as cyclophosphamide or mycophenolate mofetil is indicated in patients with serious major organ involvement. The 10-year survival rate for SLE exceeds 90%, although it is lower in those with major renal or neurological involvement.

The antiphospholipid syndrome

The antiphospholipid syndrome may occur in isolation or in association with other connective tissue diseases, particularly SLE. It is characterized by the tendency to thrombosis (both venous and arterial), recurrent early abortion, and thrombocytopenia. Diagnosis relies on the detection of either anticardiolipin antibodies or lupus anticoagulant and the treatment is based on life-long anticoagulation.

Scleroderma

Scleroderma is characterized by excessive deposition of collagen and small blood vessel obliteration, resulting in tissue ischaemia and atrophy.

Clinical features
Raynaud’s phenomenon is an early feature of the disease and severe disease leads to finger pulp atrophy or even gangrene and osteolysis of the fingertips. Fibrotic changes lead to skin tightening, which may be accompanied by calcinosis. The fibrotic process commonly causes hypomotility of the gastrointestinal tract, causing dysphagia and reflux, malabsorption due to bacterial overgrowth in a hypomotile small bowel, and pseudo-obstructions. Respiratory failure due to interstitial lung disease or obliteration of the pulmonary vessels may occur and renal involvement causes severe hypertension and rapidly deteriorating renal function. Fibrosis of the capsules of joints sometimes leads to restricted movement and to the development of contractures.

**Diagnosis**

The diagnosis is largely based on clinical features although the erythrocyte sedimentation rate (ESR) may be raised and ANAs are demonstrable in over 50% of patients. The presence of anticentromere antibodies suggests more localized cutaneous disease, whereas antibodies directed against topoisomerase 1 (Scl 70) are most commonly found in those with progressive systemic disease.

**Management**

There is no specific treatment. Raynaud’s phenomenon often responds to heated gloves, calcium-channel blockers, or sympathectomy but iloprost (a prostacyclin analogue) may be required for critically ischemic digits. Proton pump inhibitors and antibiotics may be used for oesophageal disease and bacterial overgrowth respectively. Angiotensin-converting enzyme inhibitors should be used in the management of hypertension associated with renal disease.

**Dermatomyositis and polymyositis**

These syndromes are characterized by inflammation of the muscles causing proximal muscle weakness and pain, with variable skin involvement. There is a clear association with underlying malignancy in the elderly.

**Clinical features**

The most common presentation is with progressive and symmetrical proximal muscle weakness. Progressive involvement of the pharyngeal and respiratory muscles may occur but involvement of myocardial muscle is rare. Skin involvement is very variable but includes heliotrope (lilac) discoloration of the eyelids and a scaly erythematous rash on the extensor surfaces of the fingers, elbows, and knees.

**Diagnosis**

The diagnosis is confirmed by the demonstration of markedly elevated muscle enzymes, e.g. creatine phosphokinase, and abnormal muscle biopsy and electromyography. If there is associated malignant disease it is usually clinically apparent and an exhaustive search for occult malignancy is not justified.

**Management**

Treatment is based on the use of corticosteroids and immunosuppressive agents such as methotrexate and azathioprine. The skin disease may respond to hydroxychloroquine. Although the prognosis is generally less good in the elderly, in whom an association with malignancy is more common, the overall 5-year survival rate is now nearly 90%.

**Systemic vasculitis**

The systemic vasculitides are characterized by an inflammation of blood vessel walls. Current classifications of the systemic vasculitides stratify the illnesses on the basis of the size of blood vessels involved and the detection of ANCAs (Table 10.5.2).

Polymyalgia rheumatica and giant cell arteritis

There is considerable overlap in both the clinical features and the pathology of these two syndromes. Both diseases affect the elderly and rarely present before the age of 55 years.

Polymyalgia rheumatica

This clinical syndrome is characterized by aching and stiffness of the shoulder and hip girdles. It is a common disorder in the elderly, affecting women more commonly than men. About one-third of cases are associated with coexistent giant cell arteritis. Characteristic symptoms are pain and stiffness in the muscles around the shoulder and hip girdles, in the absence of abnormal clinical signs. There is almost invariably elevation of the sedimentation rate and a mild normochromic normocytic anaemia is common. The condition is characterized by a dramatic response to low doses of oral prednisolone. Gradual withdrawal can commence once the patient is symptom-free and the acute phase has normalized.

Giant cell arteritis

Giant cell arteritis is a granulomatous vasculitis affecting large and medium-sized arteries, most typically in the territory of the external carotid. Typical features include severe unilateral headache with local tenderness of the inflamed artery (superficial temporal, facial, or occipital) and hypersensitivity of the scalp. Amaurosis fugax may occur with retinal artery involvement and this may presage complete occlusion of the vessel and blindness. There may also be claudication of the masseter muscle or tongue. The diagnosis is confirmed by biopsy findings of an affected vessel, but this should not delay the initiation of appropriate treatment in view of the potential threat to the patient’s vision. Marked elevation of the ESR and a normochromic normocytic anaemia are typical. Treatment should be started immediately, to prevent blindness or other neurological consequences, with high-dose prednisolone. Steroid-sparing agents, such as methotrexate, may also be required.

Takayasu’s arteritis

Takayasu’s arteritis is a large-vessel vasculitis affecting the aorta and its major branches, causing vascular insufficiency. The clinical picture is associated with an elevated acute phase response and a normochromic normocytic anaemia. Arteriography is diagnostic. Treatment should be initiated with prednisolone and cytotoxic agents. When the inflammatory process has been controlled surgical intervention with angioplasty, arterial reconstruction, or arterial bypass grafting may be appropriate.

Behçet’s disease

Behçet’s disease is a systemic vasculitis of unknown aetiology with a particularly high prevalence around the Mediterranean, the Middle East, and the Far East. Characteristic clinical features include recurrent orogenital ulceration, uveitis, skin disease, and arthropathy, usually mono- or oligoarticular. Diagnosis is clinical, in association with an elevated inflammatory response. Treatment relies on corticosteroids and immunosuppression.

Polyarteritis nodosa
Polyarteritis nodosa is a necrotizing vasculitis affecting medium-sized arteries, leading to aneurysm formation. It may be associated with hepatitis B infection. Presenting features include constitutional upset, weight loss, abdominal pain due to mesenteric ischaemia, renal failure and hypertension, mononeuritis multiplex, and skin disease (purpura or livedo reticularis). Diagnosis relies on an elevated acute phase response, hepatitis serology, arteriography, and biopsy of an affected organ. Treatment involves corticosteroids and immunosuppression.

Wegener’s granulomatosis

Wegener’s granulomatosis is a necrotizing granulomatous vasculitis of small and medium-sized vessels which predominantly affects the upper and lower respiratory tracts, kidneys, and eyes. There is evidence of a systemic inflammatory response and ANCA (classically cytoplasmic) are present (cANCA). Biopsy of an affected organ will also aid diagnosis. The systemic form of the disease is almost always fatal without treatment and immunosuppression should be started as soon as possible after presentation.

Churg–Strauss syndrome

Churg–Strauss syndrome is a granulomatous vasculitis affecting small and medium-sized vessels associated with a peripheral eosinophilia. It typically affects the lung (asthma, eosinophilic pneumonia), heart (myocarditis), peripheral nervous system (mononeuritis multiplex), and skin (vasculitic nodules). A peripheral eosinophilia and raised serum immunoglobulin E are typical. Treatment is with immunosuppression.

Microscopic polyangiitis

Microscopic polyangiitis is the commonest small-vessel vasculitis, leading to renal, skin, neurological, and pulmonary disease. Arthralgias, fevers, malaise, and weight loss may be prominent features. Diagnosis rests on demonstration of an elevated inflammatory response, renal biopsy, and antibodies against neutrophil cytoplasmic antigens (classically perinuclear, pANCA). Prompt treatment with prednisolone and a cytotoxic agent is crucial.

Henoch–Schönlein purpura

Henoch–Schönlein purpura is a small-vessel vasculitis characterized by immunoglobulin A deposition within vessel walls and glomeruli. The skin (especially the buttocks and lower limbs), joints, kidneys, and gastrointestinal systems are typically involved. The diagnosis again relies on biopsy of an affected organ. Children are usually affected and the disease in this age group is frequently self-limiting. Adult patients may require immunosuppression.

Further reading

Summary points

♦ Osteoporotic fractures affect one in two women and one in five men over the age of 50
♦ Previous fragility fracture increases future fracture risk and should prompt further assessment and treatment
♦ Clinical risk factors in combination with bone mineral density measurement allow identifying patients at risk
♦ Screening for secondary causes of osteoporosis is important, particularly in men and younger women
♦ Patients at high risk for future fracture should be offered appropriate treatment. Bisphosphonates together with adequate calcium and vitamin D supplementation constitute first-line therapy
♦ Compliance with treatment and clinical response need to be monitored.

Introduction

Osteoporosis is a skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue resulting in increased bone fragility and susceptibility to fracture (Figures 10.6.1 and 10.6.2).

Typically, osteoporotic fractures occur at the distal forearm, spine, and hip with increasing age. Globally, osteoporosis results in more than 8.9 million fractures annually with a lifetime fracture risk of between 30–40%. Fragility fractures are associated with high morbidity and mortality and result in significant costs to society. Given that number of osteoporotic fractures is likely to increase threefold over the next 50 years as a result of aging populations, identifying and treating individuals at risk is important. In 1994, the
World Health Organization (WHO) produced diagnostic criteria for osteoporosis based on the measurement of bone mineral density (BMD). It defined osteoporosis as bone density value that is more than 2.5 standard deviations (SD) below the mean for young adults. Low BMD and factors such as older age, prior fracture, high rate of bone turnover, risk of falls, corticosteroid use, and family history allow the estimation of individual future fracture risk and guide therapeutic decisions. Effective therapies that can reduce the incidence of fracture are available but undoubtedly underused. The pathogenesis and epidemiology of osteoporosis, fragility fracture risk assessment, diagnostic tools, and current treatments are discussed in the rest of this chapter.

Pathogenesis of osteoporosis

Bone undergoes constant remodelling which allows growth, repair, and adaptation to stress. The cycle of bone remodelling on endosteal surfaces starts with bone resorption initiated by osteoclasts. The resorptive cavity thus created is subsequently filled with new bone by osteoblasts. Mineralization of the newly laid down bone matrix (osteoid) completes the cycle which lasts 3–6 months. The balance between bone resorption and formation determines net bone acquisition or bone loss.

During skeletal growth, bone formation predominates, leading to gradual increase in bone size and density reaching peak BMD by about 25 years of age. About 50–85% of the variance in BMD is determined genetically. Low peak BMD can also result from prolonged childhood illness, low calcium intake, low body weight, or delayed puberty (Figure 10.6.3).

Reduction in BMD begins gradually, even in the early adult years in both men and women, and is thought to result from gradual reduction in new bone formation. In women, bone loss accelerates after menopause due to a significant fall in circulating oestrogen levels. This loss is particularly rapid in the first 5 years after menopause reaching up to 3% per year in the spine. Interestingly, low oestrogen levels in older men correlate positively with low BMD indicating that oestrogens are important regulators of bone formation in both genders. Bone loss in older people is influenced by a number of other factors including increased parathyroid hormone (PTH) levels, vitamin D deficiency, and low calcium intake. Other comorbidities, such as rheumatoid arthritis or medications (corticosteroids or aromatase inhibitors), contribute to accelerated bone loss and need to be considered as additional risk factors for fractures.

Epidemiology of osteoporosis and osteoporotic fractures

As BMD decreases with age, prevalence of osteoporosis rises. Among people in their late 60s, 29% of women and 12% of men have osteoporosis at the hip. These numbers rise to 57% and 36%, respectively, by the age of 85. The incidence of fractures follows a similar trend, rising steeply after the age of 50. Osteoporotic fractures are twice as common overall in women. In the United Kingdom, the lifetime risk of any fracture at 50 years of age is 53% in women and 20% in men. The commonest non-vertebral fracture sites in over 55 years of age are the wrist, upper humerus, and hip.

Lifetime risk of a hip fracture in a white woman ranges from 11.4% in the UK up to 22.9% in Sweden. In men the risk is lower and ranges from 3.1% to 10.7%. Hip fractures affect mainly those over 70 years old and in 90% of cases result from a fall from standing height. Low BMD at the femoral neck is a strong predictor of future hip fracture risk but other factors are also important, including femoral neck length, angulation, and the distribution of cortical bone within the femoral neck. Thus it has been shown that cortical bone is well preserved inferiorly from 20 through to 90 years of age while there is a strong tendency for cortical thinning superiority, with major implications for the integrity of the femoral neck in direct trauma as might happen in falls. The risk of falling itself is therefore also clearly an important risk for fracture. Hip fracture constitutes one of the commonest causes for acute admission to an orthopaedic ward and worldwide the cost of hospitalization for a hip fracture is estimated to be £10 300 per patient. Mortality after hip fracture is 10% at 30 days, rising to 30% at 1 year. Higher mortality is reported in older patients with multiple comorbidities and cognitive impairment and residual physical disability is common in this group. A year after hip fracture, 40% of survivors are unable to walk independently and 60% require assistance in at least one core activity of daily living.

Wrist fractures result from a fall on the outstretched hand and are commonest in perimenopausal women. Lifetime risk of a wrist
The risk of non-vertebral fractures in people over 55 years old increases with reduction in femoral neck BMD. This association is stronger in men and women. The strongest correlation between low BMD and fracture risk exists for wrist and hip fractures. However, only 44% of non-vertebral fractures in women and 12% in men occur in individuals with T-scores below −2.5, indicating that BMD alone is an imperfect tool for the assessment of fracture risk. The relationship between low BMD and fracture risk can be assessed using the T-score and Z-score. The T-score is the number of standard deviations below the young adult reference mean for a given bone density measurement. The Z-score is the number of standard deviations below the mean for a given age and gender-matched range. Reduction in T-score and Z-score correlates with increased fracture risk. In postmenopausal osteoporosis it is generally accepted that fracture risk increases with each standard deviation in BMD below normal. Definitions of osteoporosis and osteopenia based on T-score values are described in Table 10.6.1.

### Table 10.6.1 WHO classification based on axial BMD measurement

Although DXA is widely used in everyday clinical practice, one has to be aware of its limitations. Bone densitometry allows two-dimensional measurement of bone density and is affected by bone depth. The presence of osteoarthritis with marginal osteophytosis, previous vertebral fractures, scoliosis, obesity, or aortic calcification can falsely elevate spinal BMD. Likewise, BMD measurement at the hip can be affected by anatomical variants, osteoarthritis, Paget's disease, or leg positioning. Peripheral DXA (PDx) is used for measuring BMD at the forearm and calcaneus and can be used in fracture risk assessment if there is no access to axial DXA. DXA may also be useful to monitor patients on treatment, as the BMD is expected to rise. In younger patients, increase in BMD is most noticeable in the vertebrae where bone turnover is more rapid than in the hip. In older patients with degenerative changes in the lumbar spine, interpretation of BMD measurements may be difficult.

DXA provides an accurate and reproducible way of measuring BMD but does not provide information on bone microarchitecture. Other techniques are being developed to obtain a better understanding of factors that determine bone strength. Quantitative ultrasound measures attenuation of the ultrasound waves by the bone tissue and can be measured at the heel, tibia, radius, or phalanges. It can be helpful in estimation of the fracture risk but has not been accepted for diagnostic purposes. Magnetic resonance imaging (MRI) has use in identifying insufficiency fractures. In recent years computed tomography (CT) has been developed to assess bone microarchitecture. Volumetric quantitative computed tomography (vQCT) produces three-dimensional measurement of BMD and can separately analyse cortical and trabecular bone. It has proved precise in assessing response to treatment in clinical trials but its use is limited by higher radiation dose, cost, and availability.

### Assessment of fracture risk

#### Bone mineral density

The risk of non-vertebral fractures in people over 55 years old increases with reduction in femoral neck BMD. This association is the same for men and women. The strongest correlation between low BMD and fracture risk exists for wrist and hip fractures. However, only 44% of non-vertebral fractures in women and 12% in men occur in individuals with T-scores below −2.5, indicating that BMD alone is an imperfect tool for the assessment of fracture risk. The relationship between low BMD and fracture risk can be assessed using the T-score and Z-score.
likened to the association between hypertension and stroke. Not all patients with elevated blood pressure will sustain a stroke but the risk of stroke is considerably increased in hypertensive subjects. Full evaluation of other risk factors is an essential part of fracture risk assessment that will guide a decision on treatment.

**Previous fragility fracture**

A previous fragility fracture constitutes a very important risk factor as it doubles the likelihood of any future fractures regardless of the site of the initial fracture. For example, a woman who has sustained a wrist fracture has a twofold increased risk of hip fracture. Prior vertebral fracture results in a fourfold increased risk of subsequent vertebral fracture and this risk increases further by two to four times for each additional vertebral fracture at baseline.

**Clinical risk factors**

Patients with clinical risk factors such as low body mass index (BMI), parental history of hip fracture, or other comorbidities that could lead to low BMD should be referred for DXA (Box 10.6.1).

**Box 10.6.1 Indications for bone density scan**

- X-ray osteopenia
- Fragility fracture (unless >75 years old)
- Untreated premature menopause (age <45)
- Amenorrhea (>1 year)
- Long-term steroids (>3 months at the dose of >5mg prednisolone/day)
- BMI <19kg/m²
- Coeliac disease/malabsorption
- Primary hyperparathyroidism
- Chronic renal failure
- Post-transplant
- Cushing’s syndrome
- Hyperthyroidism
- Hypogonadism.

The WHO Collaborating Centre for Metabolic Bone disease at Sheffield, United Kingdom, has developed an algorithm which calculates a 10-year risk of major osteoporotic fracture in women and men over the age of 50. This fracture assessment tool (FRAX®) computes the probability of fractures from information about clinical risk factors (listed in Box 10.6.2) and femoral neck BMD that can be used to guide therapeutic interventions.

**Box 10.6.2 Risk factors for osteoporotic fractures incorporated in the FRAX® tool**

- Age
- Female gender
- Previous fragility fracture
- Parental history of hip fracture
- BMI <19kg/m²
- Long-term steroids
- Rheumatoid arthritis
- Presence of secondary causes for osteoporosis
- Cigarette smoking
- Excessive alcohol consumption (>3 units per day).

**Markers of bone turnover**

Biochemical products of bone formation and bone resorption, which can be measured in serum and urine, are useful in assessing the rate of bone turnover. Some of these markers are listed in Table 10.6.2. Increased bone turnover correlates with increased fracture risk. Reduction in bone turnover markers on antiresorptive treatment can be useful in assessing treatment compliance. Bone markers can be used in addition to BMD measurement in fracture risk assessment.
### Clinical features of osteoporosis

Osteoporosis is an asymptomatic condition and is often detected only after a person has sustained a low trauma fracture. Clinical features of acute hip and distal radius fractures are described elsewhere. Vertebral fractures are often unrecognized and patients present late with an established thoracic kyphosis, loss of height, and variable back pain. Acute vertebral fracture should always be suspected in an elderly person with sudden onset of severe localized back pain. The commonest site for vertebral fractures is in the lower thoracic segment and at the thoracolumbar junction where localized tenderness over the relevant vertebrae is an important clinical indicator (Figures 10.6.4 and 10.6.5).

**Fig. 10.6.4**
Lateral x-ray of the thoracic spine in a 72-year-old man with rheumatoid arthritis who presented with acute midthoracic back pain. Vertebral fractures demonstrated at levels T5, T6, and T8.

**Click to view larger**

**Fig. 10.6.5**
MRI of the thoracic spine (STIR sagittal sequence) in the same patient as Fig 10.6.4 demonstrating wedge fractures at T5, T6, T7, and T8 with high signal in T6 and T7 vertebral bodies suggesting more recent fractures...
In most patients, the acute pain settles over 6–8 weeks but more diffuse low-grade discomfort may be prolonged. Patients with multiple fractures in the thoracic segment develop a deformity known as ‘dowager’s hump’. Spinal deformity results in secondary problems such as reduced chest expansion, early satiety, and abdominal pain. Acute rib fractures can follow episodes of coughing and produce pleuritic-type chest pain and localized rib tenderness. Pelvic insufficiency fractures should be suspected in a person following a fall if there is persisting buttock/hip pain on mobilization. Insufficiency fractures can be difficult to demonstrate on plain x-rays but can be well visualized on MRI (Figures 10.6.5 and 10.6.6).

![Click to view larger](image)

Fig. 10.6.6
STIR MRI of calcaneus showing insufficiency fracture and adjacent high signal.

### Secondary osteoporosis

The majority of women who present with fragility fractures have postmenopausal osteoporosis but up to 30% of females and over 50% of males with osteoporosis have a secondary cause of bone loss (see Box 10.6.3). Patients with osteoporosis should therefore all have a set of simple blood tests to check for secondary causes (Box 10.6.4).

#### Box 10.6.3 Causes of secondary osteoporosis

- **Endocrine:**
  - Hyperparathyroidism
  - Thyrotoxicosis
  - Hypogonadism
  - Hyperprolactinaemia
  - Cushing’s syndrome
  - Premature ovarian failure
  - Anorexia nervosa
  - Vitamin D deficiency

- **Gastrointestinal:**
  - Malabsorption: coeliac disease, inflammatory bowel disease
  - Liver cirrhosis
  - Primary biliary cirrhosis

- **Inflammatory disorders:**
  - Rheumatoid arthritis
  - Polymyalgia rheumatica
  - Ankylosing spondylitis

- **Bone marrow disorders:**
  - Multiple myeloma
  - Leukemia/lymphoma
Systemic mastocytosis

Medications
- Corticosteroids
- Gonadotropin releasing hormone agonists
- Anticonvulsants
- Aromatase inhibitors
- Long-term heparin

Renal disease:
- Chronic renal failure
- Renal tubular acidosis

Collagen disorders:
- Osteogenesis imperfecta
- Ehler–Danlos syndrome

Others:
- Post transplantation
- Alcohol
- Smoking
- Prolonged immobility.

Box 10.6.4 Blood tests recommended in patients with osteoporosis

- Full blood count and ESR
- Urea, electrolytes, and creatinine
- Liver function tests
- Calcium, phosphate, and alkaline phosphatase
- Thyroid-stimulating hormone
- Serum and urine protein electrophoresis.

The commonest endocrine causes include hyperparathyroidism and thyrotoxicosis—both conditions are more common in older women. Vitamin D deficiency is common, particularly in older institutionalized patients; checking calcium, phosphate, alkaline phosphatase, and 25-hydroxyvitamin D levels is therefore recommended in those at risk. Eating disorders pose a particular therapeutic challenge and are an important cause of osteoporosis in young women. ‘Female athlete’ triad is increasingly recognized in women who sustain stress fractures and consists of disorder of eating, menstrual dysfunction, and osteoporosis. Secondary amenorrhoea is an important cause of low BMD in young women and may result from premature ovarian failure or pituitary insufficiency. Oestrogen replacement should be offered to young women with premature menopause. Gastrointestinal malabsorption should be suspected in patients with iron deficiency anaemia, low albumin levels, and hypocalcaemia. In elderly patients with an elevated erythrocyte sedimentation rate (ESR), serum protein and urine electrophoresis is mandatory to rule out multiple myeloma. Inflammatory conditions such as rheumatoid arthritis contribute to bone loss through production of inflammatory cytokines which stimulate osteoclastic activity. A number of drugs contribute to bone loss with systemic steroids being particularly important. Excessive alcohol intake is a common cause of male osteoporosis. Other causes of low bone density include heritable causes (e.g. osteogenesis imperfecta and hypophosphatasia), mastocytosis, and fibrogenesis imperfecta osseum. Mastocytosis is a rare disorder associated with osteoporosis that is caused by increased numbers of mast cells in the tissues. Clinical features include pruritus, flushing, nausea, diarrhoea, vascular instability, and a characteristic rash of urticaria pigmentosa. Fibrogenesis imperfecta osseum is an extremely rare acquired disorder in which the normal bone matrix is replaced by collagen-deficient tissue that is extremely fragile. Bone pain and multiple fractures occur and an association with paraprotein in the blood is well recognized. Some patients have responded to treatment with melphalan.

Glucocorticosteroid-induced osteoporosis

At some time in their lives, between 3–5% of the United Kingdom population receives corticosteroid treatment. Patients treated with systemic steroids have an increased fracture risk which increases within the first 3 months of corticosteroid treatment and declines towards baseline in the year following corticosteroid discontinuation. Fracture risk correlates positively with higher steroid dose and longer treatment duration but current steroid users have a twofold increased risk of fracture independent of BMD or previous steroid cumulative dose. Steroid-induced bone loss is greatest in the first 3 months of treatment and results from suppression of osteoblast function, increased bone resorption, and inhibition of intestinal calcium absorption. Fractures among steroid users occur at a higher threshold of BMD compared to steroid non-users, which needs to be considered when deciding on
treatment. Starting prolonged steroid therapy at a dose greater than 5mg of prednisolone daily should trigger risk factor assessment and, if appropriate, the use of bone protective treatment. In younger patients, bone protection usually consists of maintaining adequate calcium and vitamin D intake. In patients over 65 years, treatment with bisphosphonates should be initiated, pending the result of DXA.

**Osteoporosis of pregnancy**

Pregnancy and lactation-associated osteoporosis presents with fragility fracture (usually vertebral) that typically occurs in late pregnancy or the early postpartum period. Although uncommon, osteoporosis of pregnancy can cause considerable pain and disability. The cause is unknown but pre-existing risk factors for low bone mass, such as low BMI, family history of fragility fractures, smoking, or vitamin D deficiency are often present. DXA shows reduction in BMD, particularly at the spine, which tends to improve with weaning and calcium and vitamin D supplementation. Bisphosphonates have been used successfully in some women postpartum. The condition only rarely recurs in future pregnancies.

**Juvenile idiopathic osteoporosis**

Osteoporosis should be suspected in children with low trauma fractures or radiographic osteopenia. Osteoporosis in a child usually results from other underlying causes such as low body mass, malnutrition, juvenile arthritis, endocrine abnormalities, or steroid therapy. Hereditable disorders of connective tissue such as osteogenesis imperfecta (OI) must also be considered.

Diagnosis of osteoporosis in childhood can be problematic. Standard DXA uses adult peak bone mass as a reference and will therefore produce misleading results. Paediatric normative data are available for the lumbar spine and total body and should be used if possible. Interpretation of bone density measurement must take into account pubertal onset and child’s size. One of the most important measures is to ensure adequate intake of calcium, phosphate, proteins, and vitamin D and encourage physical activity. Bisphosphonates such as intravenous pamidronate are used in more severe cases, including the more severe forms of OI.

**Management of osteoporosis**

Elderly patients with prior fragility fracture should be commenced on treatment without the need for BMD measurement. In patients below 75 years of age, DXA can be helpful as it has additional value in treatment monitoring. For primary prevention, the intervention threshold will depend on the combination of BMD and clinical risk factor assessment as discussed earlier. A team approach is essential (Figure 10.6.7).

**Lifestyle modifications**

Lifestyle measures aimed at optimizing peak BMD are important from an early age. Adequate calcium intake of 1000–1500mg/day for an adult and vitamin D 400IU–800IU or 10–20mcg/day should be ensured. Vitamin K found in green leafy vegetables improves BMD while excessive caffeine and alcohol intake and smoking have detrimental effects on bone density. Weight bearing exercise such as walking, t’ai chi, and dancing improve balance, posture, and strength and are recommended.

**Fall avoidance**

Elderly patients with a history of falls require referral to fall services for further assessment and intervention. Hip protectors reduce the number of hip fractures but compliance is poor. They should be considered in institutionalized elderly patients.

**Pharmacological interventions**

There is an increasing number of therapies shown to improve BMD and reduce risk of fractures. They can be divided into: antiresorptive therapies, anabolic agents and those with dual mode of action (Table 10.6.3 and Figure 10.6.8).

**Bisphosphonates** are the most commonly used antiresorptive treatment. Bisphosphonate molecules contain P-C-P structure (two phosphonic acids bonded to a carbon), which binds to the hydroxyapatite on the bone surface, and two side chains which determine binding affinity and potency. Bisphosphonates inhibit osteoclast driven bone resorption and result in a modest increase in BMD in the first 2 years of treatment. In postmenopausal women, alendronate and risedronate reduce the risk of vertebral fractures by up to 50%, hip fractures by approximately 40% and other non-vertebral fractures by 20%. Ibandronate and etidronate have shown efficacy in preventing vertebral fractures only.
Oral bisphosphonates are poorly absorbed from the gut and must be taken on an empty stomach with copious water, remaining upright for the next 30–60 min to avoid oesophageal side effects. Oral bisphosphonates should be avoided in patients with oesophageal stricture or recent peptic ulcer. For patients intolerant of oral bisphosphonates, intravenous forms, such as ibandronate or zoledronate, can be used effectively. Alendronate, risedronate, and etidronate are licensed for treatment of glucocorticosteroid-induced osteoporosis, while alendronate has an additional licence for treatment of osteoporosis in men. Bisphosphonates are renally excreted and are contraindicated in patients with renal failure.

**Strontium ranelate** has a dual mode of action with a modest inhibitory effect on bone resorption and stimulation of bone formation. In women with postmenopausal osteoporosis it has been shown to reduce vertebral fracture risk by over 40% and non-vertebral fracture risk by 16%. Strontium ranelate is particularly effective at reducing hip fractures in women over the age of 75 with low BMD (T-score <−3).

**Raloxifene** is a selective oestrogen receptor modulator (SERM). It has agonistic effects on oestrogen receptors in bone but acts as an oestrogen antagonist in the breast tissue and endometrium. Raloxifene is effective in the primary and secondary prevention of vertebral fractures in women with postmenopausal osteoporosis, demonstrating risk reduction of 30% and 50% respectively. It can be considered in younger women and has the additional advantages of improving lipid profile and reducing the risk of breast cancer. However, it does increase the risk of thromboembolism.

**Hormone replacement therapy (HRT)** improves BMD and reduces the risk of vertebral fractures in postmenopausal women although it has only weak action on the hip. In this age group the beneficial effect of the HRT on the bone tissue is rather offset by other undesirable effects, including increased risk of breast cancer, and cardiovascular and thrombotic events. In contrast, HRT is safe in young women in whom it should be considered when there is premature menopause in order to prevent early postmenopausal loss of bone.

**Parathyroid hormone** in intermittent doses has a potent effect on bone formation. Two recombinant forms of recombinant human PTH, 1-34 (teriparadate) and 1-84, have been developed. Teriparadate reduces the risk of vertebral fractures by 65% and non-vertebral fractures by over 50%. It is administered by daily subcutaneous injection for 18 months. In some countries its use is currently restricted to women with severe osteoporosis, with very low BMD and who fail to respond to other therapies.

**Calcitonin**, an endogenous peptide produced by thyroid C-cells, inhibits bone resorption. Salmon calcitonin administered intranasally produces a modest reduction in vertebral fractures. Both injectable and intranasal calcitonin has additional analgesic effects in patients with acute vertebral fracture, an effect which is most pronounced within the first week.

**Vertebroplasty** may be indicated for individuals where pain from acute fracture persists beyond 6 weeks and in whom there is evidence of persistent bone marrow oedema. Small volumes of methylmethacrylate cement injected into the vertebral body have a high success rate and low incidence of complication (Figure 10.6.9).

**Monitoring treatment response**

Linear measurements of bone density in patients starting antiresorptive treatment demonstrated correlation between the increase in BMD and reduction in fracture risk (Figure 10.6.10). However, the magnitude of the fracture rate reduction cannot be explained by the often modest rise in BMD. In fact, a small reduction in fracture risk is observed in those patients whose BMD remains the same. Measurement of BMD at the spine and femoral neck every 2–5 years remains the internationally accepted strategy for monitoring treatment response or following BMD in untreated patients with risk factors. Additionally, in recent years, biochemical
markers of bone turnover have been developed to assess responses to treatment and also patient compliance. They have the advantage of providing a more rapid indication of treatment response as they reach a nadir within 3–6 months of the initiation of treatment. No formal guidelines exist on their routine use in clinical practice but failure of suppression of bone turnover markers should at least raise the suspicion that bisphosphonate compliance might be poor. Although current therapies are effective in fracture prevention some patients will continue to fracture. In such cases treatment compliance should also be reassessed and a change of the therapeutic agent considered (e.g. switching from oral to intravenous bisphosphonate).

Fig. 10.6.10
Bone density measurement at the spine in a 51-year-old female with history of two renal transplants and long-term steroid therapy.

Summary

Osteoporotic fractures are an important cause of morbidity and mortality. Patients at risk should be recognized early as current therapies offer a significant fracture risk reduction. Having a fragility fracture is a major predictor of further fractures and orthopaedic surgeons can play an important role in identifying individuals who require further assessment and treatment.

Further reading

Osteoarthritis

Summary points

- Osteoarthritis is the outcome of many different disease processes
- Correlation between radiographic appearance and symptoms is poor
- Prevalence increases rapidly with age
- A multidimensional approach in treatment should include patient education, physical therapy, analgesia, and ergonomic assessment
- Surgical approaches to treatment should adopt a holistic approach.

Introduction

Osteoarthritis (OA) is the commonest joint disorder in the world and represents a heterogeneous disease process with the final outcome being joint failure. It can be defined pathologically, radiographically, or clinically. While in the past radiographic classification grades have been used to define OA, more recently OA is seen as a failed repair of damage that has been caused by excessive mechanical stress (defined as force/unit area) on joint tissues and combines both structural and symptomatic features to describe the failed joint. There are many causes of OA and the disease process affects not only the articular cartilage but also the subchondral bone, ligaments, joint capsule, synovial membrane, and periarticular muscles. Ultimately there is articular cartilage degeneration with fibrillation, fissures, ulceration, and full thickness loss at the joint surface with sclerosis and eburnation of the subchondral bone, osteophytes, and subchondral cysts. Clinical features are characterized by joint pain, tenderness, limitation of movement, crepitus, and occasional effusion without systemic effects. The failure of the joint to repair leads to pain and dysfunction. However, many people with severe radiographic changes are asymptomatic and progression, when it occurs, is usually slow and may halt intermittently.

Epidemiology

OA is the most common joint disorder in the world. It is more common in women and the prevalence increases rapidly with age, with 10% of the world’s population aged over 60 years having symptoms attributed to OA. In 1990, OA was the tenth leading cause of non-fatal health burden in the world. In 2002, OA was the fourth leading cause of years lived with disability in the world. The global prevalence rates are shown in Figure 10.7.1. Using radiographic definitions, knee OA is present in 37% in those aged over 60 years and hip OA 27%. Symptomatic OA is much less common with rates of 4.9%. The lifetime risk of developing symptomatic knee OA is 45% (Figure 10.7.2).

Fig 10.7.1
Pathophysiology

OA is a dynamic process with a number of antecedents and represents a final common pathway for all insults to the joint. The typical initiating factor is a mechanical insult and the response of OA is a manifestation of the joint to repair and minimize the abnormal biomechanics. From community studies, at the knee OA may affect medial/lateral tibio-femoral joint (40%) and/or patellofemoral joint (60%).

Cartilage

The function of the chondrocytes in healthy cartilage is to maintain the matrix in terms of collagen, aggrecan, matrix metalloproteinases (MMPs), and cytokine constituents in response to loading. Risk factors for OA development divide into abnormal loading on normal cartilage or normal loading on abnormal cartilage. In OA, the abnormal loading experienced by the chondrocyte leads to promotion of matrix degradation and downregulating cartilage repair processes (Figure 10.7.3). The constituents of the articular cartilage change in OA with increased type II, IX, and XI collagen and aggrecan representing a matrix constitution similar to that seen in fetal development. The type of loading is critical, while repetitive loading promotes homeostasis of the articular cartilage, a single pathological compression of cartilage leads to an increase in catabolic MMP and aggrecanases in an attempt to resorb the damaged cartilage. Histologically, damage to the articular cartilage is evidenced by fibrillation, horizontal splits, partial and full thickness loss. Vascular invasion of the calcified cartilage leading to chondrocyte hypertrophy and replacement by bone further thins the articular cartilage.

Subchondral bone

There is a growing body of evidence demonstrating the role of bone as a key tissue involved in the pathogenesis of both structural and symptomatic features of OA. The principal role of the subchondral plate is mechanical with the cortical and trabecular bone compartments acting as shock absorbers, continually responding to loads applied to them by viscoelastic dampening. In the longer term, stress on the subchondral bone lead to remodelling, via the osteocyte network and Wnt signalling and alteration of the material properties. In OA, these changes in material properties reduce its capacity to absorb and dissipate the energy from loads.
through the joint. Perturbations in the trabecular structure result in increased load associated in interosseous pressure in the medullary area and this may be represented by bone marrow lesions as seen on magnetic resonance imaging (MRI), which have also been associated with arthritic pain and change in bone marrow lesions may correlate with change in symptoms.

In addition to structural changes, the subchondral plate of bone and underlying trabecular/cortical structures are innervated with nociceptive sensory nerves and there is now increasing evidence identifying bone as a source of pain in OA. From bone scintigraphy, extended bone uptake was strongly associated with knee pain in patients with knee OA (odds ratio 3.71 (2.26–6.12)). Of the neuropeptides, both calcitonin-related peptide and substance P are expressed in bone with the potential of mediating bone pain. These neuropeptides can function as both afferent nociception via substance P as well as efferent influences on bone remodelling via CGRP (calcitonin gene-related peptide), an inhibitor of osteoclast motility and stimulator of osteoblast proliferation.

Osteophytes are fibrocartilaginous outgrowths localized to the joint margins that form through a process of endochondral ossification and are the radiographic hallmark of OA (Figure 10.7.4). Recent work has highlighted the role of the Wnt signalling system as critical in their formation. The significance of osteophytes as a marker of skeletal adaption versus a pathological feature of maladaptation remains unresolved.

**Inflammation and synovitis**

While OA has been traditionally been regarded as a degenerative disease, it is now clear that local synovitis is very common in OA—these inflammatory changes are likely to be the consequence of cartilage and bone catabolism and are associated with severity of knee pain. The ability to visualize the joint non-invasively using both contrast and non-contrast imaging has demonstrated the almost universal presence of synovitis in OA. From histological specimens, the synovial membrane in OA is hyperplastic and may contain lymphocytic infiltrates. The synovium not only is a source of catabolic inflammatory enzymes but also is richly innervated and represents another source of pain.

**Meniscus**

In the knee, the semicircular fibrocartilaginous menisci cover two-thirds of the articular surface and are responsible for load distribution and shock absorbing in addition to roles in proprioception, joint stability, and joint lubrication. Damage to the menisci can be the result of trauma or degeneration. Traumatic injury to the meniscus is manifest as vertical or radial tears. Degeneration is associated with flaps, complex tears, or maceration. Damage to the menisci also commonly involves extrusion of the menisci. Meniscal damage is extremely common in OA as well as in those without joint pain and the contribution of meniscal damage as a cause versus consequence of OA is not yet clear.

**Muscle and ligaments**

Muscles not only provide movement but also provide stability for the joint and absorb reaction forces to loading. During normal walking a load of three to four times body weight is generated and at the knee, periarticular muscles are activated in specific patterns to actively absorb this energy and protect the other tissues of the joint. There is growing evidence for the role of the quadriceps weakness not only as a consequence of symptomatic knee OA but also as a determinant, through the potential role of muscle to absorb energy, facilitating patella tracking and acting as a sensory input for joint proprioception, together with mechanoreceptors in the ligaments, capsule, menisci, and skin. Damage to the cruciate ligaments is recognized as a key antecedent for knee OA, although the onset for symptomatic disease may be delayed for many years.

**Obesity**

OA is a common complication of obesity. Obesity through increased mechanical loading is strongly associated with incident and progression of OA especially at the knee and is a risk factor for total joint replacement. In addition, obesity is associated with a
loss of muscle strength relative to weight and poor balance. To compensate for this, obese people have an altered gait exerting greater forces during walking. In addition to mechanical factors, obesity is associated with low-level inflammation which may further contribute to joint damage.

**Genetics**

Despite the mechanical aetiology to OA, the significant heritability of OA has been confirmed using familial studies, twin studies, linkage analysis, candidate gene, and genome-wide association studies. Genetic influences on bone density and geometry, obesity, synovitis, and chondrocyte function all potentially influence the natural history of OA. Polymorphisms in the Wnt signalling pathway as well as metalloproteinases and cartilage constituents, such as cartilage intermediate layer protein and oligemeric matrix protein, have been associated with knee OA. While the individual genetic traits carry a modest increase in OA risk, identifying the combination of traits in the form of gene–gene and gene–environment interactions have the potential to both inform our understanding of the pathogenesis of OA as well as identify high-risk groups and potential therapeutic targets.

**Central pain processing**

In addition to local nociceptive stimulus at the joint leading to pain in OA, there is a growing body of evidence that a mechanism involving the peripheral nerves through increased innervation density, spinal cord via gating and hyperexcitability, and altered cortical processing such as locus of control, anxiety, and depression leading to altered inhibitory descending tracts have major affects on symptoms and response to therapy. The characteristic feature of central sensitization leading to chronic pain is that previously non-noxious stimuli such as walking are perceived as painful.

**Clinical risk factors**

The purpose of clinical risk factors is to assess risk of disease, aid diagnosis and identify possible therapeutic methods. They can be divided into modifiable and non-modifiable risk factors (Table 10.7.1).

Of the risk factors, some are associated with incident disease (high bone mineral density), others with progression (malalignment) and some with both (obesity).

**Clinical features**

OA presents as a gradual onset, episodic joint pain worsened by activity and relieved by rest. As pain advances, range of movement and function declines and there is a reduction in joint stability with buckling/giving way symptoms (Box 10.7.1). Finally, OA leads to pain at rest and night which through loss of sleep further exacerbates the pain. Physical examination should include assessment for obesity, joint range of motion, crepitus, bony enlargement, focal tenderness, signs of local inflammation, muscle strength, and joint alignment. It is important to exclude referred pain, e.g. hip OA presenting as knee pain.

**Box 10.7.1 Physical signs of OA**

♦ Joint line tenderness
Crepitus on movement
- Bony enlargement of joint
- Restricted joint range of motion
- Pain on passive range of motion
- Deformity
- Joint instability
- Altered gait
- Reduced muscle bulk
- Joint effusion.

**Investigations**

Imaging is used to confirm clinical suspicion and rule out other diagnosis. While radiographs may have features of OA, the absence of radiographic features does not exclude a diagnosis of OA; in addition the presence of features does not exclude other causes for the patient’s symptoms. MRI is used to exclude other diagnosis where appropriate. Blood tests cannot confirm OA and a full blood count, and renal and liver function tests should be performed if there is a plan to start non-steroidal anti-inflammatory drugs (NSAIDs), especially in the elderly. While biomarkers have been developed for OA, their use is limited to research studies at present.

**Imaging**

The aim of imaging is to diagnose, follow-up, and elucidate underlying mechanisms of disease in OA. Standard imaging assessment of a joint affected with OA is the plain projectional radiograph which gives a two-dimensional representation of the bone (osteophytes, subchondral sclerosis, subchondral cysts, and attrition) and inferences regarding soft tissue such as joint space narrowing, which represent both cartilage thickness and meniscal extrusion. The Kellgren and Lawrence score is maintained as one of the key assessment of disease severity (Table 10.7.2). More recent atlases (OARSI) classify each compartment separately. The standard views are semiflexed anteroposterior (AP) to assess joint space width and tibiofemoral bone changes, and the skyline or lateral to examine the patellofemoral joint. In contrast, MRI offers a three-dimensional view in any given plane of all the anatomical structures within the joint including cartilage (as measured by defects or volume), osteophytes, ligaments, tendons, synovium, capsule, bone contours, and marrow signal. MRI can detect lesions at an earlier stage in more subregions of the knee. In addition to structural features, the use of specific MRI sequences such as $T_2$ mapping and $T_1$rho, allow indirect assessment of the cartilage composition.

Ultrasound can easily detect cartilage thickness, meniscal integrity, synovitis, and effusion. Scintigraphy use is limited due to the radiation exposure and poor specificity. Newer computed tomography (CT) scanners are able to offer detailed imaging of the bone structures but have lower soft tissue contrast than that of MRI, for example. CT arthrography provides an indirect method to visualize the cartilage and structures within the knee.

**Treatments**

**Overview**

The treatment aims of knee and hip are to reduce clinical symptoms of pain and stiffness, improve or maintain function, reduce disability, improve quality of life and limit disease progression, both symptomatic and functional. A key aim is patient education not only in terms of OA causes and consequences but also in terms of expectations regarding treatment, a major predictor for willingness to accept arthroplasty. The recent OARSI guidance, by consensus produced a list of recommendations for the treatment of hip and knee OA (Table 10.7.3). From a mechanical perspective, therapies that reduce the abnormal joint loading are likely to result in better patient outcomes rather than tissue directed therapies.

</tr>
<tr>
<td></td>
<td>The use of weak opioids and narcotic analgesics can be considered for the treatment of refractory pain Non-pharmacological therapies should be continued in such patients and surgical treatments should be considered</td>
</tr>
</tbody>
</table>

---

**Education**

Patient education should address the contributions of biological, psychological, and social factors in OA pain. Hence the treatment should be individualized and education should be tailored to the patient’s needs and capabilities. Further, in terms of willingness to

---

**IA**, intra-articular.
accept more invasive interventions such as arthroplasty, information regarding postoperative pain and its management, expected time to recovery, and duration of benefit are all likely to influence patient expectations and reported satisfaction after surgery. While difficult to achieve, weight loss is a key management strategy for obese patients presenting with OA. A modest weight reduction of 10% is associated with clinically significant benefits. Strategies that combine incentives, raising outcome expectations and building on self-efficacy, are more likely to succeed. Further, combining weight loss with exercise leads to a preservation of muscle strength.

Exercise and physiotherapy

Exercise is an integral part of the management of the patient with OA, especially of the knee. However, failure of adherence to exercise regimens and underuse by practitioners to recommend the correct exercise or refer to physiotherapy remain key hurdles. At the knee, a key aim is to improve muscle strength. There is observational evidence that greater quadriceps strength increases disease progression in the presence of malalignment but not in those with neutral knees (±5 degrees); there is no robust interventional evidence for this. Through appropriately targeted exercise, proprioception can also be improved. An exercise prescription is now recommended for muscle rehabilitation for patients with OA (Box 10.7.2).

Box 10.7.2 Exercise prescription

1. Refer to health professional for appropriate exercise prescription
2. Recommend supervised group or individual treatments, which are superior to independent home exercise for pain reduction
3. Supplement home exercise with initial group exercise
4. Do not depend entirely on exercise handouts or audiovisual material, which alone are ineffective
5. Target quadriceps, hamstrings, and hip abductors for strengthening
6. Minimize compressive joint forces
7. Remember that the type of strengthening exercise does not influence clinical outcome
8. Use a combined program of strengthening, flexibility, and functional exercises
9. Employ strategies to maximize long-term patient compliance to exercise.

Devices

The principal aim of a walking device is to reduce the compressive load across the affected joint surface. This is maximally achieved by using the walking device in the contralateral side which not only shifts body weight from the symptomatic limb but also lessens the adduction moment. The optimal height of the cane is to the superior tip of the greater trochanter, with the arm at 20–30 degrees flexion.

A properly fitted unloader brace of the knee attempts to correct the relative alignment of tibia to femur and improve mediolateral instability. Care needs to be taken to ensure adequate adherence to using the brace and these braces are not appropriate in those with bicompartment disease. In those with symptomatic patellofemoral OA, medial taping of the patella reduces symptoms by increasing the patellofemoral contact area during weight-bearing exercise that involves knee flexion rather than maintaining the alignment of the patella.

At the initiation of the gait, the heel strike transient represents the ground reaction force at the point of initial ground contact and is attenuated by many factors including the heel fat pad. The use of viscoelastic insoles lead to a more gentle heel strike moment. The use of lateral or medial wedged insoles to counter degrees of malalignment has not been shown to produce meaningful symptomatic benefit.

Analgesics

The role of analgesics has been questioned by the observation that patients treated with a NSAID had reduced joint pain but an increase in the medial joint loading, with the potential of accelerating progression. NSAIDs and COXII inhibitors are also associated with significant side effects and careful use is advocated by national guidance. The use of topical agents represents an alternative route of administration for NSAIDs and they are better tolerated with fewer side effects and good short-term pain relief. Other topical agents such as capsacin work by initiating an intense local irritation that then depletes substance P. These agents need to be applied three to four times a day to maintain efficacy.

Intra-articular therapies

A number of intra-articular agents have been used in OA. Corticosteroids have a good short- to medium-term effect in reducing pain and improving function. The current guidance is to limit injections to four a year. Hyaluronic acid derivatives have been used to inject large joints and while they improve pain and function do not appear to have a disease-modifying role.

Nutritional supplements

Ongoing trials are evaluating the benefit of vitamin D supplementation. Vitamin K use has not been shown to be beneficial in the general population. Other micronutrients such as selenium, carotene, and vitamin E and C have not been clearly proven to improve clinical outcomes.

Complementary therapies
A large number of complementary therapies have been used in the treatment of OA pain including glucosamine, chondroitin, avocado-soybean; however none have been robustly shown to improve clinical outcomes.

Summary

Although OA is the commonest arthritis globally, we still have little understanding of why patients develop the disease, why symptoms occur in some not others, and how to predict those that will develop severe symptomatic disease. This limitation of understanding has restricted the development of clinically effective interventions to date. In contrast, there is an historical low level of utilization of non-pharmacological interventions which have been shown to improve symptoms. There is an urgent need to combine universal implementation of recent guidance together with translation research to improve patient outcomes in OA.

Chronic long bone osteomyelitis

Summary points

Pathological features of chronic osteomyelitis

- Necrotic bone
- Compromised soft tissues with reduction in vascularity
- Ineffective host response
- Sequestrum formation
- New bone formation from viable periosteum and endosteme
- Formation of involucrum:

Treatment principles in chronic osteomyelitis

- Surgical debridement – remove all devitalized necrotic tissue
- Dead space management:
  - Soft tissue defect – avoid healing by secondary intention. Consider local and free flaps
  - Bone defects – small structural with autologous bone graft, consider Papineau ‘open bone grafting’ where free tissue transfer is not an option, distraction osteogenesis with bifocal and bone transport for large defects including tibial transfer
- Bone stability – movement needs to be eliminated
- Antibiotic therapy – based on culture and sensitivity, local administration with PMMA beads or collagen sponge, Lautenbach procedure in resistant cases.

Introduction

Prolonged infection of bone differs from ‘acute osteomyelitis’ not simply by duration of symptoms but also because of pathognomonic pathological, clinical, and radiological features.

Pathology

Necrotic bone with compromised soft tissues produces the features of chronic osteomyelitis. Infection may arise either from haematogenous spread, direct inoculation (through trauma), or by contiguous spread.

The dead bone becomes isolated by fibrous tissue and chronic inflammatory cells forming inflammatory granulation tissue with a resultant decrease in vascularization. This prevents an effective inflammatory response, reduces delivery of antibiotics to the area of infection, and leads to a decrease in dead bone resorption. Thus non-viable tissue with an ineffective host response results in chronic disease. The persistent dead bone is known as the sequestrum. Due to the decreased blood supply and poor resorption it will appear sclerotic. Erosion can occur after time due to the invading granulation tissue.

New bone formation occurs from surviving periosteum and endosteum in response to the infection and increased vascularity. The periosteal bone produced may encase the dead bone, this is known as the involucrum. This is disorganized and irregular and may be punctuated by tracks through which pus may drain. The involucrum may enlarge both in size and thickness sufficiently to become a ‘new’ shaft of bone. Endosteal bone can result in obliteration of the medullary canal.

Clinical features

Systemic features of infection may or may not be present. Local infected foci can be painful with associated purulent discharge emanating from connecting sinuses. Soft tissue changes include thickening from scarring of muscle and subcutaneous tissue. There may be joint contracture and/or skin adherence to underlying bone. Pathological fracture may occur.

Following treatment the infection is stated to be ‘arrested’ rather than ‘cured’ as subsequent host suppression can lead to a further exacerbation of infection from residual dormant organisms.

Box 11.1.1 Pathological features of chronic osteomyelitis

- Necrotic bone
- Compromised soft tissues with reduction in vascularity
Ineffective host response
Sequestrum formation
New bone formation from viable periosteum and endosteum
Formation of involucrum.

Investigations

Laboratory studies

Non-specific inflammatory markers including white cell count, erythrocyte sedimentation rate, and C-reactive protein. These generally offer no indication of severity of infection. In an acute phase of osteomyelitis, blood cultures may yield a causative organism.

Imaging

- Plain radiographs. These can demonstrate bone destruction but changes lag behind the onset of infection by at least 2 weeks. Soft tissue swelling and periosteal elevation may be seen as an initial change. Lytic changes require up to 75% of the bone to be lost before becoming apparent on the radiograph. The necrotic bone will have characteristic sclerosis with isolated sequestra separate from surrounding bone
- Technetium-99m isotope bone scan. There will be increased uptake in areas of increased blood flow or osteoblastic activity. The scan is, however, non-specific for osteomyelitis—decreased uptake may highlight sequestra
- Computed tomography. Bone images enable dead bone and sequestra to be delineated (Figure 11.1.1)
- Magnetic resonance imaging. This provides more accurate limits of bone and soft tissue involvement by the visualization of oedema on T2-weighted images. Sinus tracts will also appear as areas of increased intensity (Figure 11.1.2)
- Sinogram. Continuity between skin and underlying sequestra can be highlighted and aid in operative planning. At the time of surgery, injection of methylene blue into the sinus tracts allows clear boundaries of involved tissue during surgical debridement ensuring excision of all devitalized and scarred tissue (Figure 11.1.3)
- Biopsy. Removal of infected tissue with culture and sensitivity is important in both confirmation of diagnosis and ensuring correct antibiotic administration.

Fig. 11.1.1
Computed tomography scan demonstrating cortical destruction due to chronic osteomyelitis. Note also loss of articular cartilage due to spread to ankle joint.
Classification

Cierny and Mader developed a classification which takes into account both the physiological condition of the host, the functional impairment caused by the disease, the site of involvement, and the extent of bony necrosis. All influence outcome and by association enable comparison of treatment protocols.

Physiological class:
- A host: normal, immunocompetent with good local vascularity
- B host: compromised, local (L) or systemic (S) factors that compromise immunity or healing
- C host: prohibitive, minimal disability with morbidity expected or poor prognosis for cure

Anatomical type:
- I—medullary: lesion is endosteal with splinter sequestra within the canal
- II—superficial: a true contiguous focus lesion. Compromised soft tissue results in an exposure of the underlying bone
- III—localized: full thickness, cortical sequestration, and/or cavitation. The discrete lesion is within a stable bony segment
- IV—diffuse: the lesion is permeative and circumferential. Instability is present either before or after thorough debridement. Stabilisation therefore is an essential factor in the treatment and thus differentiates a diffuse lesion from the other types

By combination of the physiological class (A–C) and anatomical type (I–IV) one of 12 clinical stages may be defined (Figure 11.1.4).
Treatment

The principles of treatment include eradication of all infected dead bone and scarred devitalized soft tissue (including contaminated hardware removal). Antibiotic therapy is administered sensitive to the causative organism; this can be either systemic or applied locally. Reconstruction of the limb requires achievement of a viable vascular environment and management of the resultant soft tissue and bone ‘dead space’ following debridement. Ideally a multidisciplinary approach best serves these complex problems, including a microbiologist interested in bone infection, plastic surgeon, and orthopaedic surgeon.

Surgical debridement

Skin incisions should allow direct exposure of the nidus avoiding devitalization of viable bone and soft tissues by raising unnecessary flaps. All sequestra, purulent material, and scarred and necrotic tissue is removed. Excise all sinus tracks. Sclerotic end caps over the intramedullary canal, from endostial new bone formation, should be opened to encourage revascularization within the canal. Viable bone will demonstrate the ‘paprika’ sign with visible bleeding from the cut edges. This aids demarcation of healthy tissue and excision margins.

Inadequate debridement can lead to recurrence. Wide resection of greater than 5mm margins from devitalized bone have been shown to significantly reduce this risk.

Repeat debridement may be required prior to definitive soft tissue cover.

Dead space management

Soft tissue

Healing by secondary intention is to be avoided due to the resultant scar tissue which may be avascular and increase risk of recurrent infection.

Coverage of soft tissue defects may require local tissue flaps or, in larger deficits, microvascular free flaps. These can be combined with associated vascularized bone transfer such as fibula or rib (with attached intercostal muscle pedicle), to treat significant bone loss.

Bone defects

In the cases of small structural defects reconstruction may be achieved with autologous cancellous bone placed under viable soft tissue.

Where a free tissue transfer is not a treatment option and local flaps are inadequate ‘open cancellous grafts’ can be considered. After initial debridement, granulation tissue is allowed to form at the base of the defect. Grafting is then placed on top of this vascular bed with protection by antibiotic-soaked dressings. These are changed every 3–5 days until the graft has stabilized. Occasionally, spontaneous epithelialization occurs; otherwise formal skin grafting covers the area.

In large bone defects the Ilizarov method may be used. Distraction osteogenesis can reconstruct both bony continuity and restore limb length. Bifocal treatment involves acute closure of the bone defect following debridement with an osteotomy and gradual lengthening through normal healthy bone undertaken either proximally or distally to the infected area (Figure 11.1.5). When the defect is too large for an acute closure then bone transport can be undertaken. A segment of viable bone is transported through the tissues, either in an antegrade or retrograde direction, producing new bone in its wake. The transport doughnut then ‘docks’ with the opposing segment and heals. One main disadvantage using these methods is the time in frame waiting for sufficient stability to occur as the regenerate consolidates before the frame can be safely removed. An estimate can be made of 30–40 days in the frame per centimetre of new bone formed. An alternative is to transport the fibula en bloc to fill a massive tibial defect utilizing the ring external fixator. Distraction osteogenesis also stimulates neoangiogenesis and this increased vascularity induces an improved host response with accompanying improved delivery of antibiotics leading to the saying ‘infection burns in the fire of regenerate’.
Fig. 11.1.5
Bifocal treatment of distal tibial osteomyelitis. The necrotic area is excised. The healthy bone ends acutely opposed. Lengthening proximally restores length.

Bone stability is essential as movement may enhance infection and delay healing. Internal fixation can be used but bacteria can adhere to implants utilizing a glycocalyx which protects from the effects of local antibiotics. Due to an absence of blood supply, systemic antibiotics also fail. External fixators are therefore the method of choice in achieving adequate bone stability: either monolateral (especially in the femur) or ring fixators can be used.

**Antibiotic therapy**

**When/which?**

Ideally antibiotics should not be administered until bone bacterial culture and sensitivities are known. Broad spectrum antibiotics can be commenced immediately following debridement and harvesting of specimens until the biopsy results are known when the optimum antibiotic may be given on advice from the microbiologist.

**Duration**

Following debridement bone takes, in general, 3–4 weeks for revascularization to take place. Antibiotics should therefore be administered for a minimum of this time and in most cases a 6-week course is advised. Long-term parental use can be facilitated by insertion of a Hickman catheter or long line. Oral therapy can be considered, often after a 2-week course of intravenous antibiotics. Occasionally, combination therapy is advocated, for example, vancomycin and rifampicin in the treatment of methicillin resistant *Staphylococcus aureus*.

**Local administration**

This can be provided by using polymethylmethacrylate (PMMA) antibiotic bead chains or collagen-impregnated sponges. Antibiotic concentration has been shown to be 200 times higher at local sites than levels achieved with intravenous therapy. Aminoglycosides are most commonly employed, specifically gentamicin. The antibiotic ttc levels diminish 2–4 weeks following placement and therefore ideally the PMMA beads should be removed. If infection persists then replacements can be placed following further debridement until the tissues are suitable for definitive reconstruction.

**Box 11.1.2 Treatment principles in chronic osteomyelitis**

- Surgical debridement—remove all devitalized necrotic tissue
- Dead space management:
  - Soft tissue defect—avoid healing by secondary intention. Consider local and free flaps
  - Bone defects—small structural with autologous bone graft, consider Papineau ‘open bone grafting’ where free tissue transfer is not an option, distraction ostegenesis with bifocal and bone transport for large defects including fibula transfer
- Bone stability—movement needs to be eliminated
- Antibiotic therapy—based on culture and sensitivity, local administration with PMMA beads or collagen sponge, Lautenbach procedure in resistant cases.

The Lautenbach procedure has been shown to be successful in treating long-standing infection when debridement and antibiotics have failed. Following intramedullary reaming, two double-lumen tubes are placed proximally and distally within the long bone traversing the whole canal. The outer tube is perforated at intervals and is used to drain the effluent. The inner tube is used to administer the antibiotics. The system provides a continuous circulation within the intramedullary cavity. Free drainage is performed for 30min every 4h. Irrigation fluid samples are taken twice weekly for culture and the tubes are removed after three negative cultures.

**Miscellaneous**

**Brodie’s abscess**

This is a localized abscess that presents with pain but often the patients have no systemic signs. Typically there is a single lytic lesion located near the metaphysis of a long bone. *Staphylococcus aureus* is the commonest organism and simple debridement is often curative with appropriate antibiotics.

**Sclerosing osteomyelitis of Garré**

Radiographically there is thickening and distension but abscesses and sequestra are absent. The cause is thought to be due to a low-grade infection but cultures following biopsy are often negative. Patients present with pain and swelling but there is no accepted treatment; fenestration of the bone may be helpful.
Chronic recurrent multifocal osteomyelitis

Described as inflammation of the bone, this is similar to osteomyelitis but without infection present. It presents with insidious onset of pain at different sites. The natural history is for fluctuating symptomatic episodes resolving spontaneously after approximately 2 years. Treatment is aimed at pain control with non-steroidal anti-inflammatory medication. There is no use for antibiotics.

Further reading

Leprosy

Leprosy is one of the oldest diseases known, and there are currently estimated to be 12–15 million cases worldwide.

Microbiology and pathology

The causative organism is *Mycobacterium leprae*. It is of very low virulence, and the incubation period varies from 3–5 years for tuberculoid leprosy and 9–11 years for lepromatous leprosy. Human beings are the only significant reservoir of the bacterium, and transmission is mainly by droplet spread and human contact via broken skin and nodules.

*M. leprae* selectively invades nerves. The extent of damage depends on the cell-mediated immunologic response of the patient. If immunity is high, bacterial multiplication is arrested early and a localized form of the disease results (tuberculoid type). An active granulomatous response occurs with destruction of axons and early neurological deficit results. If immunity is low, a severe and generalized form of the disease results (lepromatous type) with no immune response and no neural damage. These two types form the ends of the clinical spectrum of the disease, with intermediate types being described, and clinical presentation is varied.

Mixed nerve trunks are usually involved, at subcutaneous sites, often close to tight osteofascial canals or joints where the inflamed and swollen nerves are prone to further damage by joint motion and external trauma (Figure 11.2.1). The nerves involved are, in order of frequency, the ulnar nerve above the elbow (high ulnar type) or at the wrist (low ulnar type), the median nerve at the wrist, the common peroneal nerve at the fibular neck, the facial nerve, and the radial nerve.

Clinical features and treatment

The hand

The neurological deficit in leprosy is often apparent as a claw hand. The commonest combination of deficit is a high ulnar and a low median nerve paralysis. Radial nerve involvement is less common and only occurs in combination with involvement of the other two nerves.

Corrective surgery may be performed after there is a good clinical response to leprosy treatment, with no tenderness over the nerve trunks and no history of neuritis during the preceding 6 months. Surgical procedures are designed to restore grasp and pinch.

The foot
Foot drop is the commonest deformity, resulting from involvement of the common peroneal nerve as it crosses the fibular neck. Rarely, tibial nerve involvement at the level of the ankle joint produces complete intrinsic muscle paralysis of the foot resulting in clawing of the toes. The development of a neuropathic foot leads to secondary deformities in untreated cases.

Ulcers are common in the anaesthetic foot, particularly in the presence of deformity, and occur particularly over pressure points. Skeletal deformities must be appropriately corrected so that high pressure zones are removed, and prevention depends on education in the importance of proper care of the foot.

Treatment in the acute situation may involve irrigation, drainage, and antibiotics. In the case of a chronic ulcer, thorough cleaning and debridement of all necrotic and infected tissues is performed, with elevation and daily dressings. The leg is then protected in a well-moulded below-knee walking cast.

**Brucellosis**

Various strains of *Brucella* can affect the joints and cause osteomyelitis. The lumbar spine or sacroiliac joints are commonly involved (Figure 11.2.2). Brucellosis may cause a monarticular arthritis with isolation of the pathogen, or a polyarticular reactive arthritis where no organism is isolated. Differentiation from tuberculosis can be difficult, but characteristically brucellosis produces a combination of lytic and blastic lesions. X-rays show early bone repair with dense sclerosis and syndesmophytes. The characteristic radiological feature is erosion of the anterosuperior margin of the vertebral body (Pons sign) with rounding of the corner and decrease in the disc space. Doxycycline alone, or combined with streptomycin or gentamicin is usually effective.

![Click to view larger](image)

**Fig. 11.2.2**

Extensive brucellosis infection of the lumbar spine. There is less vertebral destruction than in tuberculosis infection, and there is prominent new bone formation with significant bridging spondylophytes (parrot beak appearance) even before complete cure of the disease.

**Syphilis of bone and joints**

Syphilis is caused by the spirochete *Treponema pallidum* and is sexually transmitted. The blood-borne organism lodges in the vascular metaphysis and produces a low-grade inflammatory response. In patients with inadequate host-defences, extensive necrosis of periosteum and bone occur with a yellowish gummatous sticky exudate (gumma). Beyond the central area of necrosis, an osteoblastic reaction is characteristic.

In the child, infection of the metaphysis interferes with endochondral ossification, with granulation tissue invading the zone of calcified cartilage. The long bones are particularly involved, especially the tibia, and the skull and nasal bones. The child with early congenital syphilis presents with a large tender swelling and reluctance to move the limb. Radiographs are typical, showing lucency of the metaphysis with sclerosis at the epiphyseal border. A fracture of the epiphysis may occur. Treatment usually produces rapid recovery with little subsequent interference with growth.

**Box 11.2.1 Leprosy**

- Caused by *Mycobacterium leprae*
- Low virulence, incubation period 3–5 years
- Selective invasion of nerves
- Upper limb—claw hand due to high ulnar lesion
Lower limb—drop foot due to peroneal nerve involvement
Tibial nerve involvement can result in neuropathic ulcers.

In late congenital syphilis, osteoblastic changes around the tibia, femur, and skull are seen. Asymmetric periosteal bone formation in the tibia produces bowing (saber shin). The phalanges and metacarpals appear spindle-shaped. Painless effusions of the knee may be seen in the second decade (Clutton's joints). Little residual damage is usually seen, and the child remains well.

In an adult, bone and joint lesions occur many decades after the primary stage, and are characterized by thickening of skull and long bones without pain or inflammation. Extensive necrosis of bone occasionally leads to a draining sinus. Joints are involved only secondarily by direct extension. Peripheral neuropathic changes produce Charcot joints.

**Box 11.2.2 Syphilis**

- Caused by the spirochete *Treponema pallidum*
- Metaphyseal bone involvement, bone necrosis with a yellow gummatous exudates
- Lucency with surrounding sclerosis
- Asymmetrical periosteal bone formation in the tibia produces characteristic bowing (saber shin)
- Peripheral neuropathic changes can result in Charcot joints.

*T. pallidum* is highly sensitive to penicillin and the disease is completely curable.

**Hydatid disease of the bone**

Hydatid disease is caused by the parasitic tapeworm, *Echinococcus*, and is transmitted in the faeces of hosts such as dogs. Skeletal hydatidosis is rare (0.5–4%). There is a latent period of many years or decades before symptoms manifest, so that it is only seen in the second to fourth decades.

The vertebrae, long bones, the pelvis, skull, and ribs are affected in descending order of frequency. Extension of the cyst occurs along the medullary canal, but once the cortex is breached, the cyst expands into adjacent soft tissues. Cysts elsewhere are usual (liver and lung). Clinical presentation is usually with a pathological fracture or pressure over a neurovascular structure.

Radiographs show lucent areas with thinned out cortices and expansion of the bone. Resorption of bone without a periosteal or sclerotic reaction is characteristic (Figure 11.2.3). Calcification within soft tissue shadows is reported to be an important diagnostic sign of hydatid disease.

Fig. 11.2.3
Computed tomography scan of the pelvis demonstrating hydatid disease with destruction of the acetabulum.

In the spine, the lower thoracic and lumbar vertebrae are most commonly involved. The trabeculae are eroded but the vertebrae maintain their shape until late, and the discs are relatively resistant. Large cysts form in paravertebral areas. Extension into the spinal canal often leads to neurological symptoms. Patients present with localized back pain with or without radicular pain, with paraparesis in more than 50% of cases. It is often confused with tuberculosis.

Treatment requires complete excision of the involved tissues and graft reconstruction, although this is rarely possible. Recurrence is therefore common. Drug treatment may occasionally be successful in eradicating the disease.

**Mycetoma**

Mycetoma is a fungal infection of the foot causing painless swelling, induration, and sinus formation with discharge of fungal grains.
It is common in the tropics. Infection is usually via inoculation by a thorn prick; hence it is common in agricultural workers and barefoot walkers. It is caused by two main groups of organisms: the true fungi (infections termed eumycetoma) and actinomycetes (infections called actinomycetoma).

![Click to view larger](Fig. 11.2.4)

Clinical picture of long-standing mycetoma showing 'tumefaction' with a swollen and misshapen foot. There are numerous closely placed sinuses extruding the characteristic granules which help in identification of the infecting organism.

Radiographs show erosions of bone in eumycotic infections, and small cavities with sclerosis in actinomyctoic disease (Figure 11.2.5). Streptomycin or co-trimoxazole may be successful in the treatment of actinomycetoma, although eumycetomas are more resistant to chemotherapy. Surgical excision of the affected area (usually below-knee amputation) may be required in late or resistant cases.

![Click to view larger](Fig. 11.2.5)

In advanced mycetoma, although the foot is enormously enlarged, there is extensive destruction of the bones and the metatarsals appear thinned out. Multiple cavity formation in the tarsal bones and ‘pencilling’ of the metatarsals are characteristic. There is no sclerosis until super-added secondary infection occurs.

**Salmonella infection**

*Salmonella typhi* and *S. paratyphi* can cause metastatic bone and joint infections by haematogenous spread. The long bones, chondrosternal junction, and the spine are common sites of involvement. Predisposing factors include sickle cell anaemia, young children, diabetes mellitus, and steroid therapy.

Osteomyelitis is the common mode of presentation, although septic arthritis can occur, either as direct extension from adjacent bone, or by haematogenous infection. Knee, shoulder, hip, and sacroiliac joints are commonly involved.

*Salmonella* gastroenteritis can also be accompanied by a reactive polyarthritis, presenting about 10 days following the gastrointestinal episode. Knees, ankles, and wrist joints are most commonly affected.

Radiographs show numerous punched out lytic lesions in the metaphysis extending into the diaphysis. Irregular sclerosis with subperiosteal bone formation is seen.

*Salmonellae* are highly sensitive to third-generation cephalosporins.
**Staphylococcus aureus infections associated with Panton–Valentine leucocidin**

Panton–Valentine leucocidin (PVL) is a bacterial exotoxin that is usually associated with skin and soft tissue infections and necrotizing pneumonia. However, in the last few years, an increasing number of musculoskeletal infections have been reported.

**Microbiology and pathology**

PVL can be secreted by methicillin-sensitive or methicillin-resistant strains of Staphylococcus aureus, and in Britain is secreted by 1–2% of Staph. aureus isolates. It produces a particularly virulent infection via leukocyte destruction, thereby impairing the immune response, and tissue necrosis. Deep venous thrombosis, septic emboli, and coagulopathy are common. In bones, intravascular coagulation means that pus rapidly becomes loculated, glutinous, and difficult to drain, and the true extent of bony and soft tissue involvement is often more extensive than suggested clinically.

**Clinical presentation**

Patients usually present with extremity pain with or without swelling, which may not be marked initially and may be misdiagnosed as minor trauma. If not treated appropriately and with a high index of suspicion, deterioration is rapid, with septic shock common. Full intensive care support with ventilation and inotropes may be required. Early magnetic resonance imaging (MRI) is vital to reveal the presence and extent of bone and joint involvement and guide appropriate surgery. Diagnosis requires identification of the PVL from the causative organism.

**Treatment**

A recent case series has emphasized the importance of early surgical intervention to debride poorly vascularized areas of infection. Joints must be aggressively and repeatedly washed out, with bones drilled and debrided thoroughly. Surgical eradication of all infected material is of paramount importance, and often requires repeated surgery. Clindamycin and rifampicin are usually advised as anti-staphylococcal medication, and need to be continued for many months. Decolonization therapy in affected patients and close relatives may also be required.

The incidence of musculoskeletal complications following these severe infections is high. There should therefore be a high index of suspicion for all staphylococcal bone and joint infections, with routine requesting of the PVL status of every staphylococcal infection, early MRI scanning and aggressive surgery in positive cases.

**Poliomyelitis**

An acute viral infection causing neural damage to the anterior horn grey matter of the spinal cord resulting in an asymmetrical lower motor neuron palsy. The motor neuron cells are irreparably damaged or rendered temporarily functionless. Immunization has almost eradicated polio from many developed countries but it still remains prevalent in others—in India up to 150 000 new cases a year have been reported.

**Stages of disease**

- **Acute:** fever which lasts for a few days with rapid onset of flaccid paralysis. Muscles affected may be painful to passive stretch
- **Recovery stage:** lasts for 18 months to 2 years. Progressive recovery of muscle power, most recovery is within the first few weeks
- **Permanent residual paralysis:** adaptation to weakness and possible development of secondary skeletal deformity.

The lower limb is most frequently affected. Muscle imbalance results in deformity, the most common example is equinus due to paralysis of tibialis anterior with sparing of the triceps surae. Gait is affected with weakness in knee extension. Patients will walk with their hand on their affected knee preventing collapse in stance due to quadriceps weakness (Figure 11.2.6).
Progressive deformity will occur in the skeletally immature. Lack of stretch will produce a slower rate of growth of the affected muscle resulting in further contracture and possible bone deformity.

Common skeletal deformities

- Trunk: scoliosis
- Hip: flexion contracture associated with adduction/external rotation or adduction/internal rotation
- Knee: flexion, extension, valgus deformity
- Foot: equinus, calcaneus, midfoot varus and valgus
- Upper limb: pronation, supination, and/or intrinsic hand contractures.

Treatment principles

During the acute stage, appropriate splinting and limb posturing to avoid contractures. Passive range of motion exercises to minimize deformity due to muscle imbalance.

Surgical principles

- Restoration of muscle imbalance with appropriate tendon transfers
- Joint deformity may respond to serial casting, moderate deformity corrected with tendon lengthening and capsule contracture release. Severe deformity may require corrective periarticular wedge osteotomies (e.g. supracondylar femoral extension osteotomy for knee flexion contracture)
- Joint stabilization by tendon transfer and/or orthotic support. Arthrodesis is a last resort
- Limb inequality can be achieved with shoe raises and by formal lengthening using distraction osteogenesis.

Box 11.2.3 Polio

- Viral infection
- Damage to anterior horn grey matter of spinal cord
- Stages of disease:
  - Acute fever lasts for a few days with rapid onset of flaccid paralysis
  - Recovery lasts up to 2 years, progressive recovery of muscle power
  - Permanent residual paralysis
- Immature skeleton can deform and fail to grow
- Treatment in acute phase to prevent contracture
- Surgery to restore function, tendon transfer, tendon lengthening, osteotomy, and lengthening procedures.

Tuberculosis

Tuberculosis (TB) continues to be a cause of death and disability in many parts of the world. Most commonly seen in underdeveloped countries, it is being increasingly seen in developed countries, attributed to global travel and immigration as well as increasing elderly populations and more people with suppressed immune systems—seen in patients taking immunosuppressive drugs and AIDS patients. The cause is mycobacterium, predominantly Mycobacterium tuberculosis (human type) although there are other types such as M. bovis, M. africanum (restricted to African countries), M. canetti, and M. microti.

Mycobacterium tuberculosis is an aerobic bacteria spread through air when affected patients cough, sneeze, or spit. It is a small rod-like bacillus and is classified as an acid-fast bacillus (AFB). The Ziehl–Neelsen stain dyes the AFB bright red. It does not grow on ordinary culture medium, requiring an enriched albumin base. There is a very slow growth rate with colonies only seen 2–4 weeks after inoculation.

Clinical manifestations

Pulmonary TB accounts for 75% of cases; skeletal tuberculosis is uncommon, involving 3–5% in total. Spinal involvement represents almost half of these cases (see Chapter 3.18). Haematogenous spread from a primary focus reaches the skeletal system by arterial vessels except the spine where spread via Batson’s plexus of veins can also occur.

Systemic symptoms (Box 11.2.4) include fever, chills, night sweats, appetite loss, weight loss, and fatigue. Skeletal infection is usually mono-osseous or monoarticular. Localized symptoms characteristically involve pain and loss of function. With progression...
of disease, joints become deformed by destruction and assumption of a comfortable position. Joint involvement is seen to pass through characteristic stages—initial synovitis with soft tissue swelling, slight reduction in joint movement, and little pain. Early arthritis with decrease in joint space leads to advanced arthritic changes, significant restriction in movement, and increasing pain. Eventual joint destruction with minimal movement and severe pain on movement can lead to fibrous ankylosis.

**Box 11.2.4 Systemic symptoms of tuberculosis**

- Fever
- Night sweats
- Appetite and weight loss
- Fatigue and general malaise.

Diagnosis is made with identification of the causative organism following biopsy. A high index of suspicion is often warranted in cases with minimal symptoms at presentation. A history of travel or recent immigration must be noted. The tuberculin skin test indicates exposure to the bacteria but does not indicate active disease and therefore may not be relied upon to make a diagnosis.

**Treatment**

Combination chemotherapy is mandatory, operative intervention is an adjunct to medical therapy. The choice of drug is dependant on sensitivity to the organism and must include one which is bactericidal. Multiple therapies are performed in an attempt to avoid bacterial resistance. Prolonged therapy, of several months, is necessary to eliminate small groups of ‘persistent’ bacilli. An initial intensive phase of three or four drugs is followed by a continuation phase of two drugs.

**Box 11.2.5 Stages of tuberculosis arthritis**

- Synovitis: minimal pain, doughy swelling, minimal loss of movement
- Early arthritis: painful movements, joint space narrowing, marginal joint erosions
- Advanced arthritis: fixed deformities seen, destruction of joint surfaces and adjoining bone

Surgical intervention due to the success of the chemotherapeutic drugs has a limited indication. Emergency decompression in tuberculosis paraplegia aside, abscess drainage may be conducted dependent on symptoms and functional loss and may not be required. Joint involvement requires drainage and potential debridement. Immobilization in a functional position can lead to a functional ankylosis. In the cases of joint instability, formal arthrodesis may be required. Joint arthroplasty can be considered but prolonged disease inactivity prior to surgery with 3 months of chemotherapy prior to joint replacement followed by several months of therapy postoperatively is advised.

**Box 11.2.6 Primary antituberculosis chemotherapeutic drugs**

- Isoniazid—bactericidal
- Rifampicin—bactericidal
- Ethambutol—bacteriostatic
- Pyrazinamide—bactericidal
- Streptomycin—bactericidal
- Para-aminosalicylic acid (PAS)—bacteriostatic.

Amputations and prostheses

Summary points

- Amputation surgery should produce a new end-organ for locomotion with a prosthesis or interaction with the environment
- The choice of amputation level should be based on healing, functional expectations, and prosthetic use
- Success of rehabilitation depends on multi-disciplinary input and management of complications
- The prostheses prescribed should depend on functional need and expectation.

Introduction

Amputation, from the Latin amputare (to cut away), can be considered as one of earliest surgical procedures. Initially performed as a punishment, surgical techniques have been improved, mainly pioneered by military surgeons during the great wars, to produce functional stumps to support prosthetic wear and rehabilitation.

Indications for amputation

Amputation of a limb may be indicated to relieve symptoms (e.g. ischaemic rest pain), to remove a non-viable part of a limb (e.g. gangrene or a crushed limb), to preserve life (e.g. malignant tumour), or to improve function and quality of life (e.g. neuropathic foot or congenital limb deficiency). The commonest cause for amputation in the United Kingdom remains vascular disease (67%), including arteriosclerotic large vessel disease, and diabetic vascular disease. Only 9% of amputations are due to trauma, mainly being performed late after limb reconstruction has failed. Rarer causes include infection (7%), tumours (3%), neuropathic (1%) changes, and congenital limb deficiencies. Upper limb loss is much less frequent with a greater majority being secondary to trauma. The subject of congenital limb deficiency has been considered in Chapter 13.14.

The principles of amputation surgery

The purpose of amputation is not only to remove the diseased or damaged part of a limb to produce a healed stump, but equally to produce a new end-organ for locomotion (lower limb) or interaction with the environment (upper limb)(Box 11.3.1). Meticulous handling of the soft tissues is important to create a well healed functional stump. Tourniquet should be utilized in all cases except those with peripheral vascular disease.

Box 11.3.1 Indications for amputation

- Relieve symptoms—ischaemic pain
- Remove non-viable limb—gangrene
- Preserve life—malignancy
- Improve limb function—neuropathic foot, congenital limb deficiency.

- Skin. The stump should have healthy skin coverage which should be mobile and sensate. Avoidance of scar and skin adherence to the underlying bone is paramount
- Muscle. Conventionally the muscles are cut a few centimetres distal to the bone cut to allow retraction. The muscle can be debulked in order to reduce stump size (Figure 11.3.1). If myodesis is to be performed, as in a knee disarticulation or above-knee amputation, the muscles are cut approximately 5cm distal to the bone end to allow repair of the opposing muscles without tension
- Nerves. Gentle traction of the nerves before division with a sharp knife as proximal as possible to allow retraction and avoid the nerve end in the resulting scar tissue. Avoid over traction which can contribute to neuroma formation
- Blood vessels. Individual vessels should be ligated with either absorbable or non-absorbable sutures. Personal preference is for double ligation of major arteries. Meticulous haemostasis is required to avoid haematoma formation. Tourniquet should be released prior to muscle repair. A submuscular surgical drain should be placed
- Bone. Excessive periosteal stripping should be avoided. Optimum length is determined by amputation level, proximal joint function, and prosthetic requirement. For example, if no prosthesis is intended then an above-knee amputation may be made in the supracondylar region to maintain as much length as possible to aid balance.
Fig. 11.3.1
Bulbous distal soft tissues in a transtibial stump will adversely affect limb fitting.

If gross contamination or major sepsis is present at the time of amputation, a delayed primary closure after 5–10 days is wise. Good perioperative pain control is essential. There is some evidence that epidural anaesthesia and analgesia in the perioperative period may reduce subsequent phantom limb pain.

Choice of amputation level

In general, amputations should be carried out at the most distal level at which healing can be achieved, though there are exceptions. An ideal stump for ‘prosthetic’ use of a lower limb should be of an appropriate length. In general, optimum femoral bone length is approximately 15cm proximal to knee joint level; for transtibial amputation residual bone length may be calculated as 8cm for every metre of height. Preservation of joints is important, though for prosthetic fitting adequate length and ‘clearance distance’, i.e. distance from the end of the amputation stump to the level of the contralateral joint line, is recommended. This is to ensure space to accommodate sophisticated prosthetic units and maintain level joints. Good end-bearing properties of through knee disarticulation, Gritti–Stokes amputation, or a Syme’s amputation may be crucial to maximize function but may present problems of satisfactory appearance of the prostheses. Prostheses for Syme’s amputation and knee disarticulation are cosmetically poor and these amputations should be avoided if ‘cosmesis’ is important.

Fixed contractures in proximal joints compromise alignment and leads to unsatisfactory gait and weight bearing. Excessive contractures may preclude prosthetic use. For patients who are likely to walk or stand to transfer, an attempt should be made to preserve the knee joint. However, if a patient is likely to remain bed- or chair-bound, a through knee disarticulation or Gritti–Stokes amputation may be preferable to ensure satisfactory end bearing and bed mobility.

Box 11.3.2 Principles of amputation surgery

♦ Skin: healthy, sensate, and repaired tension free
♦ Muscle: debulked to reduce stump size
♦ Nerves: gentle traction before division proximally with a sharp knife
♦ Blood vessels: double ligation
♦ Bone: avoid periosteal stripping with adequate length.

In the foot, a metatarsal amputation requires a minimum of prosthetic help and produces minimal disability. Hindfoot amputations like Chopart and Lisfranc procedures, tend to result in an equinovarus deformity, are prone to skin breakdown and are difficult to fit with a prostheses that can be worn with a normal shoe. Through hip and hindquarter amputations are fortunately rare, normally as a result of malignant disease or severe trauma. The prosthesis is required to embrace the whole pelvis and mobility remains poor.

In upper limb amputation, especially in the hand, no prostheses can adequately replace an injured hand, and so as much of the hand as possible should be preserved.

Rehabilitation

The rehabilitation programme should ideally start before the amputation. If the amputation was an elective amputation and an ‘optional’ treatment rather than a ‘necessity’, a pre-amputation consultation with the rehabilitation team is strongly recommended. Success in rehabilitation depends on the input of a multi-disciplinary team.

Physiotherapy should start early and include general mobility in bed, transfers, exercises of the stump and proximal joint, supervision of wound healing, and physical measures to control postoperative oedema. A rigid plaster of Paris dressing provides protection and reduces postoperative oedema, but there are risks of ischaemia and infection and is best avoided in dysvascular
amputations, except in specialized units. Lightly elasticated tubular bandages are used followed by use of elasticated and graduated pressure stump shrinkers (e.g. Juzo™) once wound healing is ensured. Early walking aids (EWAs) allow the patients to stand and walk early with the physiotherapist and assist in control of stump oedema, improve standing and walking and morale. Commonly used types are the pneumatic post amputation mobility (PPAM) aid (Figure 11.3.2) for the trans-tibial amputation with a maximum pressure of 40mmHg, or a Femurette™ for a transfemoral amputation (Figure 11.3.3).

**Box 11.3.3 Amputation level**

- Most distal level that healing can be achieved
- Preserve joints if possible (knee/elbow)
- Avoid amputation below joint contracture
- ‘Clearance distance’ to allow prosthetic joint placement
- In general:
  - 15cm proximal to knee joint for femoral stump
  - 8cm per metre of patient height for tibial stump
  - Syme’s amputation gives better function than Boyd, Chopart, or Lisfranc.

**Fig. 11.3.2**
The Pneumatic Post-Amputation Mobility Aid (PPAMAid) consists of an inflatable plastic sleeve within a metal frame, with rocker end.

**Fig. 11.3.3**
Femurett early walking aid for transfemoral amputees; the length and alignment are readily adjusted using a single Allen key. Adjustable sockets in three different sizes can be interchanged quickly.
Following provision of an appropriate prosthesis, gait re-education is essential. It may be particularly complex if the prosthesis prescribed has complex components like hydraulic or microprocessor-controlled prosthetic joints. Rehabilitation should be planned with targeted goals to help the patient achieve maximum potential. Their general medical condition and presence of comorbidity are obvious influencing factors.

Commonly used outcome measures are listed in Box 11.3.4. Less commonly used outcome measures are the Trinity Amputee and Prosthetic Scales (TAPES) and the Prosthetic Profile of the Amputee Questionnaire (PPA).

Box 11.3.4 Commonly used outcome measures in United Kingdom rehabilitation of the amputee with prostheses

- SIGAM Mobility Grade
- Harold Wood Stanmore Mobility Grade
- Locomotor Capability Index
- Timed Walking Test
- Socket Comfort Score
- Barthel Index for activities of daily living
- Hospital Anxiety & Depression Scale.

Laboratory gait analysis is generally reserved for research or complex gait problems.

Problems following amputation

Surgical

Early

- Haematoma: avoid with meticulous haemostasis and avoidance of dead space
- Delayed healing due to ischaemia: appropriate level selection
- Infection: consider prophylactic antibiotics
- Skin necrosis: allow adequate skin flaps sutured without tension. Extensive necrosis in ischaemic limbs may indicate inadequate peripheral circulation and need to consider re-amputation at a higher level.

Late

- Soft tissue: contractures can occur if a limb is kept in a position of comfort, for example, hip flexion following above-knee amputation. Unopposed contracture of certain muscle groups can also result in joint deformity, for example, equinus deformity following Chopart amputation, hip adduction deformity following low transfemoral amputation, or hip flexion contracture following high transfemoral amputation. Muscle migration following fixation failure to bone can result in bony prominence and painful pressure points. Detachment of the myoplasty or myodesis may require revision surgery
- Epidermoid cysts, occasionally infected, may form as a result of skin movement and pressure of the brim of the socket, generally managed conservatively with socket adjustment, wound dressing, and antibiotic therapy, but if troublesome sinuses are formed, surgical intervention may be necessary
- Bursa formation over bony prominences: may need antibiotic therapy if infected or surgical excision if recurrent and refractory to conservative management
- Neuroma formation: always form at the end of the cut nerve. This is associated with excessive traction at time of division or if the end is within scar tissue
- Bone: bony spurs can occur which can produce painful pressure points. Widespread heterotopic bone formation is associated with excessive periosteal stripping. Recently heterotopic ossification (HO) has been found to be common in amputation following blast injuries.

General

- General problems include psychological problems and difficulty in accepting the limb loss. Counselling may be helpful and it is recognized that the need for psychological help is greater in traumatic amputees and in those who have had an upper limb loss and the time of this need is greatest at 12 months after the amputation
- Other problems include the increased energy requirement for walking with prostheses. This ranges from 10% over and above normal energy requirement for below-knee traumatic amputees, 60% for transfemoral amputees, to over 200% for bilateral transfemoral amputees
- Phantom sensation and phantom pain are recognized complications, though the incidence is decreasing with improved perioperative and multidisciplinary management in rehabilitation. Phantom pain may remain troublesome in 20–30% of amputees and may require various pharmacological or physical treatment modalities. Psychological therapies like distraction,
relaxation, or cognitive behaviour therapy as part of a holistic pain management programme may be required in difficult cases. Rarely, nerve blocks or stimulator implants may be required.

- Increased incidence of degenerative changes in hip and knee joints and back pain due to mechanical factors from altered gait patterns are seen following long-term use of prosthesis.

**Principles of prostheses**

The most important part of any prosthesis is the socket, as this provides the interface between the residual limb and the prosthesis; if the socket is not comfortable, the most sophisticated prosthetic componentry will be of no benefit. Although leather and aluminium alloy are still used for some sockets, the vast majority are now made either of thermoplastic materials like polypropylene or of laminate plastic construction with glass- or carbon-fibre reinforced acrylic or polyester resin. Considerable forces have to be transmitted through the stump-socket interface of lower-limb amputees—several times body weight during vigorous activities. With the exception of amputations through or very close to joints, amputation stumps will only tolerate slight pressure directly under the distal bone end, so traditionally most sockets have been mainly proximally load-bearing, through the ischial tuberosity in the case of transfemoral, or the patellar tendon in the case of transtibial amputations. Most sockets now are of total-contact type, so that weight-bearing is spread more evenly, although the plaster cast of the stump from which the socket is made is first ‘rectified’, to increase loading in these tolerant areas and to reduce loading over areas such as the distal femur and head of fibula which are intolerant of pressure. Most sockets are worn over a cotton, wool, or polyurethane gel sock, but self-suspending suction sockets are worn next to the skin.

Most lower-limb prostheses used in the United Kingdom are now of endoskeletal construction, in which the socket is linked to the foot by an internal tubular structure of carbon fibre or aluminium, and this together with the joints, if applicable, and devices for adjusting the alignment of the socket and foot, are enclosed in a soft foam cosmetic cover with an outer woven, PVC, or silicone skin. Most, but not all, endoskeletal prostheses are of so-called modular construction, in which the component parts, apart from the socket, are prefabricated and clamped or bonded together, making assembly and subsequent adjustment or repair easier and quicker. In exoskeletal prostheses, the outer visible part of the prosthesis is the structural component.

The majority of upper-limb prostheses are of exoskeletal type. Even though they are much lighter than the natural limb which they replace, almost all prostheses feel heavy to the user, even more so for elderly amputees, so the aim is always to make the prosthesis as light as possible, compatible with strength. However, the extra comfort, stability, or function provided by more sophisticated componentry or socket materials often carries a weight penalty; this is the main disadvantage of electrically powered upper-limb prostheses. Summary of prostheses in Box 11.3.5.

**Box 11.3.5 Summary of prostheses**

- **Socket:**
  - Accommodates stump and interface between prosthesis and residual limb
  - Appropriate for load and pressure distribution, historically ischial tuberosity or patellar tendon bearing, now total surface bearing
  - Made of thermoplastic or composite, i.e. carbon fibre

- **Suspension:**
  - Rigid or soft belt
  - Self-suspension, e.g. bony contour (supracondylar/supramalleolar)
  - Silicone or gel sleeves combine good skin protection and a suction concept of suspension

- **Joints:**
  - Knee: simple locked or free knee, single axis, four bar or multilink if space limited, hydraulic or pneumatic mechanisms more functional; these are typically weight or position activated
  - Microprocessor control of swing/stance current state of art
  - Ankle and foot: simple SACH to dynamic energy storage, or specific activity (running or water activity)

- **Shaft/shank:**
  - Carbon fibre, titanium, or aluminium

- **Extras:**
  - Torque rotator (to allow rotation of the prosthesis in vertical axis)
  - Telescopic devices for shock absorption
  - Cosmesis.

**Transtibial amputation**
The two standard methods of fashioning a transtibial stump are the long posterior flap method (Figure 11.3.1), or the so-called ‘skew-flap’ technique (Figure 11.3.4). The difference is mainly in the skin flaps, as both employ a long posterior muscle flap, which is basically gastrocnemius, as most of the soleus should be removed distal to the level of bone section to avoid an excessively bulky distal stump. Both methods result in similar healing but the shape of the skew flap generally facilitates early limb fitting.

Most prosthesis for the transtibial amputation are endoskeletal construction and use a rigid plastic socket with cuff suspension and worn over a cotton sock. However, there is increasing use of silicone or gel liners which are worn next to the skin and also provide total contact and self-suspending properties (Figure 11.3.5). The figure describes this type of prostheses and not one with a cuff suspension.

The simplest type of prosthetic foot is the solid-ankle cushioned-heel (SACH) foot. More recently, various energy storage feet with different degrees of flexibility are available to suit different activity levels, including those for running.

**Transfemoral amputation**

The choice of skin flaps is less critical than for transtibial amputation, but usually equal anterior and posterior flaps are used. The anterior and posterior muscle groups are stitched over the cut end of the bone and if vascularity is not impaired, a myodesis is performed by suturing the muscles to holes drilled into the distal femur.

Most sockets (Figure 11.3.6) are ischial bearing or ischial containment, and there is increasing use of total-contact sockets. Distal soft tissue support improves proximal comfort and avoids venous congestion and chronic oedema. The anterior wall of the socket needs to be high to avoid the ischial tuberosity slipping off the posterior seating area.
The prosthetic knee may be a semi-automatic locked knee which locks itself on extension and thus ensures safety in a stiff knee gait. It is unlocked for sitting. Alternatively, an optional lock may be incorporated thus giving the individual the ‘option’ to walk with a locked knee over difficult and uneven terrain. Fitter individuals who can control a free knee require both stance and swing phase control for optimal gait. Stance stability is largely a function of the correct alignment of the prosthesis (the weight line should be slightly in front of the knee axis when the knee is extended), but mechanical ‘stabilized’ knees provide enhanced stability by locking on weight-bearing even in slight flexion (up to about 25 degrees). Polycentric knees provide stance control by ensuring that the knee extends fully (usually into slight hyperextension) even if weight is placed on a slightly flexed (up to 10–15 degrees) knee. Swing-phase control can be in the form of an extension assist spring, by controlled friction, or by means of an adjustable pneumatic or hydraulic damper. An electronically-controlled pneumatic swing phase unit can be used; this measures the swing rate of the knee, and then selects the most appropriate of three preset positions (or an intermediate position) of a needle valve, to provide the optimal setting for different walking speeds. More recently, electronic knee units are available where microprocessor controls are available for both the swing and the stance phase of gait. Heavy-duty hydraulic knees, which provide both stance and swing-phase control in one unit, suit the most active users, but are heavier than other types and most require more effort to drive them. Recently introduced hydraulic knees require less effort and suit a wider range of individuals. Polycentric knees are more compact, and are indicated when clearance above the level of the sound knee is limited. The choice of prosthetic feet is similar to those described for transtibial amputations.

**Upper limb amputations**

Most upper-limb amputations are due to trauma, and in many cases this will determine the level of amputation and the site of the skin flaps; if there is sufficient healthy skin, equal length flaps on the flexor and extensor aspects are best.

Upper limb prostheses are generally of three types:

1) Cosmetic or passive function prostheses, where there are no moving parts and the limb is essentially for ‘cosmetic appearances’, though can be used in a ‘passive manner’. If made of high-definition silicone, they look extremely realistic
2) Body-powered functioning prostheses with a range of different terminal appliances: many consider them cumbersome and cosmetically unacceptable but they remain most functional—the most versatile being the split hook. This type of prosthesis may be used for ‘targeted function’ at work or leisure
3) Myoelectric prostheses where surface electrodes are used within the socket which pick up electrical activity from the flexor and extensor muscles.

**Hand**

Even if the hand is severely injured, it is usually worth preserving as much of it as possible, although this may not apply if the remnant is devoid of sensation or if the wrist is immobile or flail. Even if only one digit remains, provided this has intact sensation, a simple opposition-type prosthesis can be fitted to give useful grip. Such a device would be needed if the thumb alone is lost (Figures 11.3.7 and 11.3.8), unless the index finger is to be pollicized. Loss of a single finger is not usually a great disability, except, for example, for a musician, but a minority do find this psychologically very disturbing and benefit from a silicone finger prosthesis, which can look very realistic. Recently, direct skeletal fixation of prosthetic fingers is being attempted. If all the digits are lost, a wrist-operated prosthesis can be fitted to provide useful grip.
Wrist and forearm

Although a through-wrist amputation has the advantage over a transradial amputation of preserving pronation and supination, it is difficult to provide a prosthesis that is both functional and cosmetically acceptable, and the choice of prosthetic hands is much more limited. The lightest, easiest to operate, and most precise terminal appliance remains the split hook (Figure 11.3.9). This is connected by an operating cord to a loop around the opposite shoulder, and shoulder flexion or elbow extension will open the hook, which is usually closed by elastic bands (the number of bands determining the grip strength and the effort required to open the hook). These devices are described as ‘voluntary opening’; voluntary closing hooks may also be used. Many, but not all, split-hook users also have a readily interchangeable cosmetic hand, which is covered in a PVC or silicone glove. Body-powered hands are heavier, provide less precise grip, and need more effort to open than split hooks, but look more natural. Electric hands provide similar function, with the option of powered wrist rotation, but many amputees reject them on account of their even greater weight. They may be operated by a switch in the prosthetic harness, or myoelectrically using electrodes within the socket which pick up the electrical activity in the flexor and extensor muscles; this has the advantage, if a self-retaining supracondylar socket is used, of obviating the need for any harness or straps. A large variety of special attachments can be fitted to non-powered arms, such as tool holders, and appliances for driving, typing, or golf. Sockets are of rigid or flexible plastic, or leather, which is often favoured by those engaged in heavy work.
Elbow

Loss of the elbow joint results in a much greater disability, and a more cumbersome and less cosmetic prosthesis, which is more difficult to operate. Therefore the elbow joint should be preserved if at all possible, and it is worthwhile considering skin grafts and free flaps if these would make this possible. Although anaesthetic skin is a considerable disadvantage, because the loads on the skin are much less than with a lower-limb amputation, it presents fewer problems in the upper limb.

Shoulder

A functional prosthesis is not usually helpful for through-shoulder or forequarter amputations. A lightweight cosmetic arm is possible using a hollow, rigid PVC hand, and a foam shoulder cap (extending only just distal to the shoulder) is valuable for the very disfiguring forequarter amputation and allows clothes to hang normally.

Developments

Recent developments being trialled include direct skeletal fixation using osseointegration or intraosseous transcantageous amputation prosthesis for attachment of the prosthesis to the amputation stump.

Acute osteomyelitis

Bacteraemia resulting in bone deposition of bacteria
Local bony tenderness, fever, and malaise may not be present initially
WCC may be normal, ESR and CRP normally raised
Plain radiographs normally take 10–12 days to occur
Staphylococcus aureus remains the commonest organism
Immediate antibiotics with surgical drainage of abscess formation.

Introduction
Osteomyelitis is inflammation of the bone caused by an infecting organism. It may be classified as acute, subacute, or chronic, determined by duration of symptoms.

Acute haematogenous osteomyelitis
Most commonly seen in children (see Chapter 13.1) it has a low incidence in adults following closure of the physis where capillary loops result in a predominance of metaphyseal childhood infection. In adults the immunocompromised host is most susceptible with infection seen most frequently in the elderly or adults with immune deficiency. The spine is the most common site (see Chapter 3.18) but any bone at any site may be involved. Bacteraemia results in deposition of bacteria at the site of bone involvement but factors such as malnutrition or localized trauma may contribute to the resulting infection.

Clinical presentation
Pain with local bony tenderness but fever and malaise may not be present initially. Local swelling is associated with periosteal or soft tissue abscess formation. Associated erythema and warmth are cardinal signs of infection. There may be loss of local joint function and with extreme pain on swollen joint movement septic arthritis must be excluded, the infection extending through the bone to directly involve the joint. In long-standing cases, cortical bone destruction can lead to pathological fracture.

Investigations
Blood tests: the white cell count may be normal. The erythrocyte sedimentation rate and C-reactive protein are usually raised
Radiological: plain radiographs in the acute phase show no changes, periosteal changes or cortical destruction normally take 10–12 days to occur
Technetium-99m bone scans will demonstrate increased uptake
Magnetic resonance imaging will show periosteal reaction, soft tissue involvement, and bone marrow inflammation.

Microbiology
The causative organism can be identified by blood cultures in approximately 50% of patients. Bone aspiration or pus specimens may be taken at surgical drainage
Staphylococcus aureus remains the commonest causative organism in adult osteomyelitis
Pseudomonas is often seen in intravenous drug abusers
Salmonella osteomyelitis is reported in patients with sickle cell disease, most often affecting the diaphysis. This, however, is still less common than Staphylococcus aureus.

Treatment (Box 11.4.1)
Systemic treatment should include limb splintage, analgesia, and fluid resuscitation
Antibiotics: intravenous administration of broad spectrum antibiotics are commenced immediately after culture specimens taken (blood and/or direct bone aspiration). Change is then directed by sensitivity and specificity after culture. Continuation is generally for 6 weeks although this is controversial. Debate also is undecided over timing of change from intravenous to oral route
Surgical drainage is indicated when significant subperiosteal or soft tissue abscesses are present. Drainage is usually via an incision centered over point of maximum tenderness. Bone drilling may be required both proximal and distal to the involved area to ensure complete drainage.
### Treatment of acute haematogenous osteomyelitis

- An appropriate antibiotic, effective prior to pus formation
- Avascular tissues and abscesses require surgical removal
- After successful removal, antibiotics should prevent recurrence and primary wound closure can be undertaken
- Surgery should not damage further already ischaemic bone and soft tissue
- Antibiotics should be continued after surgery.

- Surgical exploration may also be indicated if a patient fails to improve symptomatically after 24–48h of antibiotic treatment
- Packing of the wound with a planned second look, further debridement, and wound closure may be considered. The use of antibiotic beads or collagen sponge is not usually required.

### Outcome

Infection can recur several years following apparent successful primary treatment; most occur within 1 year, however. Therefore patients should be consented for recurrence and possible need for further treatment.

---

### Subacute haematogenous osteomyelitis

This has a more insidious onset with few symptoms. Pain may be present for some weeks with minimal systemic symptoms or signs. Often no temperature or malaise is present.

Blood tests are usually normal; the erythrocyte sedimentation rate may be slightly raised in 50% of cases. Radiographs and bone scans are positive and a classification based on radiographic changes was proposed by Gledhill and modified further by Roberts and colleagues (Box 11.4.2).

#### Box 11.4.2 Classification of subacute osteomyelitis

- Gledhill (1973):
  - I: solitary localized zone of radiolucency surrounded by reactive new bone formation
  - II: metaphyseal radiolucencies with cortical erosion
  - III: cortical hyperostosis in diaphysis; no onion skinning
  - IV: subperiosteal new bone and onion skin layering
- Roberts et al. (1982):
  - V: central radiolucency in epiphysis
  - VI: destructive process involving vertebral body

The lack of symptoms is thought to be due to increased host resistance. The differential diagnosis must include exclusion of a primary bone tumour and biopsy and curettage are advised. An organism is identified in only 60% of cases and those negative cases with a high index of diagnostic suspicion should be treated empirically with antibiotics for 6 weeks.

### Further reading

Introduction

Septic arthritis indicates inflammation of the joint due to the invading organism. Bacteria within the joint space in adult septic arthritis may occur from haematogenous spread but most commonly occurs due to direct inoculation either from trauma or iatrogenic joint penetration, for example, intra-articular injection or arthroscopy. Contiguous osteomyelitis can also spread to local joints. Once again a high index of suspicion is required in the elderly or immunocompromised with a swollen joint as other symptoms may be reduced. Associated conditions including rheumatoid arthritis and other seronegative arthropathies predispose patients to septic arthritis, especially when joint aspiration and intra-articular steroid injections are undertaken.

Following infection, synovial infiltration with inflammatory cells, initially with polymorphonuclear leucocytes, are replaced with chronic mononuclear cells by 3 weeks. The inflammatory response results in an effusion which can become large enough to result in joint subluxation or even dislocation. This will also eventually result in articular cartilage destruction although the specific mechanism of this remains unknown—it is thought to be destructive enzymes within the exudate. This occurs as early as 4–6 days following initial infection, with total joint destruction by 4 weeks.

Clinical features

- Severe pain is present. This is significantly exacerbated with any attempted active or minimal passive motion. The patients generally lie very still and even movement of the examination couch can result in a terrible increase in pain
- Systemic symptoms are often present with fever and malaise (these may be absent in the immunocompromised patient)
- Local signs include a swollen joint with an effusion, warm to touch, with possible skin erythema
- Monoarticular involvement is typical with lower limb joints most often affected, the knee being the most common.

Investigations

- Blood tests will often show elevation of the white cell count, erythrocyte sedimentation count, and C reactive protein
- Radiology is usually unnecessary to make a diagnosis. Ultrasound, however, is particularly useful in demonstrating joint effusion, especially within the hip joint where it can aid in needle placement for aspiration
- Aspiration will confirm pus within the joint which can be sent for microbiology prior to antibiotic administration. A diagnosis is indicated with a synovial leucocyte count of greater than 50 000/mm$^3$ but this may be less in immunocompromised patients.

Organism

- Staphylococcus aureus remains the most common cause
- Neisseria gonorrhoeae is very common in young sexually active patients. This presents with polyarticular septic arthritis and a popular rash. Joint cultures are often negative but positive cultures may be obtained from the pharynx or urethra. In these cases appropriate antibiotics is usually sufficient treatment with surgical drainage unnecessary
- Adults with systemic lupus erythematosus have an increased risk of Salmonella infection and Pseudomonas and other Gram-negative organisms have a prevalence in intravenous drug abusers.

Treatment

The natural history of septic arthritis is known to result in eventual joint destruction and therefore this is an orthopaedic emergency which requires immediate treatment.

The principles of treatment include joint drainage and wash out. Systemic antibiotics are administered and the joint is splinted in a position of function. A drain can be placed to allow further drainage.
Drainage can involve formal joint arthrotomy and lavage or repeated joint aspiration. Arthroscopic lavage can also be considered in knee, ankle, shoulder, and elbow infection. My personal choice is open surgical drainage and wash out with saline.

If systemic and local symptoms do not resolve further, washout including formal open arthrotomy and debridement may be required within 24–48h following initial surgery.

The duration of antibiotics should continue for 4–6 weeks even if symptoms resolve quickly. After cessation of infection, treatment is concentrated on rehabilitation and restoration of joint function. Continual passive motion may inhibit adhesions and promote better nutrition to the cartilage. Residual joint deformity may respond to traction, serial casting, or dynamic splints. In the chronic ankylosed deformity, corrective osteotomy can place the limb in an optimal functional position.

Chapter: Fracture classification

Author(s): Thomas A. DeCoster

DOI: 10.1093/med/9780198550647.003.012001

Summary points

♦ The 2007 OTA Comprehensive Classification of Fractures and Dislocations is recommended as the standard for fracture classification
♦ Practitioners should be aware of the limited reliability and reproducibility of fracture classifications.

Introduction

The jargon of fracture description is learned early in orthopaedic training and helps to facilitate communication by identifying important parameter values in a qualitative way. The selection of adjectives such as ‘a displaced comminuted closed tibia shaft fracture’ identifies characteristics of an injury. Formal fracture classification is an extension of fracture terminology with specification of a number of groups with common and distinguishing factors (Box 12.1.1).

Box 12.1.1 Qualities of a good classification system

♦ All inclusive
♦ Mutually exclusive
♦ Reliable
♦ Reproducible
♦ Clinically relevant
♦ Logical
♦ Facilitates communication.

The benefits of classification include: 1) facilitates communication; 2) identifies prognosis and complication risks; 3) directs treatment; 4) enhances research.

All inclusive classification system

The classification should allow for all theoretical and practical patterns. A good example is the Neer classification of proximal humerus features which defines four anatomical parts to be considered. Since these four parts are present in every proximal humerus the classification is all inclusive.

Mutually exclusive classification system

The classification should allow for only one category for each pattern seen. A good example is extra-articular vs partial articular vs total articular. A poor example is the Gustilo and Anderson (1976) classification of open fractures. Type 1 open wound which is low energy, less than 1 cm long, and generally caused by bone piercing from the inside out while a type 2 wound is considered 1–5 cm with a moderate amount of soft tissue damage. A given injury which is 0.9 cm long with moderate soft tissue injury has qualities of both type 1 and type 2.

Reliability

Two different physicians should be able to identify the appropriate group or class to which each fracture should be assigned. Therefore it is necessary to select criteria which can themselves be reliably assessed and which physicians can learn, remember, and are willing and able to apply. Reliability can be measured by the kappa statistic which varies from −1 to 1 based upon agreement of two different reviewers: −1 indicates complete disagreement, 0 is random agreement, and 1 is complete agreement (Figure 12.1.2). It is a generally accepted consensus that values of 0–0.2 represent slight agreement, 0.21–0.4 fair agreement, 0.41–0.6 moderate agreement, and 0.61–0.8 substantial agreement (Figure 12.1.3). Other statistical measures of agreement reported in the literature which range between −1 and +1 include weighted kappa, Cronbach’s alpha, and SAV of O’Connell. Weighted kappa gives partial credit for being close in contrast to kappa which is most applicable to a system where observations either agree or not. Alpha is particularly applicable to rank order analysis.
The OTA/AO comprehensive classification of fractures method is based on the radiographic appearance of the fracture location and geometry. The reliability of this system decreases with increasing complexity and specificity at the group (fracture geometry) or subgroup (communion pattern) level. The absence of a more reliable classification system is one measure of adequate reliability.

Box 12.1.2 Measuring reliability and reproducibility by definition

- +1 complete agreement
- 0 random agreement
- –1 complete disagreement.

Box 12.1.3 Qualitative descriptors of $\kappa$ as a measure of reliability

- 0.81–1.00 excellent agreement
- 0.61–0.8 substantial agreement
- 0.41–0.6 moderate agreement
- 0.21–0.4 fair agreement
- 0.01–0.2 slight agreement.

Reproducibility

The appropriate classification should be consistent when one physician reviews the same case at different times. Reproducibility can also be measured by kappa or a similar statistic as previously described. The best classification is highly reproducible.

Clinical relevance

The classification should assist the physician in the care of the patient. Identifying prognosis, associated injuries, complication risks, and directing optimal treatment are the most common forms of clinical usefulness. Associated injuries may not be recognized without clues to their existence. The presence of associated injuries may make a dramatic difference in the significance of a fracture pattern. Recognizing a distal fibula fracture with talar shift as a Lauge–Hansen SER-4 helps identify by deduction the ligamentous injuries to the deltoid, anterior and posterior inferior tibiofibular ligaments which are not directly visualized on the radiographs.

Logical algorithm

The classification system is better if it is based on a logical algorithm. It should be possible to systematically answer a series of related questions about the fracture to arrive at the specific classification. The number of categories should be the fewest possible to effectively discriminate similarities and differences between groups. Allowance should be given for future developments in the field which may require subsequent revision of the classification system in a logical manner.

Facilitates communication

A classification system should facilitate verbal and written communication between clinicians. It should use standard terminology.
that is clearly defined and accepted and the definition should not change over time. Facilitation of communication could be considered a form of clinical relevance but is of sufficient importance to warrant specific inclusion as a desirable quality.

**Problems with classification systems**

The usefulness of a classification is usually time dependent. In the late 1970s intramedullary nailing of femoral shaft fractures was gaining clinical acceptance. The presence of comminution was associated with a significant incidence of complication of the technique, including poor rotational control and shortening. Winquist proposed a classification of femoral shaft fractures based upon increasing comminution and identified the percentage of circumference of the bone necessary to be in contact after nailing to reduce malunion to acceptable rates. At that time the classification was useful. Prior to intramedullary nailing there was no difference in outcome as a function of amount of circumference comminuted so the classification would not have been useful. Subsequent development of interlocking nails changed the usefulness of the classification from defining an indication for nailing to defining an indication for interlocking. Improvement in ease of interlocking made the technique useful without regard to amount of comminution so the Winquist classification of femoral shaft fractures was no longer of particular significance or usefulness. This illustrates that the Winquist classification of femur shaft fractures was clinically relevant during the time of difficult interlocking nails being prevalent.

The widespread tacit acceptance of most fracture classifications used clinically has been strongly challenged in recent publications. The reliability of applying various fracture classifications by different surgeons or reproducibility of a surgeon on two different occasions has been shown to be much lower than previously assumed. Current studies should and are focusing on the source of this variability. There is clearly a tendency for surgeons to adjust the classification based upon their own experience. In addition, clinicians have a limited and imperfect recall of definitions involved in classifications and this will result in some real error. Consensus classification has been proposed as a method to salvage classification schemes with poor reliability. Although this is appealing in theory, consensus classification has not yet been shown to be reproducible or reliable among different groups.

The radiographic interpretation of fracture lines is highly variable and dependent upon radiographic quality (contrast, completeness, obliquity). Reports of accuracy of radiographic measurements suggest more variability than commonly believed. For example, the imprecision in measuring Bohler’s angle after a calcaneus fracture or the percentage of lost height in a lumbar spine fracture or the millimetres of displacement of a proximal tibia fracture all limit the usefulness of classifications which require those measurements. Another common problem is that the classification requires information not available from radiographs. Malleolar distal tibia fractures with large posterior tibial fragments have been considered for internal fixation based on the percentage of articular surface involved in the fragment. This is a two-dimensional concept, however this fragment is very poorly visualized on the anteroposterior or mortise radiograph and only one dimension can be measured on the lateral (see Figure 12.1.1). As more diagnostic information (computed tomography, magnetic resonance imaging, etc.), about a particular injury becomes available, the initial classification may not stand the test of time.

![Click to view larger](image)

Fig. 12.1.1

Example of a poor fracture classification system. A) A lateral radiograph of a posterior lip distal tibia fracture where the fragment appears to be a small percentage of the distal articular surface (one-dimensional image of a two-dimensional concept). B) Demonstrates this fragment to be a large percentage of the distal tibial articular surface.

Not all of the problems are with the classifier. Classifications may give general typical scenarios without precise category definitions such as the Gustilo and Anderson open fracture classification. Open fractures caused by tornadoes are defined as type 3 without regard to their size. That may have helped explain the risk of infection in the patients treated in Minnesota but is not a generally good fracture classification scheme to be utilized worldwide.

A common mechanism of injury has often been applied to patterns of injury and fracture classification, such as the nightstick fracture (isolated ulna shaft) from fending off an attack by someone wielding a nightstick (truncheon); or boot-top fracture (midshaft tibia) from ski boot binding design in the 1970s. This technique is highly variable as the true mechanism of injury for a given patient is seldom known with certainty and hence speculation is usually required.
Eponyms have also been used to designate a certain fracture pattern by the person recognized as first publishing and being referenced on the significance of that particular injury. Thus distal radius fractures are commonly referred to as Colles fractures. Eponyms suffer from lack of precision and rarely mean the same thing to the speaker, the listener, or the original author. Fortunately these shortcomings have become recognized and the frequency of use of eponyms is rapidly fading in orthopaedic traumatology. There are probably better ways to pay tribute to our musculoskeletal forefathers than use of eponyms.

Current classification schemes and outcome measures suffer statistically from the tendency to clump rather than spread data across parameter values. For example, most clinical scores range from 0–100 but the range actually reported tends to be much more narrow, for example 50–89. In the extreme, if all patients score 70 then there can be no correlation of any variable to the outcome. When pain is scored as: no pain = 50 points; occasional mild pain with strenuous activity = 40 points; some pain with some activity = 30 points; severe pain with activity = 20 points; severe pain at rest = 10 points, then there will be a strong tendency toward 30 points. The more the results are clumped the less likely there is to be a correlation between variables and outcomes. Therefore a good fracture classification may poorly predict clinical outcome due to problems with measuring clinical outcome rather than deficiency in the classification system. Some authors have suggested rank order analysis to avoid the clumping problem of other outcome measures. Rank order forces the spreading of parameter values across the entire range. However, a drawback to this form of analysis is the lack of general applicability to patients outside the study.

### AO/Orthopaedic Trauma Association classification system

The 2007 modification and republication of the Orthopaedic Trauma Association (OTA) fracture and dislocation classification compendium provides the current standard for the classification of fractures. This classification has now achieved widespread recognition, understanding, and acceptance in publications and orthopaedic practice. The 2007 version has reconciled differences that existed between the previous OTA and AO classifications by cooperation between the two groups and now the two are identical. This classification has been established as the standard by OTA, AO, SICOT, the Journal of Orthopaedic Trauma, and many other organizations and publications and can now be recommended as the standard fracture classification for general use.

The 2007 OTA fracture classification provides a complete system of fracture classification for all bones in the body that uses consistent methodology throughout the skeletal system. It is based on Muller’s original principle of classification of long bone fractures with designation of a bone, then three bone segments/bone, three types/segment, three groups/type and three subgroups/group. This classification fulfills the criterion for a good classification system (Figure 12.1.2) and provides a wide spectrum of specificity. It can be used as a standard for terminology for very gross fracture types or extremely specific patterns for research purposes.

The OTA classification involves an alpha-numeric designation of the fracture which is particularly important with the current use of computerized search engines to look for information on a specific entity. The first number identifying the BONE (1–9), the second the bone SEGMENT (1–3), then a letter designating TYPE (A,B,C) followed by numbers (1–3) for GROUP and SUBGROUP separated by a decimal point. For example a comminuted fracture of the medial condyle of the distal femur would be coded 33.B2.3 (femur, distal, partial articular, medial, multifragmentary).

There are fundamental differences between various TYPES of bone SEGMENT fractures. Proximal and distal segments of long bones are classified as extra-articular (A), partial articular (B), and total articular (C). Diaphyseal fractures are classified as simple (A), wedge (B), and complex (C). For the flat bones there are three types based on the same principle of increasing complexity. For example the types of talus (81) fracture are avulsion or process fractures (A), talar neck fracture (B), and talar body fracture (C).

The GROUP designation of fracture pattern typically involves anatomical specificity. For example, partial articular distal humerus (13B) fractures have three groups: lateral or capitellar (13B1), medial or trochlear (13B2), coronal plane (13B3). When anatomical specificity is not relevant, the groups are typically designated by degree and pattern of comminution. For example, total articular distal humerus fractures (13C) are grouped as articular simple, metaphysis simple (13C1), articular simple metaphysis multifragmentary (13C2), articular multifragmentary (13C3). This corresponds with the relative complexity of fracture, the treatment and the prognosis. There are a total of nine categories at the group level for each bone segment and this level of specificity would be more than adequate for the vast majority of clinical situations.

The SUBGROUP level of designation is useful when very detailed and specific categories are desirable as might be the case in research, database, or subspecialty discussions. It is more detail than would be necessary for most clinical situations. For example, distal humerus medial fractures (13B2) is sub grouped by the pattern of fracture as medial or Milch 1 (13B2.1), groove or Milch 2 (13B2.2), multifragmentary (13B2.3). There are three subgroups for each group (for example three subcategories of fractures of the trochlea of the distal humerus). There are a total of 27 categories at the subgroup level for each bone segment (all distal humerus fractures).

The OTA classification has been criticized as being overly complex. However, as illustrated earlier, the level of desired complexity can be chosen to match the needs of the user. If the information for the group or subgroup level is not known or needed, then designation at the level of type can be used. Furthermore, as illustrated by the example of trochlear fractures, the complexity at the level of subgroup is well within the skill set of the average orthopaedic surgeon with good quality plain radiographs, especially with easy accessibility to the standard reference.

The 2007 version of the OTA fracture classification is different from the 1996 version in several areas including hand, foot, flat bones dislocation, and the newly developed AO classification of fractures of bones with open growth plates (paediatric fractures).

### Conclusion
A classification system may be imperfect; however it can still be useful. We should use the classifications which are the best available to help direct treatment and predict outcome. Directing treatment is one of the best forms and a classification which correctly partitions a family of related injuries into categories with unique treatments would be ideal. This correlation rarely survives more than a few years. We should continually strive to improve by testing and updating (perhaps once per decade) our classification systems to be logical, reliable, reproducible, and clinically relevant to direct treatment and identify risk.

Future directions

The 2007 OTA fracture classification is likely to continue to gain acceptance as the standard. New information about this classification in particular will be use to shape future modifications and improvements in the decades ahead. New information about fracture patterns and the predictors of treatment and outcome will also be forthcoming and this information will also result in modification of future versions (2017) of the classification.

Recognition of problems with current fracture classifications and the ongoing desire to optimize patient outcome will result in improved classifications in the future. Old and new classifications will be scientifically scrutinized and the reliable, reproducible, logical, clinically relevant ones will be selected for utilization. Ongoing efforts will focus on identifying and minimizing the sources of error or disagreement so as to optimize reliability and reproducibility. Factors will be scientifically and statistically analyzed for predictive value and important factors will be incorporated into fracture classifications.

There will be ongoing efforts to learn from our past and review clinical results as a function of existing fracture classifications. Treatments and outcomes as a function of fracture classification will continue to be reported with the potential for improvement as the tools we use (e.g. prospective fracture classification) are themselves improved.

New methods of classification will be further investigated. Consensus classification by a panel of experienced surgeons may be of benefit. Rank order and other non-parametric statistical analysis may also help solve the problems of poor agreement. The methodology by which we assess classification reliability will be standardized and improved.

There is considerable benefit and interest in generalized fracture classification systems (OTA, AO, SICOT). The ease of computerized and internet accessibility to fracture classification standards and educational tutorial tools will improve the accuracy and generalized utilization of the 2007 OTA fracture classification (e.g. OKO). Increased utilization and widespread acceptance will also depend upon the effectiveness of the classification and its ability to lump similar and distinguish dissimilar injuries in a comprehensible and usable manner.

Chapter: Complications of fractures

Author(s): James Wilson-MacDonald and Andrew James

DOI: 10.1093/med/9780199550647.003.012002

Summary points

- Fat embolism syndrome is defined as the presence of globules of fat in the lungs and in other tissues and occurs occasionally in long bone fractures
- Reflex sympathetic dystrophy is characterized by intense prolonged pain, vasomotor disturbance, delayed functional recovery, and trophic changes
- Avascular necrosis typically affects intra-articular bone after fracture and can occur in up to 70% of displaced talar neck fractures
- Immobility associated with recovery from fracture is associated with deep vein thrombosis, which carries a risk of pulmonary embolism, and should be treated with anti-coagulants
- Gas gangrene is a rapidly-spreading infection of devitalized tissue, removal of the affected area and treatment with penicillin is required
- Compartment syndrome within a closed compartment can result in tissue ischaemia and necrosis followed by fibrosis and muscle contracture

Introduction

Complications of fractures include fat embolism and fat embolism syndrome, reflex sympathetic dystrophy, avascular necrosis, vascular injuries, crush injuries, gas gangrene, and tetanus. Vascular injuries are dealt with in Chapter 12.9. Avascular necrosis is discussed in the chapters on hip fractures and scaphoid fractures (Chapters 12.29, 12.50, and 12.51).

Fat embolism syndrome

Fat embolism syndrome is defined as the presence of globules of fat in the lungs and in other tissues. It occurs occasionally in long bone fractures (3.5%) and can rarely occur without trauma. It is commoner after multiple trauma (10%).

There is little correlation between the amount of fat in the lungs and the severity of the condition. Figure 12.2.1 summarizes the inflammatory cascade which occurs. Lipase is released by the lung which acts on the fat releasing free fatty acids and glycerol which are toxic to the lung.

Click to view larger

Fig. 12.2.1
Pathophysiology of fat embolism syndrome.

The condition usually manifests itself 1–2 days after injury. Many features remain unexplained:

- It mainly affect the young
- It mainly occurs after lower limb fractures
- Most are closed fractures
- The elderly do not seem to be affected (e.g. hip fractures).

Table 12.2.1 summarizes the classical symptoms and signs (major and minor features). Tachypnoea, dyspnoea, and cyanosis are the earliest respiratory signs, but hypoxaemia may be detected earlier. Cerebral irritation can include headache and irritability to
convulsions and coma. Embolization of fat into the dermis causes petechiae. They are transient but can be seen on the chest (Figure 12.2.2) neck, axillae, palate, eyelid (Figure 12.2.3), conjunctivae, and retina.

Plus fat macroglobulinemia

![Click to view larger](Fig. 12.2.2)

Petechial hemorrhage on chest wall.

![Click to view larger](Fig. 12.2.3)

Petechial hemorrhage on eyelid.
The diagnosis is based on clinical and laboratory tests. These include:

- Low PO$_2$
- Macroglobulinaemia.

These should be combined with one major and four minor signs (see Table 12.2.1).

Pulmonary infiltrates on the chest radiograph, right heart strain, and ST segment changes on the electrocardiogram (ECG), together with anaemia, thrombocytopenia, and elevation of erythrocyte sedimentation rate, add support to the diagnosis but are not specific.

**Management**

The incidence of fat embolism syndrome can be reduced by appropriate early management of the trauma victim. Adequate fluid resuscitation and oxygen therapy with fracture splintage and careful transport are important first aid measures. There is no evidence that intramedullary reaming increases the incidence. Specific therapies have been proposed, including heparin, alcohol, and aspirin, but the findings were equivocal. Steroids have been studied in both prophylaxis and treatment. They are reported as effective in maintaining arterial oxygen levels and reducing serum free fatty acids, but the dose required is high and complications can be severe. At the present time they are not in routine use.

**Results**

The mortality rate approaches 15% mainly due to respiratory complications. Morbidity is mainly due to cerebral irritation. A high index of suspicion and early treatment improves results.

---

**Complex regional pain syndrome/reflex sympathetic dystrophy (Chapter 1.11)**

Reflex sympathetic dystrophy is a syndrome characterized by intense or unduly prolonged pain, vasomotor disturbance, delayed functional recovery, and trophic changes. Many terms, including causalgia, Sudeck’s atrophy, and algodystrophy, have been used to describe the condition. It can occur as a response to trauma. Up to 30% of patients with tibial fractures and distal radial fractures may be affected. The cause is not known. Livingston’s theory (Figure 12.2.4) is that there is a vicious circle initiated by capillary stasis, increased local pressure, and exudation, which is maintained by afferent fibre stimulation due to anoxia. The importance of inflammatory mediators and cytokines has been investigated but to date there is no reliable marker for reflex sympathetic dystrophy.

---

**Clinical evaluation**

The severity of reflex sympathetic dystrophy is not related to the magnitude of the initial traumatic insult. The condition commonly affects the periphery, although it is being increasingly recognized in the knee and shoulder. The elbow and hip are rarely affected. It is more common in middle years but is recognized in children.

The clinical presentation is varied but three phases are commonly identified:

1) Acute or hyperaemic phase
2) Dystrophic or ischaemic phase
3) Atrophic phase.

The acute phase may occur soon after injury but may be delayed for several weeks. Pain and tenderness are the first signs. Hyperaesthesia (increased sensitivity to a noxious stimulus) and allodynia (pain caused by stimuli usually not noted to be painful) are common. In the acute phase the limb is swollen, dry, hot, and pink (Figure 12.2.5), with increased hair growth. In the second phase the limb often remains swollen but becomes blue, cool, and damp with sweat. It may be several months before the third stage is entered. This is characterized by atrophy and joint contractures.
Investigation

The diagnosis is primarily clinical. Several investigations are useful in assessing the severity and stage of the disease. Tenderness can be assessed using dolorimetry, joint stiffness can be recorded, and thermography can be used to assess vasomotor function. Bone scans are positive in the early stages, and when they return to normal there is visible demineralization on plain radiography.

Management

Early diagnosis is the key to successful management as the first two phases are reversible. The primary treatment of reflex sympathetic dystrophy involves reassurance, analgesia, and physiotherapy to maintain joint movement. In severe cases, treatment involves sympathetic interruption, for example, with intravenous guanethidine. Surgical sympathectomy is rarely indicated. A multidisciplinary team approach, including physiotherapists, pain specialists, and, in certain cases, psychologists, is helpful.

Results

Even in a mild form reflex sympathetic dystrophy gives rise to severe and permanent morbidity. There is little evidence in the literature for efficacy of the various treatments. It is essential to maintain movement to avoid long-term contractures after recovery.

Avascular necrosis

This typically affects intra-articular bone after fracture (talus, hip, scaphoid, humeral head). In displaced talar neck fractures it may occur in up to 70% of cases.

Post-traumatic avascular necrosis may be due to any of these mechanisms. Avascular necrosis of the femoral head may occur as a result of tamponade due to intracapsular haemarthrosis or by vessel kinking or rupture. The degree of displacement and the interval between injury and reduction are important predictors of the likelihood of the occurrence of avascular necrosis.

The progression of the condition is independent of the initial mechanism. Within 2 weeks of injury, there may be histological signs of marrow necrosis with osteocyte death. Cell death leads to liposome release and tissue acidification. Saponification occurs in the presence of free fatty acids and calcium. Marrow oedema and tissue necrosis lead to the earliest detectable signs on magnetic resonance imaging (MRI). This may be associated with a quantifiable increase in intraosseous pressure. Commonly these changes are confined to the medullary bone of the metaphysis and do not involve the subchondral plate.

Repair occurs by creeping substitution and may take 2 years.

Without a viable cell population the normal process of remodelling does not occur and microfractures cannot be repaired. This can result in collapse of the subchondral bone and chondral flaps, both of which then lead to joint incongruity and arthritis.

Classification

Table 12.2.2 summarizes the classification.

**Evaluation and investigation**

Early diagnosis is important to limit transarticular load.

- MRI scan is the mainstay of investigation. Changes in marrow oedema can be identified
- Intraosseous pressure measurements may help with diagnosis
- Plain radiographs may show subchondral osteopenia (Hawkins sign seen in the body of the talus) which denotes continued vascularity in the absence of normal load. If there is no blood supply the bone is not resorbed
- Scintigraphy may show an area of reduced blood supply.

**Management**

Management is directed at preventing the complications of avascular necrosis, such as segmental collapse and osteoarthritis.

Clinical studies have shown clear evidence that the incidence of avascular necrosis in many injuries can be correlated with the severity of the initial injury and the delay to reduction. Therefore prompt accurate reduction with secure fixation can lessen the incidence of avascular necrosis, particularly in weight-bearing joints. This must be accompanied by evacuation of the associated haemarthrosis to reduce the effect of tamponade.

Early diagnosis allows preventive measures such as limiting weight bearing to be instituted to prevent propagation and segmental collapse.

Procedures to enhance revascularity have been advocated. Most commonly, these have been for the management of femoral head avascularity after intracapsular fractures of the proximal femur. Posterior muscle pedicle grafting has been used as an acute procedure and to enhance vascularity in established avascular necrosis. These techniques are infrequently used in modern practice, particularly with the increasing acceptance of hip arthroplasty.

Once segmental collapse has become established and symptomatic, reconstructive procedures such as arthroplasty and arthrodesis are indicated.

**Vascular injuries**

See Chapter 12.9.

**Crush injuries**

Major crush injuries of the limbs are mercifully rare. All structures can be injured by crush. Fractures may occur and prolonged crush can cause ischaemia. Muscle repair may be accompanied by fibrous tissue, and myositis ossificans can occur (20% of those with quadriceps haematoma).

In response to trauma, there is a tendency to hypovolaemia with expansion of the extracellular space. This results in an active antidiuresis with rapid renal tubular resorption. Excreted myoglobin and haemoglobin become concentrated in the renal tubules, causing tubular blockage, and may lead to acute renal failure. Sudden release and reperfusion of the affected limb may lead to metabolic acidosis and rapid rises in plasma potassium levels sufficient to cause cardiac arrest.

**Investigation**

On admission, a detailed assessment should include an ECG, relevant radiographs, measurement of electrolytes, arterial blood gases, and measurement of urinary output. Estimation of urinary myoglobin and haemoglobin are indicated if compromise of renal function is thought likely. Special investigations may include angiography if an associated vascular injury is suspected.
**Management**

General resuscitative measures should be instigated with administration of analgesia, intravenous fluids, and insertion of a urinary catheter. Electrolyte and acid–base derangement should be corrected. In the case of an open wound, precautions against infection should be taken with administration of broad-spectrum antibiotics and antitetanus prophylaxis.

Specific management of the injuries will be required. This will include fracture reduction and fixation, arterial exploration and reconstruction if indicated, and the limb deemed viable. The fracture pattern may demonstrate extreme comminution.

Decompressive fasciotomy of myofascial compartments surrounding and distal to the crush injury will be required. All non-viable tissue including muscle and bone should be excised. Wounds should be dressed without skin closure.

**Complications**

Complications can be local or general. General complications may include cardiac arrhythmias and acute renal failure. Cardiac manifestations of hyperkalaemia are reduction in P-wave amplitude and widening of the QRS interval into the ST segment. Sudden rises in serum potassium may result in cardiac arrest. Renal failure may occur as a result of myoglobinuria in the presence of hypovolaemia.

### Deep venous thrombosis

The incidence of deep venous thrombosis (DVT) in trauma patients is high. A number of demographic studies have demonstrated an incidence approaching 80% after trauma. This may reach 80% in patients with femoral and tibial shaft fractures and in those with spinal cord injuries.

**Pathology**

The lower limb veins are most commonly affected due to local endothelial damage, venous stasis, and post-traumatic hypercoagulability and age. Direct trauma to the venous endothelium releases thromboplastic substances and exposes the basement membrane, initiating local thrombosis by the extrinsic coagulation mechanism. Trauma remote from the venous lining may also initiate these changes, explaining the widespread distribution of thrombi. Stasis, in association with immobilization and bed rest, may cause accumulation of platelets around valve cusps which promote the thrombotic process by the release of procoagulants. The frequency of deep venous thrombosis has been shown to rise with increasing periods of immobilization.

Pulmonary embolism may occur in up to 5% of patients.

**Diagnosis**

The clinical symptoms and signs of DVT are pain, tender swelling of the limb distal to the thrombus, and peripheral oedema. It is frequently associated with a low-grade pyrexia of less than 38°C. However, these signs are difficult to interpret, and clinical diagnosis may be difficult and will underestimate the number of cases seen.

**Investigation**

Impedance plethysmography and contrast venography are widely available to confirm the diagnosis of DVT. Contrast venography is the most specific test, but is invasive and requires transfer to the radiology department. Impedance plethysmography may be performed at the bedside, but is less specific for smaller distal DVT where proximal veins are patent.

**Management**

**Prophylaxis**

Prevention is best. Early mobilization and prophylaxis with low-molecular-weight heparin is widely used. The National Health Service in the United Kingdom has published NICE (National Institute for Health and Clinical Excellence) guidelines for prophylaxis. They recommend graduated DVT stockings for all adults, and 4 weeks of low-molecular-weight heparin for patients undergoing surgery for hip fracture. They also support the use of intermittent pneumatic compression where possible, and emphasize the importance of risk assessment for DVT.

Useful pharmacological agents include aspirin, heparin, fractionated heparin, and oral anticoagulants. The use of these agents in prophylaxis has to be balanced against the risk of haemorrhagic complication. For this reason, use of heparin in patients with acetabular, pelvic, or spinal fractures is not indicated in the first 48h after injury. Studies in patients with below-knee casts indicate that the incidence of DVT can be reduced by the use of fractionated heparin.

**Treatment**

Treatment of DVT depends on the anatomical site of the thrombus; asymptomatic below-knee thrombus may not require specific therapy. The standard treatment of symptomatic DVT is anticoagulation, initially with heparin, and commencement of warfarin therapy. Oral anticoagulants should be continued for 6–12 weeks, and clotting should be monitored to ensure that the dosage is within the therapeutic range.

In the event of a pulmonary embolus occurring during treatment of DVT, consideration can be given to insertion of inferior vena caval filters to prevent the formation of further emboli.
The complications of DVT include pulmonary embolism and postphlebitic limb.

**Gas gangrene**

Gas gangrene is a rapidly developing, spreading infection of devitalized tissue by toxin-producing clostridial species, especially *Clostridium perfringens* (formerly known as *Clostridium welchii*). It is a Gram-positive, anaerobic, capsule, and non-motile bacillus. The most characteristic feature is the spore, which is produced whenever the organism faces adverse conditions. It is accompanied by profound toxemia, massive tissue necrosis, and gas production, and is invariably fatal unless treated. Clostridial contamination is reported in up to 39% of wounds. The incidence is related to the interval between injury and treatment, as well as to the site and severity of injury.

Clostridial infection can be classified into three types:

1. Clostridial contamination occurs when the organisms are present without clinical disease
2. In clostridial cellulitis there is evidence of disease in the absence of dead muscle and little or no toxin production
3. Clostridial myonecrosis is the severe form known as ‘gas gangrene’.

The exact processes by which clostridial contamination and cellulitis lead to gas gangrene are not clear, but a reduction in local oxygen potential is an important factor. The inoculum of *C. perfringens* required to produce fatal gas gangrene is reduced by a factor of 10^3 if the tissue is devitalized or contaminated with sterile dirt. The most important exotoxins are the α-toxins (lecithinase), although several others are well recognized (e.g. collagenase, hyaluronidase, and protease).

Muscle carbohydrate is fermented to lactic acid and ‘gas’ (mainly hydrogen and carbon dioxide). Putrefaction follows extensive necrosis. At this stage the characteristic smell is produced and the evolution of ‘gas gangrene’ is complete.

**Clinical features**

The original insult often involves a penetrating injury to muscle. The buttock and thigh are common sites. The incubation period can be as long as 4 days or as short as 6h. The progression of the disease can be rapid and devastating. Sudden onset of pain is the first symptom, followed by oedema and a thin serous ooze. The pain increases in severity and the skin becomes stretched, developing a ‘bronzed’ discolouration. Haemorrhagic vesicles may appear before areas of frank necrosis. Tachycardia out of proportion to temperature elevation and mental awareness marked by a ‘terror of death’ are characteristic. Profound shock follows in the untreated case, and death occurs within 48h. The mortality rate is about 30%.

**Management**

Emergency surgical debridement is required to save the patient’s life, and compartment decompression. X-rays may show gas in the soft tissues, but its absence does not exclude the diagnosis.

A patient with suspected gas gangrene should receive intravenous penicillin. Consideration should be given to adding broad-spectrum antibiotics to cover other organisms. Hyperbaric oxygen is recognized to be of benefit in reducing toxin production and improving oxygen delivery to devitalized tissues.

---

**Tetanus**

Tetanus is a rare but often fatal disease caused by *Clostridium tetani*. All the clinical effects are caused by the effects of an exotoxin (tetanospasmin) on various receptor sites.

The incidence of tetanus is now rare in Western countries. In developing countries, where standards of hygiene and primary wound care are poor and the majority of the population are not immunized, it remains an important cause of mortality.

*C. tetani* is a Gram-positive, anaerobic, motile, and non-capsulate bacillus which forms a characteristic terminal ‘drumstick’ spore. The spore is very resistant and may remain dormant in wounds for long periods.

*C. tetani* is found in soil and faeces, but frequently contaminates the skin. A wound is identified as the portal of entry in only 60% of cases. Two factors favour progression of the infection: wounds with low oxygen potential or ischaemic tissue and wounds infected with other organisms. The initial traumatic lesion may appear innocuous compared with the outcome as clinically ‘tetanus’ is a disease of the central nervous system.

The incubation period varies from 3–21 days and is generally shorter in more severe cases. The period of onset is the time from first symptom to first spasm. This can vary from less than 24h to over 10 days; the shorter the period the more severe is the tetanus.

*C. tetani* produces two exotoxins. Tetanospasmin is a powerful neurotoxin which is carried slowly by peripheral nerves to the central nervous system, where it is avidly taken up by gangliosides. It is responsible for the characteristic clinical features of the disease. The toxin does not affect sensory nerves, the cerebral cortex, or the cerebellum. Tetanolysin is haemolytic and may contribute to the overall clinical picture.

The transit of the toxin in the peripheral nerves is slow; the first effect is produced in muscle groups with short motor neurons, i.e. the head and neck muscles. Severe trismus and dysphagia due to masseteric spasm (‘lockjaw’) are seen, and facial muscle spasm produces the characteristic risus sardonicus. The muscular spasm spreads to affect the neck, back, abdomen, and limbs. Opisthotonos—severe spasm such that the whole body is arched off the bed—may be seen.
Muscle spasm of increasing severity and duration may lead to crush fractures of the vertebrae and death from respiratory failure and exhaustion.

**Diagnosis**

The diagnosis is clinical. The organism is only cultured in one-third of cases, reflecting the specific anaerobic growth requirements of *C. tetani*.

**Management**

The treatment incorporates specific measures including wound care, passive immunization, and antibiotics. When a wound is identified it should be excised along with all devitalized tissue. *C. tetani* remains sensitive to penicillin, which should be given. Human tetanus immunoglobulin should also be given.

Supportive therapy may be needed depending on the severity of the case and sedation is often helpful. The most important factor is the maintenance of respiratory function and mechanical ventilation via a tracheostomy is required in severe cases.

Active immunization with absorbed tetanus toxoid is extremely safe and effective. If the wound is severe, passive immunization with tetanus immunoglobulin should be given. The American College of Surgeons Committee on Trauma (1986) has published a guide to prophylaxis against tetanus in wound management.

---

**Compartment syndrome**

**Definition**

Raised pressure within a closed compartment resulting in tissue ischaemia and if untreated, necrosis followed by fibrosis and muscle contracture.

**Pathophysiology (Figure 12.2.6)**

The capillary bed pressure is usually 20–30mmHg, and this is sufficient to create an adequate tissue perfusion, with an interstitial pressure of about 5mmHg. Compartment syndrome occurs when tissue pressure rises and tissue perfusion decreases or ceases. An increase in interstitial tissue pressure is possible in closed compartments, either by intrinsic or extrinsic causes. An increase in the volume in a contained compartment, giving rise to an intrinsic compression, may be caused by blood or other fluid shifts. Extrinsic compression similarly affects an increase in pressure.

If the pressure in the veins does not rise above the compartment pressure, the veins will remain collapsed, venous pressure rises and perfusion ends. Capillary pressure will then rise towards arterial pressure and there will be rapid diffusion of fluid out of the vascular compartment into the extracellular compartment of the muscle. The pressure in the compartment will continue to rise and the muscle becomes ischaemic. This hypoxic cellular injury causes a release of vasoactive substances, such as serotonin and histamine, which further increase endothelial permeability and extracellular fluid accumulation. Muscle necrosis will occur and myoglobin will be released.

It is important to note that arteries passing through this compartment are not squeezed shut during this process. This is because their intraluminal pressure is high (arterial blood pressure) and their walls are thicker and therefore resist compression. Therefore the presence of distal pulses does not exclude a compartment syndrome.

**Prognosis**
The prognosis is dependant on the speed of diagnosis and treatment. Acute compartment syndrome is a true surgical emergency. Once a compartment syndrome is established, some measurable changes in the affected muscle may occur within 2h. Within 4 –6h these changes will have significant long-term effects. After 12h there is likely to be severe irreversible damage.

### Box 12.2.1 Causes of compartment syndrome

- **Intrinsic:**
  - Direct traumatic injury
  - Fracture
  - Bleeding and haematoma
  - Extravasation of fluid (arthroscopy)
  - Following vascular repair
- **Extrinsic:**
  - Crush and entrapment
  - Burns
  - Tight cast or bandage
  - Prolonged tourniquet
  - Drug or alcohol induced stupor

**Causes (Box 12.2.1)**

Acute traumatic compartment syndromes can be divided into primary intrinsic, where swelling within the compartment is primarily responsible for the rise in pressure, and primary extrinsic, where there is a constricting cast or bandage. Intrinsic are much more common.

**Intrinsic causes**

Intrinsic compartment syndrome develops when the volume in an injured compartment rises following a traumatic injury. It is important to note that even open injuries may have intact fascial compartments. Bleeding or direct tissue injury may initiate the pressure increase. Manipulation and intramedullary nailing may precipitate compartment syndrome. This should not be used as a reason to delay these procedures but the surgeon must be aware of the possibility.

**Extrinsic causes**

Pure extrinsic causes are much less common and are unlikely to produce a compartment syndrome unless there is damage to tissues within the compartment leading to swelling. However, it is important to consider this when planning treatment, as removal of a cast alone can reduce compartment pressure by as much as 30%.

**Non-traumatic**

- Chronic exertional compartment syndrome is most commonly seen in high-level athletes. It is commonly bilateral and is frequently associated with small muscle hernias through the fascia. The differential diagnosis includes periositis, tenosynovitis, tumours of bone or soft tissue, stress fracture, and nerve entrapment
- Acute exertional syndrome can present acutely in individuals who are not fit, but who are suddenly involved in strenuous exercise. The diagnosis here is given by the history which can only really be confused with acute tenosynovitis. If the symptoms do not rapidly resolve with rest, a fasciotomy is indicated
- Following vascular reconstruction: there may be acute swelling of muscles immediately after emergency embolectomy, especially if the limb has been critically ischaemic for some time.

**History**

There is a history of trauma, although this may have been quite minor, followed by a history of increasing pain over a period of hours. Pain as a clinical sign is unreliable if the patient’s level of consciousness is altered. Most specifically, the patient will be extremely unwilling to move any part of the limb, especially the extremities. The patient may also complain that the limb feels numb or cold.

**Examination**

The cardinal sign is pain, especially when increasing or out of proportion. The patient has immediate and severe pain on passive stretching of the muscles of the involved compartment. It may be useful to distract children to ensure that it is not their fear of the injured limb being touched which produces the response.

Examination should then include a full release of any bandages down to skin and opening of any casts. This may produce some
relief. The limb may also feel cold, have reduced sensation, and be pulseless; these are late signs and suggest a poorer prognosis. However, it must be emphasized that the presence of normal sensation and pulses distal to a possible compartment syndrome does not exclude the diagnosis.

Investigation

The main diagnosis of compartment syndrome is based on clinical examination. A high index of suspicion is one key to making the diagnosis. Prompt decompression should not be delayed and if there is any doubt the surgeon should err on the side of caution and perform a fasciotomy. Intracompartmental pressure measurement can be performed and has a role in unconscious patients, and in those with unclear or unreliable clinical signs, such as children. Continuous monitoring may be needed in obtunded patients.

There are various methods available, most commonly a pressure transducer, is flushed, zeroed at the compartment level, and inserted into each compartment in turn to obtain a reading. Reproducibility and reliability of these measurements is poor. The pressure obtained can be used as an absolute value, or related to the diastolic or mean blood pressure.

Prevention

Circumferential bandages and casts should be avoided if at all possible in the first 12h after trauma or surgery. If they are used they should be split, and then closed or replaced when the swelling is no longer increasing.

All patients sent home with bandages or casts should be warned of the possibility of the development of a compartment syndrome.

Treatment

Casts, bandages, and padding need to be removed down to the skin. Soft cotton dressing soaked in blood can produce a tight constricting band. If removal of the cast compromises the reduction of the fracture, then this must be accepted. A compartment syndrome takes priority over fracture position. If there is not immediate and sustained improvement in pain and movement once the dressing has been released, an immediate surgical fasciotomy is required.

Fasciotomies should be performed open, as the skin itself can constrict compartments in severe swelling. Open fasciotomy allows the surgeon to avoid damaging nerves with a variable path through the fascia. The anatomy needs careful review before embarking on the fasciotomy. All compartments at risk need to be split along their whole length.

The fasciotomy should be left open, both to reduce pressure and to allow regular reinspection of the muscle. If any parts of the muscle fail to revascularize, they should be debrided. A second look should be performed at 48h and closure can be considered. Complete closure is often not possible and other methods of skin cover will be required. Mechanical closure devices are available but split-skin grafting, which can be later excised is the most commonly used technique. When compartment syndrome has occurred in the presence of an underlying fracture, the fasciotomy creates an open fracture, and should be managed with early coverage to avoid problems with hospital acquired infection.

Late fasciotomy

Delayed fasciotomy following a crush injury or failed revascularization can potentially do more harm than good. If there has been a full compartment syndrome for more than 12h, the chances of the muscle recovery is remote. Fasciotomy will result in extensive debridement of the compartments and expose large volumes of devitalized tissue to hospital-acquired organisms. Late fasciotomies have been associated with a high frequency of morbidity and mortality related to sepsis. Non-operative treatment will be associated with dangerous levels of muscle breakdown products and the risk of renal failure. Temporary dialysis or amputation will need to be considered.

Site

Compartment syndromes occur wherever muscles are bound within rigid fascia compartments. All muscles have an investing fascia, but some are more constrained than others, and it is these which seem to be most susceptible to compartment syndrome. Compartment syndromes of the hands and feet, and their treatments, are described in their relevant chapters. The classic site is the flexor compartment of the forearm. In the lower leg it is the anterior tibial and the deep posterior compartments. However, compartment syndromes are well described in all of the five compartments of the lower leg (including the separate tibialis posterior compartment).

Further reading

Orthopaedic approach to the multiply injured patient

Summary points

- Major trauma results in a systemic stress response proportional to both the degree of initial injury (1st hit) and the subsequent surgical treatment (2nd hit).
- The key physiological processes of hypoxia, hypovolaemia, metabolic acidosis, fat embolism, coagulation and inflammation operate in synerge during the days after injury/surgery and their effective management determines prognosis.
- The optimal timing and method of long bone fracture fixation after major trauma remains controversial. Two divergent views exist between definitive early intramedullary fixation and initial external fixation with delayed conversion to an intramedullary nail once the patient's condition has been better stabilised.
- There is agreement that the initial skeletal stabilisation should not be delayed and that the degree of initial injury has a more direct correlation with outcome and the development of subsequent systemic complications rather than the method of long bone fracture stabilisation.
- Trauma patients can be screened to identify those more ‘at risk’ of developing systemic complications such as respiratory insufficiency. Specific risk factors include: A high injury severity score; the presence of a femoral fracture; the combination of blunt abdominal or thoracic injury combined with an extremity fracture; physiological compromise on admission and uncorrected metabolic acidosis prior to surgery.
- The serum concentration of pro-inflammatory cytokine interleukin (IL) 6 may offer an accurate method of quantifying the degree of initial injury and the response to surgery.
- The effective management of the polytraumatised patient involves a team approach and effective communication with allied specialties and theatre staff. A proper hierarchy of the injuries sustained can then be compiled and an effective surgical strategy made.

Introduction

Injury is a leading cause of morbidity and premature death in the young. The initial treatment of seriously injured patients has improved with advances which include: minimizing the time at the accident scene; a more structured training for those involved in front-line trauma management; designated trauma centres with appropriate and adequate support from allied specialities. These improvements, combined with the early initiation of resuscitation protocols and early emergency interventions, have been attributed to improved patient survival after serious injury.

Orthopaedic trauma produces a systemic stress response, which is related to the degree of initial injury. Clinical outcome is determined by the magnitude of response both to the initial injury and its subsequent surgical management. The term ‘second hit’ has been applied to the process whereby an injured and physiologically vulnerable patient is exposed to further trauma as a result of the surgical management of his injuries. Therefore, the initial orthopaedic management of a seriously injured patient must balance between limited physiological tolerance and the optimal volume of fracture stabilization surgery initially required.

Pathophysiology (Box 12.3.1)

A number of physiological processes should be considered in managing the multiply injured patient. Hypoxia, hypovolaemia, electrolyte imbalance, pulmonary and systemic embolization, coagulopathy, and inflammation all evolve over the initial hours and days after injury. The processes overlap and can operate in synergy to produce indirect end-organ hypoxia and subsequent tissue damage. The pathophysiology is also affected by the injury severity with direct associated injuries (for example, blunt trauma to the chest), which can render the patient more vulnerable to the effects of initial fracture management. A patient’s individual response to injury can also vary considerably, with acute respiratory distress and major organ dysfunction being the most serious sequelae.

Hypovolaemia

The stabilization of pelvic fractures which are causing haemodynamic instability is an obvious priority. Isolated adult femoral shaft fractures can also result in a range of blood loss from 300–1300mL and transfusion rates of up to 40% with a direct correlation to the degree of preoperative haemorrhage. Blood loss and transfusion requirements are higher after multiple lower extremity fractures and there is an increased frequency of acute respiratory distress.

The direct effects of hypovolaemia are to reduce end-organ tissue perfusion and oxygen delivery. This results in impaired aerobic metabolism and subsequent tissue damage. Indirect effects include the activation of platelets and the production of a hypercoagulable state. Proinflammatory cytokines are also upregulated during the early phase after injury as a direct result of hypovolaemia with overproduction being related to increased rates of acute respiratory distress, multiple organ failure, and mortality. Cytokines are acute-phase proteins implicated in the activation of the complement cascade and the expression of fibrinogen. Interleukin-6 (IL-6) is a predominantly proinflammatory cytokine secreted by macrophages and T lymphocytes. It has a relatively long half-life with a peak concentration that occurs 4–8h after injury and persists for several days. This makes it a potentially useful prognostic marker after injury where levels have been shown to correlate with mortality rate. In addition, excessive...
proinflammatory cytokine production stimulates the breakdown of muscle proteins and further contributes towards tissue damage after hypovolaemic shock.

Box 12.3.1 Pathophysiology

- Impaired aerobic metabolism
- Interleukin-6 prognostic marker
- Acidosis may reflect inadequate resuscitation
- Fat embolism may complicate fractures
- Emboli may inhibit pulmonary function
- Proinflammatory cytokines may be prognostic.

Metabolic acidosis and base deficit

The correction of hypovolaemic shock is paramount to any trauma resuscitation protocol. However, standard measurements of heart rate and blood pressure do not always accurately indicate adequate tissue and end-organ perfusion. ‘Oxygen debt’ and ‘occult hypoperfusion’ are terms which have been applied to the haemodynamically stable patient, who has persistently elevated lactate levels and a deficit in tissue oxygenation after trauma. This type of patient is inadequately resuscitated and has uncorrected metabolic acidosis. A twofold increase has been demonstrated in postoperative complications in patients undergoing early (<24h) femoral fracture fixation with elevated lactate levels (i.e. >2.5 mmol/L) that were not corrected prior to surgery. The complications involve a range of systems including respiratory (acute respiratory distress syndrome, ARDS), as well as an increased incidence of infection. Higher rates of multiple organ failure and respiratory complications have been demonstrated after major trauma in patients with persistent (>24h) and uncorrected metabolic acidosis. Such patients are more susceptible to the ‘second hit’ phenomenon caused by emergency surgery. Adequate haemodynamic and acid–base resuscitation is essential prior to surgery in order to optimize outcome and improve mortality after serious injury.

Pulmonary and systemic fat embolism

Fat embolus is defined as fat within the circulation and can occur with or without clinical sequelae. Most long-bone fractures produce a mild, asymptomatic, and transient hypoxaemia detectable on pulse oximetry. The severity of hypoxaemia is correlated to pulmonary fat embolic load and tends to be greater after high-energy trauma or multiple long-bone fractures. Subsequent episodes of hypoxaemia can occur after manipulative or operative procedures on the fractured extremity.

The clinical manifestations of fat emboli are usually explained on the basis of mechanical effects. Fat globules are forced into the venous circulation as a consequence of pressure changes within the medullary canal. They are then transported in the venous system to the right side of the heart and thereafter enter the pulmonary circulation where they obstruct small arterioles and capillaries. Systemic fat embolization can occur due to arteriovenous shunting of emboli through the pulmonary circulation. In addition, a patent foramen ovale can also predispose to systemic effects by allowing emboli to enter the left atrium directly and bypass the pulmonary filtration process.

However, fat emboli also produce ‘biochemical’ effects after trauma. Lipase enzyme stimulation and catecholamine production stimulate the conversion of benign fat to toxic free fatty acids which can potentially damage end-organ endothelial lining. These toxic products contribute to the stimulation of coagulative and inflammatory processes (systemic inflammatory response syndrome, SIRS), which form part of a patient’s systemic stress response after trauma.

Surgical procedures that instrument the medullary cavity are associated with increased intramedullary pressure and fat embolus production. Instrument design and surgical techniques have concentrated on reducing this fat embolic load. The use of unreamed nails, reamer aspiration irrigation systems, and intramedullary canal venting are all surgical techniques available to reduce the pulmonary and systemic fat embolic load during intramedullary long-bone fracture fixation.

Fat and bone emboli can enter the systemic circulation via a patent foramen ovale. Paradoxical embolization can also occur through arterial–venous shunts in the pulmonary circulation. Transcranial Doppler ultrasound has correlated shunt size to the volume of embolic material detected in the cerebral circulation. Chest injury is commonly associated; an altered pattern of pulmonary circulation caused by the chest injury may increase the degree of blood shunting within the pulmonary.

Coagulation

Trauma and subsequent surgery activates thrombogenic and fibrinolytic pathways within the pulmonary and systemic circulations. Increased perioperative levels of prothrombin fragments 1 and 2 and fibrin degradation products have been demonstrated in isolated femoral fractures treated with intramedullary fixation.

This activation and possible loss of coagulation control has been linked to the development of acute lung injury and other systemic complications after major trauma. Therefore a synergistic embolic and coagulative response can occur after trauma which can affect pulmonary function. The more severe clinical responses can produce a clinical picture similar to disseminated intravascular coagulation. Localized disseminated intravascular coagulation within the lung has been attributed to acute lung injury due to the production of microthrombi.

Inflammation
In the minutes that follow a traumatic event, the direct tissue damage and change in haemostasis produce an inflammatory response. This involves the activation of monocytes and granulocytes that produce pro- and anti-inflammatory mediators. The term systemic inflammatory response syndrome (SIRS) has been applied to the generalized inflammatory response to trauma. This initial proinflammatory response is produced predominantly from macrophages and is primarily involved in removing damaged tissue and beginning repair processes. This initial stress response is relatively short lived and the monocytes soon become deactivated and unable to respond to fresh stimuli. A compensatory anti-inflammatory response (CARS) is then activated with mediators directly linked to the development of immunosuppression after trauma.

Therefore this imbalance can result in a period of compromised immunity after serious injury. A more pronounced immunodepression is seen with increasing levels of haemorrhage and tissue damage. The clinical effects of this immune imbalance are an exacerbation of shock, increased fluid transudation into end-organ interstitial spaces, coagulative activation and a predisposition to infection. These processes are apparent in the days after injury and correspond to the scheduling time for many surgical procedures, which will involve further tissue trauma.

A recent development has been the use of pro- and anti-inflammatory markers in the prediction of patient outcome after serious injury. Elevated IL-6 levels have been demonstrated in the polytraumatized patient with further increases measured after intramedullary femoral fracture fixation.

Excessive release of proinflammatory cytokines appears to be central in the pathogenesis of complications such as acute respiratory distress. Amplified levels of proinflammatory cytokines IL-1β and IL-8 have been demonstrated from bronchoalveolar lavage samples in patients with high injury severity scores. However, there was no corresponding rise in systemic (serum) concentrations.

The accumulation of neutrophils and proinflammatory mediators has been demonstrated in the alveolar space during early acute respiratory distress. The alveolar space appears to be converted into an area of intense localized inflammation. Inflammatory cytokines can act as chemoattractants to draw neutrophils from the plasma into the interstitial space. This was demonstrated in a prospective clinical study, where neutrophils were isolated and examined from peripheral blood samples taken from healthy volunteers and from patients after major musculoskeletal trauma. The chemoattractant properties of IL-8 were demonstrated with enhanced neutrophil migration across porous tissue culture inserts in the injured group. The coupling of enhanced neutrophil migration with elevated IL-8 levels may be central to the development of pulmonary and other end-organ inflammation.

### Intraoperative planning and strategy in the polytraumatized patient (Box 12.3.2)

**General considerations**

Care of patients who have sustained multiple injuries requires a team approach. During the initial phase in the Emergency Department this is usually coordinated by an accident and emergency consultant, with other specialties intervening in a coordinated and timely fashion, following ATLS protocol. The role of the orthopaedic team is to firstly assess for any musculoskeletal injuries that require urgent intervention. The haemodynamically unstable pelvis is an obvious example. Open fractures require antibiotic and tetanus prophylaxis with the application of a sterile dressing. Obvious skeletal deformity such as that caused by a dislocated ankle or long-bone fracture can also be reduced and temporarily splinted.

**Box 12.3.2 Intraoperative planning**

- ATLS protocol with trauma team
- Radiolucent table best
- Prioritize procedures, e.g. pelvic fixation
- En bloc debridement and stabilization for open injuries
- Immediate/early reconstruction best.

A careful secondary survey performed at this stage will often identify other orthopaedic injuries not identified during the initial Emergency Department assessment. Appropriate plain x-rays can be ordered to assess these areas, but in a timely fashion to minimize treatment delay. At this stage a list of injuries should be compiled and effective communication with allied specialties will allow a hierarchy of injuries to be established. The most urgent life- or limb-threatening injuries should be dealt with first.

It is important to identify any logistical problems that may impede the surgical treatment plan. The optimal department for the patient’s continued care should be established with intensive care specialists involved at an early stage if required. The availability of theatre and the relative orthopaedic trauma experience of the available theatre staff should be ascertained. Good communication with regards to the type and availability of the appropriate surgical hardware required will save time and allow adequate theatre preparation time. Inform the theatre staff of the likely sequence of surgical procedures and whether simultaneous management of different injuries is being considered. The availability of a radiolucent table greatly eases simultaneous fixation of long-bone and pelvic injuries. The intramedullary stabilization of long-bone fractures without the need for skeletal traction in the multiply injured can also reduce operative time, but requires adequate experience and good surgical assistance.

The physiological status of the patient throughout surgery should be monitored with the help of the anaesthetist. Appropriate invasive monitoring should be instigated with the insertion of a central venous and arterial lines and use of a Swan–Ganz catheter.
These give vital information regarding the true haemodynamic and metabolic status of the patient with pulmonary arterial pressure measurements being proportional to the degree of arterial hypoxaemia. The most urgent surgical procedures, such as the external fixation of an unstable pelvic fracture or the adequate tissue debridement of an open fracture, should be performed initially. Extremity injuries often require being redraped in order to ensure sterility. A few minutes of discussion before surgery in order to formulate a surgical plan can minimize the operative time. The management of contralateral upper and lower extremity injuries can be facilitated by a team approach with simultaneous fracture fixation, but requires adequate staff numbers. The floating knee can be stabilized with femoral and tibial intramedullary nails inserted through the same small incision in a retrograde and antegrade fashion respectively. Priority should also be given to injury types where bone, cartilage, and soft tissue damage is likely to progress with time. The dislocated shoulder or ankle may have been already reduced in the emergency department; however, a femoral head fracture/hip dislocation or displaced femoral neck or talar fracture are examples of injuries where a delay in treatment affects prognosis.

Open fractures

The Gustilo and Anderson classification system for open fractures is most commonly used and effectively describes the degree of soft tissue injury, periosteal stripping, and vascular injury. The vascularity and perfusion of damaged tissue should be assessed and allied specialties such as plastic surgery involved early. The wound should be minimally re-exposed and inspected as this may increase the contamination risk. Antibiotic prophylaxis reduces the incidence of infection and is usually prescribed for 3 days. The regimen can be altered depending upon the likely degree of contamination. Cephalosporins are most commonly administered with the addition of an aminoglycoside and penicillin (to cover *Clostridium*) in more contaminated wounds. Double antibiotic therapy is more effective specifically after type 3 open fractures.

A soft tissue debridement is only effective if it removes all necrotic and contaminated material. Serial debridement removes only tissue which is clearly necrotic on each operative visit. An immediate and more extensive ‘en bloc’ excision into viable tissue allows removal of all affected material and minimizes the infection risk of subsequent bone stabilization and reconstructive procedures.

An adequate excision of skin, subcutaneous fat, fascia, and muscle must be performed. Bone fragments contaminated or free from soft tissue attachments should also be removed. There is debate about the best type of lavage to use. Pulsatile lavage will not compensate for an inadequate tissue debridement and may obscure the tissue planes and cause secondary tissue damage. The use of normal saline or Ringer’s lactate with low pressure lavage should suffice after an adequate debridement.

The initial soft tissue and bone excision should not be compromised by concerns about subsequent tissue defects and wounds should not be closed under tension. Skeletal stabilization should then be performed after the initial debridement. If the initial soft tissue debridement was considered inadequate then a second debridement should be considered within 48h. Early plastic surgery input with regards to soft tissue reconstruction is vital. The reconstructive ladder describes the available soft tissue options which range from primary closure or a simple split skin graft, to pedicled or free flap transfers. Immediate reconstruction is recommended and has been shown to reduce complication rates and speed patient rehabilitation. Delayed reconstruction (>72h) after extremity trauma increases the incidence of flap failure, delays bone healing, prolongs hospital stay, and increases the number of subsequent operative procedures required.

Pelvic injuries

The management of a haemodynamically unstable pelvis is a priority after serious injury. The mechanism of injury and accident details will often give an accurate guide to the most likely pattern of injury sustained. For example a rollover car vehicle accident is associated with a lateral compression (LC) pattern; a fall from a height would more likely produce a vertical shear (VS) fracture; forceful leg abduction and external rotation of the hemipelvis, (common after a motorcycle accident) can produce an anterior–posterior compression (APC) injury. Physical examination includes one gentle pelvic manipulation to assess stability and a physical examination includes one gentle pelvic manipulation to assess stability and a

Definitive pelvic fixation involves anterior symphyseal plating for displacements greater than 2cm. A vertically unstable posterior ring injury requires closed reduction and percutaneous screw fixation or direct open reduction with plates and screws.
Upper extremity injuries

The age, hand dominance, profession, previous injuries sustained, associated medical problems (e.g. diabetes), and drug history are all important factors to obtain once the life-threatening injuries have been stabilized. The time from injury allows an estimation of the ischaemic duration and likely tissue viability, whilst the mechanism and nature of the injury are indicators of the degree of tissue damage and contamination. Whilst circulation can be adequately assessed under an anaesthetic, motor and sensory function to the upper limb extremity should be assessed in the emergency department. This vital information should be obtained quickly and calmly with minimal distress or discomfort to the patient with adequate analgesia given prior to assessment. Plain radiographs should be obtained, with other useful diagnostic adjuvant being Doppler ultrasound and compartment pressure monitors. Preoperative planning should involve an estimation of the likely surgical time. This has implications with regard to the type of anaesthetic used (regional or general) and the application of a tourniquet.

After serious skeletal injury, limb revascularization is the first priority before soft tissue debridement and skeletal stabilization. Early intervention with vascular surgery aims to restore both arterial and venous blood supplies. Important considerations are:

- The use of an autologous reverse saphenous vein graft
- The hazardous systemic effects of restoring venous blood supply after prolonged tissue ischaemia and accumulation of toxic metabolites
- The use of temporary shunts to re-establish arterial blood flow quickly and minimize the tissue ischaemic time.

Reconstructive options include: primary closure (immediate or delayed); skin grafts; local, regional, pedicle, and free flaps. Amputation can be considered if functional reconstruction is not possible. This decision may be subjective, but is best made after the combined good judgement of the surgical team rather than any one individual. Scoring systems such as the mangled extremity severity score (MESS) are less applicable to the upper limb.

Early skeletal stabilization of upper limb injuries allows early rehabilitation, facilitates nursing, and reduces patient discomfort and morbidity. Open reduction and internal fixation of long-bone diaphyseal fractures after polytrauma with dynamic compression plates and screws is standard. External fixation or intramedullary long-bone stabilization is less successful than in the lower limb with higher iatrogenic and soft tissue complication rates. Concerns with regards to increased infection and non-union rates after open fractures or operations through contused soft tissues should not alter the method of fracture fixation. Acceptable (<15%) rates of non-union and infection after fixation of open forearm fractures with good functional results have been demonstrated in the majority of patients. Bone shortening is a useful technique which can achieve a stable construct following extensive bone and soft tissue loss. This is well tolerated in the upper limb. Intra-articular fractures of the shoulder, elbow, and wrist require reduction and stabilization. Options include: splint immobilization; open reduction and internal fixation; arthroplasty and arthrodesis.

Tendon and nerve injuries are best managed by early reconstruction. The location of the injury (e.g. zone 2 flexor tendons), the extent of the surrounding soft tissue damage, and the patient’s associated injuries all influence outcome. Primary tendon repair restores anatomy with the ipsilateral palmaris longus tendon or long toe extensors being the most commonly used donor grafts if tendon substance has been lost. Although early reconstruction improves outcome, tendon transfer procedures are usually performed at a later stage once the patient has recovered and an accurate assessment of any functional deficits has been made. The key to successful rehabilitation is dynamic splinting whilst adequately protecting the tendon repair. Nerve reconstruction generally produces less satisfactory results even after direct repair in a clean and well vascularized environment. Nerves should be sutured without tension and if this cannot be achieved due to soft tissue damage, then nerve transposition or free non-vascularized grafts (e.g. sural nerve) for more extensive defects are commonly used options.

Lower extremity injuries

The initial patient assessment should determine patient age, pre-injury level of function, mechanism of injury, time from injury, and haemodynamic status. Associated injuries to the head, chest, abdomen, and pelvis should be documented. Peripheral nerve function and the vascular status of the lower limb are assessed, with specific injuries more likely to compromise neurovascular function. Examples include the dislocated hip which can affect sciatic nerve function and medial tibial plateau fractures which are associated with a higher incidence of popliteal vessel and common peroneal nerve injury. Sensation over the plantar aspect of the foot and the presence of pedal pulses (use Doppler ultrasound if required) should be determined in the severely traumatized lower limb as they affect likely limb prognosis. Open wounds are assessed with an estimation of tissue loss and contamination, with the application of sterile dressings and administration of antibiotic and tetanus prophylaxis. Obvious lower limb deformity can be corrected under adequate analgesia, prior to appropriate radiographs being obtained and splints or plaster being applied to ease patient discomfort.

There has been much recent debate with regard to the merits of limb salvage versus amputation. The MESS is one tool available to help assess the need for amputation. The measured parameters include: patient age, haemodynamic status, tissue ischaemic time, and the degree of soft tissue injury and contamination. Such scoring systems cannot substitute for sound clinical judgement, experience, and a team approach.

The main principles in the treatment of lower limb injuries are: adequate reduction and stabilization of long bone fractures; reduction and restoration of joint surfaces; and the maintenance of a viable soft tissue envelope. Reamed intramedullary stabilization of closed and open femoral and tibial diaphyseal fractures in the polytraumatized is standard with the main indications for external fixation being: severe soft tissue injury; poor patient physiological status; skeletally immature bone; and a narrow intramedullary canal. Intramedullary fixation is preferred for all other types of open fracture. Unreamed intramedullary nailing theoretically reduces the pulmonary fat embolic release from the fracture site. However, the stimulation of the periosteal blood supply and generation of autogenic bone grafting produced by reaming are thought to be reasons for the higher rates of non-union and implant failure associated with unreamed intramedullary fixation of both open and closed fractures.
The use of a radiolucent table can reduce operative time in the polytraumatized patient. It allows easier access to multiple injuries. Antegrade nailing is predominantly performed, with the main indications for retrograde femoral nailing being: the obese patient; distal femoral fractures; ipsilateral femoral and tibial shaft fractures (i.e. the ‘floating knee’); ipsilateral femoral neck and shaft fractures; and the pregnant patient.

The joint disruption and associated soft tissue swelling that can accompany pilon or tibial plateau fractures can be initially treated with a spanning external fixator. This stabilizes the injury, restores limb length, and allows the soft tissues to recover, whilst ligamentotaxis aids articular surface reduction. Definitive internal fixation using minimally invasive incisions can then be performed initially if the soft tissues and patient’s physiological status allow. However, a staged procedure with initial external fixation and definitive stabilization performed 1–2 weeks after injury is a reasonable alternative with low risks of infection and complications. Displaced intracapsular hip fractures, hip dislocations, and acetabular fractures with radiological evidence of incarcerated bone fragments are the more common examples of proximal lower limb injuries that require urgent surgical intervention in order to reduce the incidence of bone necrosis and articular cartilage damage.

**Box 12.3.3 Risk factors**

- High ISS
- Over or under transfusion
- Long bone/male/<30 years/hypoxaemia
- Elderly

**Risk factors for systemic complications after trauma surgery (Box 12.3.3)**

Direct pulmonary injury can occur due to aspiration, pneumonia, pulmonary contusion, and toxic inhalation. Indirect end-organ damage can also occur as a result of sepsis, multiple transfusions, over-aggressive fluid management, and disseminated intravascular coagulation. Severe chest injury is relevant to orthopaedic trauma patients as there is much debate regarding the optimal method of long-bone fracture fixation in order to minimize secondary pulmonary damage. A higher Injury Severity Score (ISS) increases the likelihood of developing systemic complications after injury. This has been confirmed in a retrospective review of 1278 trauma patients. A correlation was established between: ISS, the systemic inflammatory response to trauma (SIRS), and the incidence of acute respiratory distress and multiple organ dysfunctions.

The screening of trauma patients to identify those ‘at risk’ of developing respiratory insufficiency and symptoms related to fat embolus is key to the early diagnosis and treatment of the condition. Following long-bone injury, males under the age of 30 years with significant and early hypoxaemia are considered to be at a higher risk of developing respiratory insufficiency. Age may be a key factor in the development of symptoms related to fat embolus. In a consecutive series of 274 patients with isolated femoral shaft fractures, a 4% incidence of fat embolism syndrome (FES) occurred. There were no cases in patients aged over 35 years. The risk of developing FES was also reduced by early intramedullary fracture stabilization within 10h of admission. All 11 cases of FES in this study occurred in patients aged under the age of 35 years who had delayed (>10h) femoral fracture stabilization. Elderly patients are also more susceptible to the systemic effects of trauma with a lower (50%) lethal ISS required in patients aged over 65 years. Prolonged bed-rest and poor mobility are associated with increased morbidity and mortality in this age group.

Predictors for respiratory distress in adults include youth, high ISS, the presence of a femoral fracture, the combination of abdominal and extremity injuries, and physiological compromise on admission.

**Damage control orthopaedics versus early total care following polytrauma**

**Background**

Peripheral limb injuries that involve long-bone diaphyseal fractures constitute a leading cause of hospitalization related to non-fatal injury. The initial treatment of these injuries was often delayed in order to ‘optimize’ a patient’s condition. Immediate surgical treatment to stabilize these injuries was thought to worsen prognosis owing to further tissue damage and haemorrhage. However, it became apparent that early skeletal stabilization actually reduced the incidence of complications and improved outcome. Early intramedullary long-bone fracture stabilization reduces mortality rate in seriously injured patients, with reduced respiratory complications, reduced mortality and length of stay.

A policy of early long-bone fracture stabilization has been recommended to improve and reduce the frequency of respiratory and systemic complications after injury. The term ‘early total care’ has been applied to the definitive and early (<24h from injury) reamed intramedullary fixation of long-bone fractures and is considered the optimal form of treatment and a surgical priority in the seriously injured.

However, concerns have been raised with regard to secondary pulmonary and systemic embolic events, possibly linked to reamed intramedullary surgical techniques in the seriously injured. Patients with a low injury severity benefited from early long-bone stabilization with fewer respiratory complications. However, this benefit was not seen in patients with an ISS of greater than 18.

The concerns regarding the physiological effects of early reamed intramedullary femoral stabilization have been extensively investigated by the Hanover group, and they concluded early reamed nailing in high ISS patients increases the risk of ARDS and...
Conservative surgical techniques that reduce operative time and tissue insult were proposed in seriously injured patients to minimize the ‘second hit’ caused by surgery. The term ‘damage control’ was applied to these surgical techniques. The types of patients thought to benefit from ‘damage control’ were those who had sustained serious penetrating or blunt injury with persistent hypothermia, coagulopathy, and acidaemia despite resuscitation. In such patients, the risk of metabolic failure from surgery was considered greater than the risk of failing to complete the initial definitive procedure. The broad principles of ‘damage control’ surgery include: limited procedures to control haemorrhage and stabilize life-threatening injuries; physiological patient monitoring within an intensive care environment; definitive surgery once the patient’s condition has been optimized.

A practical application of ‘damage control orthopaedics’ (Box 12.3.4)

There is no general agreement about which patients are suitable for ‘damage control orthopaedics’ (DCO) but it should be considered in multiple trauma patients with a significant chest injury or an ISS probably in excess of 30. Other patients can be treated by standard methods of long-bone fixation. Uncorrected metabolic acidosis in the seriously injured appears to be a key feature with increased pulmonary and systemic complications after fracture fixation surgery. The clinical indicators used by the Hanover group, where DCO techniques have been most widely reported are: ISS higher than 20 with an associated chest injury; polytrauma with abdominal/pelvic trauma and shock (systolic blood pressure <90mmHg); ISS higher than 40 with no chest injury; x-ray evidence of bilateral lung contusions; mean pulmonary arterial pressure greater than 24mmHg; increase of more than 6mmHg in pulmonary arterial pressure after intramedullary reaming.

They have also described certain clinical parameters associated with a poor outcome after serious injury. These include: inadequate resuscitation, coagulopathy, hypothermia, multiple blood transfusions (>25 units), multiple long-bone fractures, excessive surgical time (>6h), metabolic acidosis (pH <7.24), and an exaggerated inflammatory response judged to be an IL-6 measurement of >800pg/mL.

Damage control techniques have also been extended to include aspects of initial patient resuscitation. Aggressive fluid therapy has the potential to exacerbate lung interstitial oedema. Therefore, the concept of delayed fluid therapy may form part of a ‘damage control’ surgical protocol in order to avoid this complication. Imvasive monitoring of central venous, arterial, and pulmonary arterial pressures allows a more accurate assessment of hypoxaemia and true haemodynamic status. The effects of surgery and other therapeutic interventions can then be closely monitored with regular blood sampling allowing oxygen, carbon dioxide, and lactate levels to be closely monitored.

Ventilatory strategies in polytraumatized patients have also altered. Conventional therapy is aimed to maximize oxygen delivery and obtain normal arterial blood gas measurements. This often involved the use of high tidal volumes and pressure ventilation techniques. These may have the potential to cause secondary pulmonary damage and could predispose to the development of acute respiratory distress after injury. Lung protective protocols are now often implemented in the seriously injured which involve less aggressive ventilatory intervention. The goals are to facilitate pulmonary recovery and to prevent any further alveolar damage. Low tidal volumes are used with pressure limited ventilatory techniques and non-toxic concentrations of inspired oxygen to achieve ‘adequate’ arterial blood gas concentrations.

Box 12.3.4 Prevention of complications

- Urgent long bone stabilization
- May be best to ex-fix long bones initially
With regards to surgery the 'DCO' concept can be extended out with the most recent debates with regard to femoral fracture fixation. A pelvic ring injury, where haemorrhage is poorly controlled and exsanguination imminent, can also be suitable for DCO. The role of angiography and arterial embolization has been debated. The time taken to perform this procedure has been shown to correlate with mortality rate. In order to avoid delay some trauma centres advocate minimally invasive pelvic fixation (with a pelvic binder or external fixator) followed by pelvic packing if this does not obtain haemodynamic control. Any haemodynamic, metabolic, or coagulative problems can then be corrected in an intensive care environment and definitive pelvic surgery arranged as a secondary procedure, once the patient’s condition has been optimized.

There have also been concerns about intramedullary fracture fixation in the multiply injured patient with a head injury, but these have not been confirmed. Early fracture stabilization has the potential to reduce pain and minimize further soft tissue damage and fat embolism release, and should form part of the initial management of patients with a head injury along with adequate resuscitation. Improved neurological outcome does appear to be related to intracranial pressure monitoring and aggressive management if required. Optimal outcomes have been demonstrated by maintaining a cerebral perfusion pressure of above 70mmHg with intracranial pressures of below 20mmHg.

Further reading

Summary points

- The orthopaedic trauma surgeon will be involved in the majority of poly trauma patients.
- It is essential that the associated non-orthopaedic injuries are identified and appropriately managed.

It is my contention that failure to care for the surgical patient… is the most powerful disincentive to know the science of surgery. A surgical registrar who has not been exposed to the trauma patient and to intensive care is incompletely trained, unqualified, and unprepared for surgical practice or specialty training.

Donald Trunkey, Address to the Association of Surgeons of Great Britain and Ireland, 1988

Head trauma

Extracranial injury

Scalp injuries

Laceration of the scalp may be associated with significant bleeding. Control with a compression dressing, and follow with deep sutures if necessary: debride and repair later. ‘Haemostasis before cosmesis.’ Haematomas under the galea can attain considerable size, and there is a significant danger of sepsis so these should be drained, rather than aspirated. Scalp infections may spread intracranially via the emissary veins.

Skull injuries

Skull fractures are described according to integrity of the overlying skin. A fracture can be diagnosed by digital exploration of the wound, or radiographically. Skull fractures can be divided into:

- External (skull vault)
- Simple
- Compound
- Fracture of base—diagnosis of basilar fractures is usually clinical:
  - Cerebrospinal fluid leaking from the nose or ear
  - Periorbital ecchymosis (‘roacoon eyes’)
  - Ecchymosis behind the ear (Battle’s sign)
  - Blood in the external canal is considered as a basilar fracture until proven otherwise by computed tomography (CT) scan.

Depressed skull fractures

Traditionally all depressed skull fractures (Figure 12.4.1) were elevated when the depth of the depression exceeded the thickness of the adjacent skull table, to alleviate compression of the underlying cortex. However, not all fractures need elevation in the absence of underlying focal injury.

Fig. 12.4.1
A) CT scan of depressed fracture of skull. B) Three-dimensional reconstruction of same patient—45-degree view.

Intracranial injury

Brain injuries
Severe brain injury accounts for almost half of all deaths from trauma and is a major cause of residual disability in trauma patients. Any other treatment (including orthopaedic or spinal fixation) should not prejudice the brain, or cause further damage. Any patients sustaining major injury should be suspected of having an associated cervical spine injury.

The availability of CT (Figure 12.4.2) scanning has been shown to reduce mortality, as the time taken to diagnose and evacuate an intracerebral haematoma is critical in determining outcome. However, the majority of patients with brain injury do not have a lesion suitable for neurosurgical intervention.

Brain damage is divided into:

**Primary brain injury**

This occurs at the time of injury and is irreversible, i.e. lacerations, contusions, axonal injuries of the white matter due to shearing forces. Only 35% of deaths due to brain injuries are due to primary brain injury.

Primary brain injury may be:

- **Focal**—focal injuries, which are usually caused by direct blows to the head, comprise contusions, brain lacerations, and intracerebral haemorrhage leading to the formation of a haematoma in the extradural, subarachnoid, subdural, or intracerebral compartments within the head
- **Diffuse**—diffuse brain injury causes diffuse damage to the axons. The distal segment of the axon undergoes degeneration. Profound deficits may result from this diffuse axonal injury.

**Secondary brain injury**

This occurs at a later stage, may be preventable, and to a significant extent, reversible, and is the cause of 65% of mortality due to brain injury. The injury is due to hypoxia, hypovolaemia causing hypoperfusion, and hypothermia. An understanding of these is fundamental, and the treatment of a head-injured patient should emphasize early control of the airway, adequate ventilation and oxygenation, correction of hypovolaemia, and limiting hypothermia. Hyperventilation is no longer routinely used. No surgery is possible and management is dependent on appropriate intensive care management of the patient.

**Adjuncts to care**

**Antibiotics**

Broad-spectrum antibiotic prophylaxis is recommended for both military and civilian penetrating craniocerebral injuries, including those due to sports or recreational injuries. Generally, a cephalosporin, or amoxicillin/clavulanate is recommended.

Prophylaxis is not recommended for fracture of the base of the skull.

**Anticonvulsants**

Seizure activity in the early post-traumatic period following head injury may cause secondary brain damage as a result of increased metabolic demands, raised intracranial pressure, and excess neurotransmitter release.

For patients who have had a seizure after a head injury, anticonvulsants are indicated and are usually continued for 6 months to 1 year.

Recent review of the available evidence has demonstrated that while prophylactic antiepileptics are effective in reducing early
seizures, there is no evidence that treatment with prophylactic antiepileptics reduces the occurrence of late seizures, or has any effect on death and neurological disability.

Burr holes

Patients with closed head injury and expanding extradural or subdural haematomas require urgent craniotomy for decompression and control of haemorrhage.

In remote areas where neurosurgeons are not available, non-neurosurgeons (often orthopaedic surgeons) may occasionally need to intervene to avert progressive neurological injury and death. Surgeons in remote, rural hospitals in the United States of America have shown that emergency craniotomy can be undertaken with good results where clear indications exist.

Craniofacial injuries

Introduction

Face and neck injuries can be the most ‘difficult-to-manage’ wounds encountered.

Immediate management

Focusing on ABC priorities is vital: airway distress due to upper airway obstruction above the vocal cords is generally marked by inspiratory stridor.

- During airway control, maintain cervical spine immobilization. Up to 10% of patients with significant blunt facial injuries will also have a cervical spine (C-spine) injury. Obtunded patients with blunt facial trauma should be treated with C-spine immobilization. Unstable C-spine injury is very rare in neurologically intact penetrating face and neck wounds.
  - The airway may be partially or wholly obstructed from:
    - Blood or oedema resulting from the injury
    - The tongue may obstruct the airway in a patient with a mandible fracture
    - A fractured, free-floating maxilla can fall back obstructing the airway
    - Displaced tooth fragments may also become foreign bodies
    - Remove foreign bodies (strong suction, Magill forceps)
    - There is a real danger of airway obstruction due to haematoma. Early intubation is a key management requirement. Cricothyroidotomy or emergency tracheotomy may be necessary.
- Injuries to the face are often accompanied by significant bleeding. Control of facial vascular injuries should progress from simple wound compression for mild bleeding to vessel ligation for significant bleeding. A Foley catheter inserted blindly into a wound and inflated, may rapidly staunch bleeding. Vessel ligation should only be performed under direct visualization after careful identification of the bleeding vessel. Blind clamping of bleeding areas should be avoided, because critical structures such as the facial nerve and parotid duct are susceptible to injury. Intraoral bleeding must be controlled to ensure a patent and safe airway. Do not pack the oropharynx in the awake, unintubated patient, due to the risk of airway compromise: first secure the airway with an endotracheal tube.
  - Complete assessment of remaining injuries (fractures, lacerations, oesophageal injury, ocular injuries).
  - Penetrating injury may not follow classic Le Fort patterns but may have a significant soft tissue injury component (base of tongue, soft palate).

Evaluation

After initial stabilization, cleanse dried blood and foreign bodies gently from wound sites in order to evaluate the depth and extent of injury. Examination of the bony orbits, maxilla, forehead, and mandible and a complete intraoral examination of all mucosal surfaces for lacerations, ecchymosis, step-offs or mobile segments and malocclusion suggestive of a fracture, should be performed.

A cranial nerve examination must be performed, to assess vision, gross hearing, facial sensation, facial muscle movement, tongue mobility, extracranial movements, and to rule out entrapment of the globe.

CT scan ideally with three-dimensional reconstruction (Figure 12.4.18) and with coronal views (Figure 12.4.3) gives an accurate assessment of the damage.
Nasal fractures

The most common fracture. Diagnosed clinically by the appearance and mobility of the nasal bones. Epistaxis must be controlled with direct pressure, anterior pack-gauze, or Foley catheter balloon tamponade.

Treatment is by closed reduction of the fractured bones and/or septum into their correct anatomical positions, up to 7 days after fracture. A blunt elevator is placed into the nasal cavity in order to elevate the depressed bony segment, while simultaneously repositioning the bone with the surgeon’s thumb placed externally. The nose may then be fixed with tape or a splint in order to maintain the reduction.

Fractures of the mandible

The mandible is a ‘ring structure’ and in 50% of cases (like the pelvis) may be fractured in more than one site. The most common site is the subcondylar region.

Patients present with limited jaw mobility or malocclusion. Confirmation of the diagnosis is best by CT scan with coronal reconstruction. Dental Panorex is the single best plain film. PA mandible serves as a less reliable but satisfactory study (though subcondylar fractures are difficult to see).

Treatment is determined by the location and severity of the fracture and condition of existing dentition. Remove only teeth that are severely loose or fractured with exposed pulp. Even teeth in the line of a fracture, if stable, and not impeding the occlusion, should be maintained.

Immediate reduction of the mandibular fracture and improvement of occlusion can be accomplished with a bridle wire (24 or 25 gauge) placed around at least two teeth on either side of the fracture. More severe fractures with malocclusion will require immobilization with maxillary–mandibular fixation for ± 6 weeks.

Major midfacial fractures

These multibone injuries may be life threatening due to loss of airway, haemorrhage, or spinal injury. The haemorrhage is commonly from epistaxis, oral haemorrhage, or combination bleeding. Occasionally it can be catastrophic. Control is usually by a combination of pack tamponade and direct pressure. If uncontrolled, early sedation and intubation of the patient followed by appropriate packing may be life saving.

The fractures are associated with a significant amount of energy. They are particularly associated with central nervous system, cervical spine, and orbital injury.

Le Fort’s classification of facial injuries

Facial bony injuries are classified into Le Fort type fractures (Figure 12.4.4 and Table 12.4.1), although not infrequently, the injuries may be a combination of several different components. Diagnosis is primarily by CT scan, with specific coronal views but clinical examination can be helpful and is performed by a gentle attempt to mobilize the hard palate and midface while stabilizing the skull.
Diagrammatic representation of Le Fort fractures.

### Table 12.4.1 Anatomical and clinical presentation of facial fractures

<td>Manipulation of the maxilla results in gross movement of the whole face</td>
</tr>
</tbody>
</table>

Place the thumb and forefinger of one hand on the nasal bridge to stabilize, then with the other hand, determine mobility of maxilla by placing the thumb on alveolus and forefinger on the palate and attempting gentle distraction in an anterior–posterior direction.

Penetrating injury may not follow classic Le Fort patterns but may have a significant soft tissue injury component (base of tongue, soft palate). Normal principles of systemic palpation and inspection apply, looking for crepitus, tenderness, internal and external ecchymosis, and subconjunctival haemorrhage that might suggest fractures.

**Management of facial fractures**

The goals of fracture repair are realignment and fixation of fragments in correct anatomical position with dental wire (inferior, but technically easier), or plates and screws. With the exception of fractures that significantly alter normal dental occlusion or compromise the airway (e.g. mandible fractures), repair of facial fractures may be delayed for 2 weeks.

Wounds should be gently cleansed with saline and light scrub solutions; foreign bodies should be meticulously cleaned from wounds prior to closure. Devascularized wound edges require only minimal debridement. Facial lacerations should be closed in layers within 24h.

If the patient’s jaws are wired together, it is imperative that wire cutters be available next to the patient at all times.

---

**The thorax**

### Introduction

Following major injury, 50% of fatalities are due to primary brain injury, 25% due to chest trauma, and in another 25% (including brain injury), thoracic injury contributes to the primary cause of mortality. Injury to the chest wall and thoracic viscera can directly impair oxygen transport mechanisms. Hypoxia and hypovolaemia resulting, may cause secondary injury to patients with brain injury, or may directly cause cerebral oedema. Conversely, shock and/or brain injury can secondarily aggravate thoracic injuries and hypoxaemia by disrupting normal ventilatory patterns or by causing loss of protective airway reflexes and aspiration.

A significant number of thoracic trauma-related deaths occur at the time of injury, for example, rapid exsanguination following traumatic rupture of the aorta in blunt injury or major vascular disruption after penetrating injury. Of those survivors with thoracic injury who reach hospital, a distressing proportion dies in hospital as the result of misassessment or delay in the initiation of treatment. These deaths occur early as a consequence of shock, or late as the result of adult respiratory distress syndrome (ARDS) and sepsis.

Most life-threatening thoracic injuries can be simply and promptly treated after identification by needle or tube placement for drainage. Only around 25% of injuries will require surgical intervention.

Thoracotomy performed in the Emergency Room (ERT) has specific indications, and is generally reserved for immediate control of haemorrhage following penetrating injury.

**The spectrum of thoracic injury**

Thoracic injuries are grouped into two types (Table 12.4.2):

- Immediate threat to life
- Potential threat to life.
Table 12.4.2 Life-threatening thoracic injuries

The entity of the ‘traversing mediastinal wound’ in penetrating injury warrants specific mention. Injuries of this type frequently involve damage to a number of the mediastinal structures and are thus more complex in their evaluation and management.

Patients arrive in two general physiological states:

- Haemodynamically stable
- Haemodynamically unstable.

In patients with penetrating injury to the upper torso who are haemodynamically unstable, and the bleeding is into the chest cavity, it is important to insert a chest tube as soon as possible during the initial assessment and resuscitation. In the patient in extremis who has chest injuries or where there may be suspicion of a transmediastinal injury, bilateral chest tubes may be indicated. X-ray is not required to insert a chest tube, but is useful after the chest tubes have been inserted to confirm proper placement.

In patients who are haemodynamically stable, and those with blunt injury, x-ray remains the simplest initial screen for pneumothorax or haemothorax and to exclude pulmonary contusion. In these patients it is preferable to have the x-ray completed before placement of a chest tube—the decrease in air entry may not be due to primary lung pathology, and especially following blunt injury may be due to pulmonary contusion, or a ruptured diaphragm with bowel or stomach occupying the thoracic cavity.

**Diagnosis**

Diagnosis of thoracic injury is usually made, depending on the stability of the patient, using a combination of clinical examination, chest x-ray, CT scan, angiography, and magnetic resonance imaging (MRI) scan.

**Clinical examination**

The clinical examination of the chest will yield a significant amount of information. The trachea is checked for its position (central), the chest is examined in the standard fashion for pain, dullness to percussion, and alteration in breath sounds, and the heart is examined. It is essential to perform an examination of the chest posteriorly at an early stage, using a log-roll technique to protect the spine. The spine is examined for tenderness which may indicate vertebral injury. In penetrating injury, a search is made for additional wounds on the back.

**Chest x-ray**

A chest x-ray, initially taken supine will add valuable information to the clinical examination. Specific attention should be paid the ‘ABCs’ of the chest x-ray

- A: airway—including tracheal deviation, etc.
- B: breathing—lung fields, presence of contusion
- C: circulation—mediastinum and heart, particularly presence of a wide mediastinum
- D: diaphragm—the placement of a nasogastric tube may help clarify the position of the oesophagus, stomach, and left hemidiaphragm
- E: environment—rib fractures, associated fractures of scapula, etc.

**CT scan of the chest**

The chest CT scan is generally regarded as the ‘gold standard’ for diagnostic imaging. The scan should be performed with contrast, allowing CT angiography as required. The scan gives excellent information regarding the chest wall, lungs, mediastinum, great vessels, and bony structures.
CT scan should never be performed in the haemodynamically unstable patient.

Management of immediate threats to life

Tension pneumothorax

Tension pneumothorax is air under pressure in the pleural cavity due to a valve effect. It is associated with life-threatening cardiorespiratory compromise due to collapse of the affected lung, compression of the normal lung, and decreased venous return to the heart.

The presentation is dramatic, with a panicky patient who on examination has dyspnoea, cyanosis, tachypnoea, shock, distended neck veins. The symptoms are similar to those caused by cardiac tamponade. The trachea is shifted to the opposite side, best felt just above the sternal notch. Breath sounds are reduced or absent, and there is hyper-resonance on the affected side. The diagnosis is clinical. There is no time for x-rays! (Figure 12.4.5.)

![Fig. 12.4.5 Chest x-ray showing an untreated tension pneumothorax.](image)

Treatment is immediate decompression to relieve the pressure, by placement of a needle in the second interspace, midclavicular line, followed by a tube thoracostomy in the fifth interspace, anterior or midaxillary line.

Open pneumothorax

The incidence of open pneumothorax or significant chest wall injuries following civilian trauma is quite low, certainly less than 1% of all major thoracic injuries. True open pneumothorax is most often associated with close range shotgun blasts and major industrial injury. There is usually a large gaping wound commonly associated with frothy blood at its entrance. Respiratory sounds can be heard with to-and-fro movement of air. The patient often has air hunger and may be in shock from associated visceral injuries. Initial treatment is by sealing the wound with a flap valve allowing egress of air, but preventing entrainment of air into the pleural cavity. The valve is fashioned using an occlusive clean dressing such as thin plastic sheet or foil, sealed on three sides to create a valve. Once the chest wound has been sealed it is important to realize that a tube thoracostomy may be immediately necessary because of the risk of converting the open pneumothorax into a tension pneumothorax, if there is associated injury to the lung. Many of these wounds will require a formal thoracotomy for repair.

Flail chest

Anterior or lateral fractures of three or more adjacent ribs in two or more places, causes a flail segment, which moves inwards during inspiration (paradoxical respiration). For flail chest the threat to life stems from the dual pathology of an underlying pulmonary contusion, and a decreased tidal volume (the chest wall moves inwards, rather than the lung expanding, on inspiration) causing a ventilation-perfusion defect, and thereby respiratory failure.

Diagnosis is initially based on the clinical examination and x-ray chest: Initial x-ray may not show pulmonary contusion. The initial blood gases may be normal—the first sign of respiratory failure is often a decreased arterial PCO$_2$ (due to hyperventilation), followed by a decrease in PO$_2$/FiO$_2$ ratio.

Traditionally, flail chest has been managed by adequate ventilation with humidified oxygen, symptomatic relief of pain (allowing more comfortable breathing), and, if necessary, internal splinting using artificial ventilation ('internal pneumatic stabilization'). While this undoubtedly is the method of choice in most instances, there has been increasing interest in open reduction and fixation of multiple rib fractures. In uncontrolled trials, there have been considerable benefits shown, with a shortening of hospital time, and improved mobility.

Massive haemothorax

Massive haemothorax is equally life threatening. Approximately 75% of patients with hilar, great vessel, or cardiac wounds expire shortly after injury, mostly due to a major injury of a great vessel. In about 15% of cases, the bleeding is from deep pulmonary
lacerations. In blunt injury, with fractured ribs, this is most commonly an intercostal artery or the internal mammary artery. In a few patients, there may be injury to the hilum of the lung or the myocardium.

The diagnosis of massive haemothorax is invariably made by the presence of shock, ventilatory embarrassment, dullness to percussion, and shift in the mediastinum. Chest x-ray (Figure 12.4.6), will confirm the extent of blood loss but generally, tube thoracostomy is done immediately to relieve the threat of ventilatory embarrassment. Where possible, autotransfusion should be initiated. Note that clamping the drain does not tamponade the bleeding. The treatment of massive haemothorax is to stop the bleeding, and to restore blood volume. Essentially all such patients will require urgent thoracotomy.

![Chest x-ray showing massive haemothorax.](Click to view larger)

Complications of haemothorax or massive haemothorax are almost invariably related to the visceral injuries. Occasionally there is a persistence of undrained blood which may result in empyema.

Injuries to the great vessels

Injuries to the great vessels from penetrating forces are infrequently reported, mainly due to the relative lack of survival prehospital. In those patients who present to the Emergency Department the injury has usually sealed. Diagnosis is usually made by CT scan with contrast, or using arteriography. The injuries can be treated by intravascular stenting or open surgery.

Penetrating cardiac injury and cardiac tamponade

In urban trauma centres, cardiac injuries are most common after penetrating trauma and constitute about 5% of all thoracic injuries. The diagnosis of cardiac injury is usually fairly obvious. The patient presents with a combination of exsanguination or cardiac tamponade. Patients with tamponade due to penetrating injuries usually have a wound in proximity, decreased cardiac output, increased central venous pressure, decreased blood pressure, decreased heart sounds, narrow pulse pressure, and, occasionally, paradoxical pulse.

Every stable patient with a potential cardiac injury and every patient with a penetrating precordial chest injury requires mandatory investigation. The diagnosis is made primarily by ultrasound, and every patient with a penetrating injury in the cardiac ‘box’ should have full echocardiography.

Pericardiocentesis has been suggested as a temporizing manoeuvre. However, it is technically unreliable, may exacerbate the injury, and may fail to diagnose a true tamponade. The treatment of all cardiac injuries is immediate thoracotomy, ideally in the Operating Room, but for the patient in extremis, thoracotomy in the emergency department can be life saving. The great majority of wounds can be closed with simple sutures or horizontal mattress sutures of a 3/0 or 4/0 monofilament suture. In an uncontrolled situation, a skin stapler is an excellent temporizing measure. A Foley catheter can be placed in the hole, the balloon inflated, and gentle traction applied until definitive surgery can take place.

Air embolism

Air embolism is an infrequent event following trauma. It occurs in 4% of all major thoracic traumas, mostly following penetrating injury. These patients present with focal or lateralizing neurological signs, or sudden cardiovascular collapse. Any patient with chest injury, without obvious head injury, who has focal or lateralizing neurological findings should be assumed to have air embolism.

The treatment of air embolism is immediate thoracotomy. Survival rates are poor.

Management of potential threats to life

Rib fractures

Fractures of first three ribs or three or more ribs have a mortality of more than 10% due to the energy required to cause such injury, and associated injury. It is essential to exclude associated injuries.
- Ribs 1–3: aorta, subclavian vessels, trachea or major bronchi
- Ribs 4–8: lung contusion, cardiac contusion or rupture
- Ribs 9–12: diaphragmatic rupture, spleen, liver or kidney.

Diagnosis is primarily clinical. Anteroposterior compression of the chest elicits pain.

Fractures of ribs and fractures at the costochondral junction may not be seen on the chest x-ray.

Treatment is primarily symptomatic to allow adequate breathing:

- Pain control using a combination of narcotic and non-steroidal analgesia, e.g. ibuprofen 600mg three times a day orally, and morphine titrated intravenously (NB properly titrated, morphine will not cause respiratory depression)
- Intercostal nerve block
- Epidural analgesia
- Interpleural analgesia—very effective if a chest drain is already in place: 10mL of bupivicaine 0.5% and 10mL of lignocaine 1% are added to 30mL of sterile water and instilled into the pleural cavity via the chest tube, which is clamped for a short while
- Strapping the chest to splint the ribs is strongly contraindicated to avoid atelectasis.

**Pneumothorax**

The presence of free air in the pleural cavity, where the lung has been pierced by a fractured rib, or penetration of overlying chest wall has occurred.

Clinically, the presentation is often asymptomatic, although there may be associated dyspnoea, and the thorax may be resonant to percussion. Diagnosis is usually made on chest x-ray, although smaller ones may be missed, and may only be seen on a CT scan.

Significant pneumothoraces require a chest drain. There is usually an associated with a haemothorax. Small stable pneumothoraces (<2cm lung collapse on x-ray, normal blood gases, no dyspnoea) may be managed on oxygen, without drainage. This approach does not apply to patients scheduled for general anaesthesia or assisted ventilation, or interfacility transfer by air, because of the danger of developing a tension pneumothorax. In these instances, chest drainage is required. An adequate sized drain (36FG) is inserted through the fourth or fifth intercostal space, anterior axillary line. Chest physiotherapy immediately after insertion of the drain is of paramount importance. A single dose antibiotic prophylaxis is adequate.

**Haemothorax**

Defined as free blood in the pleural cavity, and are often asymptomatic (similar to a pneumothorax). A haemothorax is best diagnosed on erect chest x-ray. If a fluid meniscus is seen in the costophrenic angle on the erect film, this usually implies a minimum of 250mL of free blood, and an intercostal chest drain should be inserted as for pneumothorax.

**Pulmonary contusion**

Pulmonary contusion represents bruising of the lung, usually in association with direct chest trauma. In blunt injury, decreased air entry is most usually due to pulmonary contusion, and is often associated with multiple rib fractures. The pathophysiology is the result of ventilation-perfusion defects and shunts. This is treated symptomatically, and the patient may require early assisted ventilation and cardiovascular support.

**Tracheobronchial injuries**

Penetrating injuries to the tracheobronchial tree are uncommon and constitute less than 2% of all major thoracic injuries. Disruption of the tracheobronchial tree is suggested by haemoptysis, airway obstruction, subcutaneous emphysema, tension pneumothorax, and significant persistent air leak after placement of a chest tube. Diagnosis is usually by bronchoscopy. Most lesions are within 2cm of the carina. Initial management is a chest drain to treat the pneumothorax. Most distal lesions close spontaneously, but the remainder require surgical closure, or stenting.

**Blunt cardiac injury**

Blunt cardiac injury (previously known as myocardial contusion) is caused by direct blunt trauma over the precordium. It is commonly overdagnosed. The most common presentation is suspicious mechanism of injury, and cardiac arrhythmia. Diagnosis is made on electrocardiogram and specifically on transoesophageal echo. Cardiac enzymes are not usually helpful, and are not part of the routine investigation of such injuries.

**Contained rupture of the thoracic aorta**

Aortic rupture is usually associated with acceleration/deceleration injury, either from road traffic crash, or from fall from a height. 80Eighty per cent are immediately fatal because of free rupture into the pleural cavity. The remaining 20% of ruptures are contained by the remaining adventitia, often with leakage into the (intact) pleura. There are often associated orthopaedic injuries.

Diagnosis is initially made on the basis of a high index of suspicion, and should be verified by:

- Chest x-ray (Figure 12.4.7A), which may show some or all of the following:
• Widened upper mediastinum (>7cm)
• Obliteration or loss of clarity of the aortic knuckle
• Deviation of the trachea
• Depression of the left main bronchus
• Deviation of the nasogastric tube to the right
• Left haemothorax or left pleural apical cap
• Fractures of the first and second rib—widened mediastinum is often present on supine x-ray. Once vertebral fractures have been excluded, an erect x-ray chest may be used to verify the ‘widening’ of the mediastinum. This manoeuvre is not entirely sensitive and specific to exclude ruptured aorta

• CT scan with contrast—the spiral CT scan (Figure 12.4.7B), with contrast is currently the ‘gold standard’ for diagnosis, since it will also help to differentiate the other causes of widened mediastinum, including prevertebral haematoma from a thoracic vertebral injury
• Transoesophageal echo—this is a useful, less invasive diagnostic tool in the stable patient and can be used to rule out associated blunt myocardial injury
• Aortic angiography—this is invasive, and is only suitable for the stable patient. The diagnostic procedure may, however, allow therapeutic stenting at the same procedure.

---

Fig. 12.4.7
A) Chest X-ray showing widening of mediastinum and other signs suggestive of aortic rupture. B) CT scan showing traumatic dissection of thoracic aorta.

Keep the systolic blood pressure and pulse rate as low as possible (80–90mmHg) using beta-blockers to avoid converting a contained rupture into free (and fatal) rupture. Do not insert an intercostal drain, unless a free haemothorax is present.

Diaphragm injuries

Diaphragmatic injuries occur in approximately 6% of patients with midtorso injuries from penetrating trauma. The diaphragm normally rises to the fifth intercostal space during normal expiration. Any patient with injury to the chest wall below the fifth intercostal space is at risk of transdiaphragmatic penetration of the abdomen, and therefore intra-abdominal injury must be ruled out.

In blunt trauma, especially of the pelvis, there is a significant association with (particularly left-sided) diaphragmatic injury. Patients should have a nasogastric tube passed prior to chest x-ray (Figure 12.4.8), and visualization of the stomach in the chest is diagnostic.
The chest x-ray (preferably erect in the stable patient) may be helpful, and CT scan with contrast may assist. Laparoscopy is preferable to thoracoscopy, as it allows the diagnosis of intra-abdominal injury as well as the assessment of whether there has been breach of the diaphragm.

Optimally, all diaphragmatic injuries should be repaired, even small penetrating puncture wounds of no apparent importance. Those injuries that are not repaired will present late, usually with incarceration of the small bowel, stomach, or colon, into the hemia defect. Subsequent strangulation may occur, and may be life threatening.

**Oesophageal injuries**

The incidence of oesophageal injury is very low. Occasionally, patients may present late with signs of posterior mediastinitis. Injuries to the thoracic oesophagus may present with pain, fever, pneumomediastinum, persistent pneumothorax in spite of tube thoracostomy, and pleural effusion with extravasation of contrast on gastrograffin swallow. Injuries to the cervical oesophagus are somewhat more frequent and are usually detected at the time of exploration of zone I and II injuries of the neck. In general, with penetrating injury of the neck, and penetration deep to the platysma, especially in inexperienced hands, the threshold for exploration should be very low.

Diagnosis is best using a combination of CT scan with contrast, or oesophagography. Once found, closure is performed, with drainage.

Complications following oesophageal injuries include wound infection, mediastinitis, and empyema, and if diagnosed late, the injury can be lethal.

**Emergency Department thoracotomy**

Improved emergency medical response times, and advances in prehospital care, have led to increased numbers of patients with cardiac and thoracic injury (who previously would have died in the prehospital environment), arriving in resuscitation _in extremis_. Salvage of these patients often demands immediate control of haemorrhage by thoracotomy and direct control. However, thoracotomy has often been attempted in hopeless situations, following both blunt and penetrating injury, and failure to understand the indications and sequelae will almost inevitably result in the death of the patient. With the increasing financial demands on medical care, and the increasing risk of transmission of communicable diseases, a differentiation must be made between the true emergency department thoracotomy, and futile care.

Thoracotomy may be divided into:

- **Resuscitative thoracotomy** which is an emergency procedure to treat haemorrhage in the chest. This can be performed in the Emergency Department (Emergency Department thoracotomy, EDT) or in the Operating Room
- **Planned thoracotomy** to repair damage in a relatively stable patient.

There is an extremely high mortality rate associated with all thoracotomies performed anywhere outside the Operating Room, especially when performed by non-surgeons.

**Objective**

The primary objectives of EDT in this set of circumstances are to:

- Release cardiac tamponade
- Control intrathoracic bleeding
- Control air embolism or bronchopleural fistula
- Permit open cardiac massage
- Allow for temporary occlusion of the descending aorta to redistribute blood to the upper body and possibly limit subdiaphragmatic haemorrhage.

**Indications and contraindications**

There are instances where EDT has been shown to have clear benefit. These indications include:

- Those patients with penetrating injury in whom there is a witnessed arrest and high likelihood of isolated intrathoracic injury, especially in penetrating cardiac injury (‘salvageable’ postinjury cardiac arrest)
- Those with severe postinjury hypotension (blood pressure <60mmHg) due to cardiac tamponade, air embolism, or thoracic haemorrhage
- Planned cross-clamping of the aorta in penetrating injury below the diaphragm, to allow circulation of the brain until local direct control has been achieved.

EDT is contraindicated when:
In cases of blunt trauma

There has been cardiopulmonary resuscitation in the absence of endotracheal tube intubation in excess of 5min or for more than 10min with endotracheal tube intubation.

Results

The results of EDT vary according to injury mechanism and location and the presence of vital and life signs. EDT has been shown to be beneficial in around 50% of patients presenting with signs of life after isolated penetrating cardiac injury and only rarely in those patients presenting without signs of life (<2%). In non-cardiac penetrating wounds, 25% benefit when signs of life and detectable vital signs are present, compared to 8% of those with signs of life only and 3% of those without signs of life.

Following blunt trauma, only 0.1% of patients requiring EDT are salvaged, regardless of their clinical status on admission.

When to stop Emergency Department thoracotomy?

EDT is a ‘team event.’ It should not be prolonged unduly but should have specific end points. If there is an injury repaired, and the patient responds, he/she should be moved to the Operating Room for definitive repair or closure.

EDT should be terminated if:

1. Irreparable cardiac damage has occurred
2. The patient is identified as having massive head injuries
3. Pulseless electrical activity (PEA) is established
4. Systolic blood pressure is less than 70mmHg after 20min
5. Asystolic arrest has occurred.

The abdominal cavity

Introduction

Delay in the diagnosis and management of abdominal injuries is one of the most common causes of preventable death from trauma, with death usually resulting from major undiagnosed bleeding. Approximately 20% of abdominal injuries will require surgery. In the United Kingdom, Western Europe, and Australia, the trauma is predominantly blunt in nature, while in the military context, and in civilian trauma in the United States of America, South Africa, and South America, it is predominantly penetrating. There are significant differences between blunt and penetrating abdominal trauma, with regard to the assessment, investigations, and treatment.

Blunt intra-abdominal injuries may occur by means of three mechanisms:

1. Crushing of an organ against the spine or pelvis or the abdominal wall
2. Deceleration forces
3. Sudden increase of the intraluminal pressure and bursting of a hollow viscus.

Penetrating injury caused by stab wounds, (limited energy transfer) results in damage confined to the tract. Bullet or missile wounds have higher energy, resulting in energy transfer to the tissues surrounding the bullet tract, with direct damage from the missile, explosion of gas in hollow viscera, and degeneration or cell death beyond the confines of the tract itself.

It is important to appreciate the difference between surgical resuscitation and definitive treatment for abdominal trauma. Surgical resuscitation includes the technique of ‘damage control’, and implies only that surgery which is necessary to save life by stopping bleeding and preventing further contamination or physiological injury. It is part of the resuscitation process only, and the definitive surgery is initiated at a later stage when the patient is stable (see Chapter 12.3).  

Resuscitation

Resuscitation of patients with suspected abdominal injuries should always take place within the ATLS® context. Attention is paid to adequate resuscitative measures, including pain control. Adequate analgesia (titrated intravenously) will never mask abdominal symptoms, and is much more likely to make abdominal pathology easier to assess, with clearer physical signs and a cooperative patient.

The diagnosis of injury following blunt trauma can be difficult. The knowledge of the mechanism can be helpful. Shoulder harnesses can cause blunt trauma to the liver and duodenum or pancreas, and rib fractures can cause direct damage to the liver or spleen. Lap belts can cause spinal injury, and shearing injury to intestine and mesentery, especially when incorrectly placed above the iliac crest. Pelvic fracture are high-energy injuries and there is a significant association with intra-abdominal solid viscus injuries and rupture of the diaphragm.

Blood is not initially an irritant, and therefore it may be difficult to assess the presence or quantity of blood present in the abdomen. Bowel sounds may remain present for several hours after abdominal injury, or may disappear following trivial trauma. This sign is therefore particularly unreliable.

Investigation and assessment of the abdomen can be based on three presenting groups:
1) The patient with the normal abdomen
2) An equivocal group requiring further investigation
3) The patient with an obvious injury to the abdomen.

Virtually all penetrating injury to the abdomen should be explored promptly, especially in the presence of hypotension.

**Diagnosis**

Diagnostic modalities depend on the nature of the injury.

- Physical examination
- Diagnostic peritoneal lavage (DPL)
- Ultrasound (FAST—focused abdominal sonography for trauma)
- CT scan.
- Diagnostic laparoscopy.

**The haemodynamically normal patient**

There is ample time for a full evaluation of the patient, and a decision can be made regarding surgery or non-operative management.

**The haemodynamically stable patient**

The stable patient, who is not haemodynamically normal, will benefit from investigations aimed at establishing:

- Has the patient bled into the abdomen?
- Has the bleeding stopped?

Thus, serial investigations of a quantitative nature will allow the best assessment of these patients. FAST also may be helpful in establishing the presence of free blood, though dependent on the operator. CT scan with contrast is currently the modality of choice (Figure 12.4.9).

**The haemodynamically unstable patient**

Efforts must be made to try to define the cavity where bleeding is taking place, e.g. pelvis or abdominal cavity, or even chest. Diagnostic modalities are of necessity limited, since it may not be possible to move an unstable patient to CT scan, even if it were to be readily available. FAST is the most useful, but is very operator dependent—important if the individual doing the scan is inexperienced in the trauma patient. DPL, although now rarely used in most European countries, remains one of the most common, most sensitive, cheapest, and most readily available and reproducible modalities to assess the presence of blood in the abdomen.

**Treatment**

The management of abdominal injury in association with orthopaedic injury should be contemplated as a ‘Team’ effort, with the goal being to treat threats to life first, using a combination of non-operative and operative methods.

**Retroperitoneum**

Injuries to retroperitoneal structures carry a high mortality and are often underestimated or missed. Rapid and efficient access techniques are required to deal with exsanguinating vascular injuries, where large retroperitoneal haematomas often obscure the exact position and extent of the injury. CT scan with contrast enhancement should be used wherever possible as the diagnostic tool of choice.
The retroperitoneum is explored when major abdominal vascular injury is suspected, or there is injury to the kidneys, ureters and renal vessels, pancreas, duodenum, and colon. Because of the high incidence of intraperitoneal and retroperitoneal injuries occurring simultaneously, the retroperitoneum is always approached via a transperitoneal incision. The decision to explore a retroperitoneal haematoma is based on its location and the mechanism of injury, and whether the haematoma is pulsating or rapidly enlarging.

**Summary**

Management of the patient with multiple truncal soft tissue and orthopaedic injuries presents a major challenge in the care of the trauma patient. It is critical in a successful outcome to:

- Appreciate which injuries are present
- Which injuries are major threats to life
- Prioritize and treat accordingly.

Evidence based practice management guidelines on the management of trauma, can be found at the Eastern Association for the Surgery of Trauma web site: [http://www.east.org/tpg.asp](http://www.east.org/tpg.asp)

Summary points

- Treatment of anaemia has changed substantially since the early 1990s
- Although massive transfusion may be necessary, trauma surgeons have modified their practice to provide aggressive control of haemorrhage, prevent hypothermia and acidosis, optimize haemodynamic management in intensive care units, and rationalize transfusion support in severely injured patients. The result has been an improvement in the outcomes of these patients
- Given the importance of early intervention in the care of the injured, understanding the physiology and true indications for early massive transfusion in trauma care has the potential to save many lives.

Definition

Massive transfusion is often defined as the transfusion of ten or more units of red blood cells in less than 24h, or more than 50% of the blood volume in 3h. A suitable massive transfusion protocol is suggested in Box 12.5.1.

Box 12.5.1 Guidelines for massive blood transfusion

Definition

Replacement of the whole blood volume within 24h, or 50% of the blood volume in 3h.

Activation

The protocol will be activated automatically by the Blood Bank after 2 units of packed red blood cells (PRBC) have been issued to a patient, and a request for a further 4 units of blood or more is subsequently requested within any 24-h period.

Blood specimens

- Group and crossmatch:
  - Leucodepleted blood should be used wherever it is available
  - Crossmatched blood if available
  - Uncrossmatched group O blood
- The following baseline blood specimens are required:
  - Full blood count including platelets
  - Prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, international normalized ratio (INR), fibrinogen, D-dimer
- Repeat after every 6 units PRBCs.

Avoid hypothermia

- Use an appropriate blood warmer
- Keep the patient warm using an appropriate patient warming device
- Maintain a warm environment.

Blood and blood products

- Blood Bank will issue the following products (as part of a 2- or 6-unit ‘massive transfusion pack’). NB multiple 2-unit packs are preferable as they can be returned if the ‘cold chain’ is intact:
  - 2 units or 6 units of packed red cells using freshest blood available
  - 2 units or 6 units of FFP
• 2 units or 6 units of platelets

or

♦ For every 6 units of blood issued:
  • 1 apheresis unit of platelets.

**Administration**

♦ Microaggregate filters are not advised.

♦ Once administration of the ‘massive transfusion pack’ blood is begun, administer all the above in a 1:1:1 ratio, 
  (blood:FFP:platelets) or 6× 1:1 = 6:6: 1 apheresis platelet unit. After every 6 units of red cells, if ongoing bleeding or need 
  for transfusion is present:
  • Give a further 4 units of FFP if PT or APTT are >1.5× mid normal
  • Give 10 units of cryoprecipitate if fibrinogen <1g/L
  • Give 10mL 10% calcium chloride only if the above additional doses are given
  • Give at least 1 unit of pooled platelets if platelet count <75000/mm³.

♦ Return all unused ‘massive transfusion packs’ to Blood Bank as soon as possible

**Endpoints of transfusion**

♦ Any active surgical bleeding has been controlled
♦ No further need for red cells
♦ Temperature >35°C
♦ pH >7.3.

---

**The coagulopathy of massive trauma and haemorrhage**

Among the most devastating of the complications of massive blood loss and fluid resuscitation is a bleeding diathesis. 
Paradoxically, although clotting is accelerated at the capillary level because of shock and tissue damage, the circulating blood 
becomes hypocoagulable. The coagulopathy of trauma is a syndrome of non-surgical bleeding from mucosal lesions, serosal 
surfaces, and wound and vascular access sites, the tissue oozing that continues after identifiable vascular bleeding has been 
controlled. It occurs in the presence of profoundly depressed concentrations of blood coagulation proteins and platelets, but also in 
the situation where normal clotting factors are present, but do not work. By the time that a trauma coagulopathy becomes obvious, 
the depletion of all clotting factors and platelets is already severe (Box 12.5.2). Even best case standard of care does not take into 
account the insensible losses of blood into tissue compartments, and the consumption of clotting factors at the site of injury.

**Box 12.5.2 Factors predictive of a severe coagulopathic state include:**

♦ Massive rapid blood transfusion
♦ Persistent cellular shock:
  • Oxygen consumption index <110mL/min/m²
  • Lactate concentration >5mmol/L
♦ Progressive metabolic acidosis:
  • pH <7.2
  • Base deficit >14mmol/L
  • Lactate >5mmol/L
♦ Refractory core hypothermia (<34°C).

In the initial phase of massive bleeding and massive transfusion, an important goal is to maintain reasonable concentrations of all 
the pro- and anticoagulant factors. Procoagulant factors and platelets help minimize surgical bleeding and prevent coagulopathic 
blooding. Anticoagulant factors prevent clotting from spreading and causing further tissue injury. During massive transfusion, the 
major effort must be the maintenance of perfusion and oxygen transport. The early addition of plasma and platelets can help the 
coagulopathy of trauma. Stored blood is deficient in factors V and VIII and platelets but replete with fibrin split products and 
vasoactive substances. Timely administration of FFP and platelets will minimize the risk of coagulopathy after massive transfusion.
NB The use of starches is contraindicated in the actively bleeding patient, since all starches deplete the von Willebrand/Factor VIII complex, and may make the actively bleeding patient more coagulopathic, both from factor depletion and dilutional coagulopathy.

Also germane to the initial period of massive blood transfusion are the potential complications of acidosis, hypothermia, and hypocalcaemia. Hypothermia (<32°C) causes platelet sequestration and inhibits the release of platelet factors that are important in the intrinsic clotting pathway. In addition, it has consistently been associated with poor outcome in trauma patients. Core temperature often falls insidiously because of exposure at the scene and in the emergency department and because of administration of resuscitation fluids stored at ambient temperature.

The use of bicarbonate in the treatment of systemic acidosis remains controversial. Moderate acidosis (pH <7.2) impairs coagulation, myocardial contractility, and oxidative metabolism. Acidosis in the trauma patient is caused primarily by a rise in lactic acid production secondary to tissue hypoxia and hypothermia, and usually resolves when the volume deficit has been corrected and efficiency of circulation restored. Administration of sodium bicarbonate may cause a leftward shift of the oxyhaemoglobin dissociation curve, reducing tissue oxygen extraction, and it may worsen intracellular acidosis caused by carbon dioxide production. On the other hand, adrenergic receptors may become desensitized with protracted acidosis. Bicarbonate infusion, therefore, should be limited to persons with protracted shock.

Hypocalcaemia caused by citrate binding of ionized calcium does not occur until the blood transfusion rate exceeds 100mL/min (equivalent to 1 unit every 5min). Decreased serum levels of ionized calcium depress myocardial function before impairing coagulation. Calcium gluconate or calcium chloride should be reserved for cases in which there is electrocardiographic evidence of QT interval prolongation or, in rare instances, for cases of unexplained hypotension during massive transfusion.

### Fresh frozen plasma

Most trauma patients will need fresh frozen plasma (FFP) well before losing one blood volume. This is different from most recommendations which are based on more controlled circumstances, and is based on computer simulation of the amount of FFP required to avoid excessive plasma dilution compromising haemostasis. Most patients will require one unit of FFP for every unit of blood transfused. A unit of FFP also contains most of the citrate anticoagulant from the unit of blood from which it was originally derived. It contains about 0.5g fibrinogen, and normal levels of pro- and anti-coagulants. Solvent-detergent (SD) treated/freeze-dried plasma (Bioplasma) carries about 20% less of these per unit given.

### Cryoprecipitate

Cryoprecipitate contains fibrinogen, von Willebrand factor/Factor VIII complex, and fibrin stabilising factor/Factor XIII. Cryoprecipitate may not be required in all cases of trauma. One unit of FFP (250mL) contains 0.5g of fibrinogen. One unit of cryoprecipitate contains 0.25g of fibrinogen, but in 10mL (rather than 250mL). Therefore in most cases, FFP will supply the needs required.

### Platelets

A fall in platelet count occurs somewhat later than the loss of clotting factors. Unfortunately, a platelet count is not simple, since it gives no indication as to the function of the remaining platelets. Hypothermia affects platelet adhesion more than the enzymes, above 33°C, while hypothermia affects all aspects of coagulation below 33°C. There is some evidence in which there appears to be a survival advantage of receiving approximately 0.8 units of platelets per unit of red blood cells.

### Recombinant factor VII

There is increasing use of activated recombinant factor VII (rFVIIa). Currently it is not approved for trauma patients.

### Further reading

Summary points

- Unlike civilian trauma, most ballistic injuries are due to penetrating wounds.
- Although weapons may change, the principles of treatment remain the same: prevent death by stopping bleeding, and prevent infection by removing dead and foreign material.
- The severity of the injury is related to the energy transfer to the tissues as well as the specific structures injured.
- Mass casualty situations may require triage of the casualties.

Introduction

The principles of military surgery, to control bleeding and to prevent infection, are not new, and were documented during the Roman Empire by Celsus. However, following the introduction of gunpowder in the Middle Ages, there have been major changes in the weapons of war, and this has led to a different spectrum of injuries.

Conventional weapons can be divided into:

- **Small arms**: these include pistols, rifles, and machine guns, and the injuries result from the interaction of the projectiles produced by the weapon and biological tissue the projectile strikes.
- **Explosive munitions**: these include shells, bombs, and grenades, and in addition to the wounds caused by their projectiles, injury may also result from the effect of blast on the tissue.

Projectiles

In most wars, the majority of penetrating injuries are due to fragments rather than bullet wounds. During the First Gulf War, 90% of penetrating injuries seen in one British military hospital were due to fragments. These fragments may be from parts of a shell or grenade, or from objects such as nails or ball bearings packed around the explosive. In addition, any object in the vicinity of the blast, which is ‘blown up’ and accelerated away from the site of the explosion, can produce fragment wounds. Therefore it is appropriate to consider bullet and fragment injuries together as projectile (or missile) injuries.

Projectiles can cause tissue damage by either direct or indirect mechanisms. With low-energy injuries such as from handguns, tissue damage is confined to the wound tract, and is caused by cutting or crushing. Significant injury will only occur if a vital structure is directly damaged by the weapon.

However, with higher-energy missiles such as bullets, energy may be dissipated to the surrounding tissues, to produce indirect damage outside the wound tract, and a vital structure may be damaged without actually being involved in the wound tract. This is more likely to occur with high-energy wounds, especially, although not invariably, from high-velocity rifle bullets, and results in a cavitation effect, with the formation of a temporary cavity, behind the missile.

Cavitation

As the projectile passes through the tissue, energy is transferred to anything in contact with the projectile, and as a result of this energy, the tissue is accelerated away from the projectile. This results in the formation of a temporary cavity as the inertia of the tissue results in continued displacement even after the projectile has passed through the tissue. As well as the obvious injury caused by the compression and shear forces applied to the tissues, the negative intracavity pressure (with respect to atmospheric pressure), can result in increased contamination of the wound tract, by drawing material into the wound.

The effect of indirect damage is one of the factors in the increased mortality from high-velocity bullet wounds. In a report from Vietnam, bullets were responsible for 30% of penetrating wounds, but caused 45% of the deaths. It has been estimated that a casualty struck by a bullet, in a military conflict, has a 1 in 3 chance of dying. This compares to a 1 in 7 chance of dying if struck by fragments from a shell, and 1 in 20 if struck by a fragment from a grenade.

It is not, however, the energy transfer that determines the outcome, it is the specific tissue damage that occurs. Low-energy wounds to the heart or brain are more likely to be fatal than high-energy injuries to the limbs.

A number of factors affect the energy transfer from the projectile to the tissue (Figures 12.6.1–3).
Velocity of the projectile

As the kinetic energy possessed by a projectile is given by the formula:

\[
\text{Kinetic energy} = \frac{1}{2} \times \text{mass} \times \text{velocity}^2
\]

changes in velocity have a significant effect on available kinetic energy, and the greater available energy accounts for the severe tissue damage seen after high-velocity missile injuries. However, high-velocity bullets do not invariably cause severe wounds, as the missile may pass through tissue without transferring significant energy. This occurs when the resistance of the tissues is low and the wound track is short, such that the bullet is not slowed, and therefore little energy is transferred.

Box 12.6.1

Treat the wound not the weapon

For this reason it is incorrect to divide wounds into high or low velocity.
In addition, severe injury can occur from low-velocity projectiles, not only when a vital structure is directly injured, but also when the mass of the projectile is large. This is particularly true for close-range shotgun injuries, which can cause severe tissue injury.

Therefore it is the energy transferred to tissues that defines the work done in mechanical injury, and is the most appropriate index of physical injury.

**Shape of the projectile**

The smaller the area of the projectile presented to the tissue, the lower the resistance, and therefore the lower the energy transfer. Thus there is likely to be a lower energy transfer from a spherical object, such as a ball bearing, than a flattened irregular piece of shrapnel, for the same available energy.

With a bullet, the resistance afforded by the tissue is related to the orientation of the bullet. If the long axis of the bullet is aligned with the direction of travel, less energy is transferred than if the bullet yaws (or tumbles) and presents a greater surface area. Bullets are inherently unstable in tissues, and the resistance of the tissue may be sufficient to cause a bullet to tumble. This will result in greater energy transfer to the tissue and thus greater tissue damage. This is one reason why entry wounds are often small, and may be no larger than the diameter of the bullet, whereas exit wounds may be much larger, with torn skin, and a ragged star-like appearance.

In addition, any deformation, or breaking up, of a missile will result in greater energy transfer and more extensive wounding. This is the main reason for soft nose, or hollow nose bullets, or dum-dum bullets when the bullet was deliberately notched to encourage breaking up, producing more severe injuries. Such modifications were made illegal by the Hague Declaration of 1899. Even with standard bullets fragmentation can still occur, particularly if the bullet strikes bone, and this is accompanied by more severe wounding (Figure 12.6.4).

**Resistance of the tissue**

The energy transfer is also affected by the tissue involved in the wound tract, and is related to the resistance offered by the tissue. Muscle is denser than lung tissue, and greater energy transfer occurs when a projectile passes through muscle. More rigid tissue such as bone resists deformation, and offers a greater resistance, resulting in greater energy transfer.

The size of the cavity, although one determinant of the severity of an injury, is not the most significant factor; again it is the properties of the tissue injured which mainly determines the outcome. Muscle is able to withstand the distension produced by the temporary cavity, due to its elasticity, and although the tissue may be contused, recovery is possible (Figure 12.6.5). Less elastic tissue, particularly if enclosed by a fibrous capsule (e.g. liver), is unable to withstand the distension and severe disruption is possible. Brain is also very susceptible to distension, and the severe injury resulting from the compression and shearing is usually unrecoverable. This is one of the reasons that most high-energy transfer wounds in survivors are seen in the limbs, and are associated with extensive soft tissue injury, multifragmentary fractures, and highly contaminated wounds.
There are a number of factors that are important to appreciate at this stage (Box 12.6.2). Despite the division of wounds into high- and low-energy transfer, it is important to realize that these are merely two ends of a spectrum. It is, therefore, wrong to base treatment protocols, on the basis of a division of wounds into two types. The temporary cavity is not an all-or-none phenomenon, and the size of the cavity is related not only to the energy transfer, but also to the tissue involved. In addition, although the exit wound of a high-energy transfer wound is usually ragged and large, this is not always the case, and smaller entrance and exit wounds may be present despite high-energy transfer.

**Box 12.6.2 Factors affecting type of injury caused by projectiles**

- Cavitation
- Velocity of projectile
- Shape of the projectile
- Resistance of the tissues.

**Explosive munitions**

In addition to fragment wounds, explosive munitions can also cause injury from the blast and other mechanisms (Figure 12.6.6). Blast injuries can be considered as:

- Primary blast injury: including blast lung due to over pressure wave
- Secondary blast injury: including penetrating injuries from debris
- Tertiary blast injury: blunt injury due to blast wind throwing the casualty
- Quaternary blast injury: burns, fumes, building collapse, mental health, exacerbation of chronic disease.

**Fig. 12.6.6**

This photograph of a large explosion illustrates several of the components responsible for blast injury. The thin line farthest from the blast center is caused by the difference in refraction between the compressed gas at the blast front and the surrounding air. In addition, debris can be seen being accelerated peripherally (particularly at ground level) and the size of the fireball can also be appreciated. (Reproduced from Zajtchuk et al. (1990).)
Despite the different mechanisms, most injuries in survivors of explosions are due to penetrating trauma from fragments. Both the blast wave and blast wind are fatal close to the explosion, and this distance is dependent on the size of the explosive. However, the effects of the blast fall rapidly with increasing distance from the point of detonation, and therefore there is a very small zone where a casualty will survive the blast, but sustain significant injuries directly due to the blast wave or wind.

As a result, previous studies have demonstrated that 90% of fatalities occur before or very soon after arrival at hospital and most patients who survive are not severely injured, and have a relatively low Injury Severity Score (ISS <16, mean 8). Of the fatalities occurring after initial resuscitation, approximately 50% were due to severe head injuries, which would not have been amenable to treatment and would have been graded with an ISS of at least 16. In addition, burns may also be very severe if the casualty was close to the blast, but most of these patients will die from the other effects. In survivors, burns directly caused by an explosion are often superficial and confined to exposed areas. However, if the bomb was specifically designed as an incendiary device, or secondary fires result, then burns may be a significant problem.

Two other specific mechanisms should be considered—antipersonnel (landmines) and improvised explosive devices (IEDs) which are being used in current operations in Afghanistan and Iraq.

**Landmine injuries**

In general, landmines are designed as terror weapons, or to deny ground rather than to kill. The psychological effect of a survivor, with a traumatic amputation, is believed to be much greater than a death. A retrospective analysis from the International Committee of the Red Cross, of 757 victims of antipersonnel mines, has identified three patterns of injuries amongst survivors. Pattern 1 injuries occur when a buried mine is stepped on. Severe limb injuries including traumatic amputations of the lower injuries are common, as well as genital injuries. With pattern 2 injuries, the device explodes near the victim, this may be due to a buried mine activated by another individual, or due to a pull-action mine which is placed above ground level and is activated by pulling on a wire connected to the device. Lower limb injuries occur, but are less severe than in pattern 1, with traumatic amputations less likely. Injuries to the head, chest, and abdomen are common. Pattern 3 injuries occur when the device explodes whilst the victim is handling it. Severe facial and upper limb injuries are common in this group.

In addition other injury patterns can occur with specific devices. The M-16 series antipersonnel mines, which are designed to be propelled 1m into the air and explode 3s after the mine has been stood on. Most victims of properly functioning devices died, with severe injuries to the upper body and traumatic amputations of the upper limb being common.

**Outcome of landmine injuries**

Retrospective reviews of hospital admissions reports a low mortality rate after antipersonnel mine injury, 0–0.8%. When prehospital mortality is included a fatality rate of 1.7% has been reported.

Despite the low mortality rate, the morbidity after pattern 1 landmine injury is very high. As previously discussed, severe lower limb injuries, including traumatic amputations, can occur in approximately 90% of reported cases. In one study, patients required definitive surgical amputations. In addition, most of the patients sustained injuries to the other limb, and 13% of the patients sustained genital injuries. The majority of contralateral limb injuries were, however, salvageable.

Of the pattern 2 injuries, only 5% of the patients required amputation, but with pattern 3 injuries 80% of the victims sustained traumatic upper limb amputations, and many of the survivors required a definitive surgical amputation for non-salvageable injuries.

Multiple casualties and different injury patterns occur in victims of anti-tank mines, which contain far more explosive, and the outcome varies depending on the device and the type of vehicle involved. A 44% mortality rate has been demonstrated from injuries from the much larger anti-tank mines, due to severe central and head injuries. Many victims of anti-tank mines will die at the scene, and survival may be unlikely even if advanced medical care is available. Amongst survivors who reach medical care, the mortality appears to be relatively low. If significant delays are present, only patients with peripheral injuries will survive to reach hospital, resulting in an apparently low hospital mortality rate.

**Improvised explosive devices**

The United States Department of Defence defines these as devices placed or fabricated in an improvised manner incorporating destructive, lethal, noxious, pyrotechnic, or incendiary chemicals, designed to destroy, disfigure, distract, or harass and often incorporate military stores. In Iraq, they have been the leading cause of death amongst coalition troops, and during 2003–2008 resulted in 1680 fatalities.

The IEDs in Iraq are often camouflaged and are either laid under the road or by the roadside. Therefore targeted vehicles are in very close proximity to the device when it is detonated. The injury profile is related to the use of the explosive formed projectile (EFP). These are cylindrical charges, fabricated from commonly available metal pipe, with the forward end closed by a concave metal disc-shaped liner to create a shaped charge. Explosive is loaded behind the metal liner to fill the pipe. When the explosive is detonated, the conical metal plate (or lens) is deformed and reshaped into an aerodynamically efficient penetrator moving at high velocity (>1500m/s). The EFP then hits the target at high speed, delivering significantly high mechanical energy that could have only been previously provided with a large gun. Typically an EFP will perforate a thickness of armour equal to the diameter of its charge.

It appears that casualties caught in the trajectory of the EFP suffer catastrophic injuries whereas those sitting adjacent to the projectiles path suffered relatively less severe injuries. In addition, the types of injuries encountered were predominantly secondary blast injuries related to being hit by the large metallic EFP or large fragments of the EFP.
General principles in the management of military trauma

Golden hour

Much of civilian trauma planning has been based around the concept of the trimodal distribution of death, and in particular the golden hour (or first 2h after injury), when significant numbers of casualties can be saved by medical interventions.

There is now good evidence to demonstrate that there is no equivalent second peak military trauma, and that most deaths in conflict cannot be prevented.

A report on casualties of the 1982 war in the Lebanon, documented that 94% of deaths occurred within an hour, a further 2% over the next 3h and the remaining 4% over the next 75 days. This was with good initial treatment and evacuation. Moderately and severely injured casualties reached a physician within 30min in 80% of the time and within 60min for 95% of the casualties.

A report from Israel, during a period of low intensity conflict, reported 77% of deaths occurred within 30min, mostly from head and trunk injuries, and a further 6% died in next 30min, with 11% between 1–3h and 2% after 1 day.

This data suggests that there is a rapid, exponential drop in survival rate in those who ultimately die after military trauma, rather than the peaks seen with civilian trauma. To attempt to improve the survival rate after military trauma would, therefore, mean getting to the casualty very quickly after wounding.

However, even with very rapid evacuation to a medical team, survival is not possible for the majority of casualties who ultimately die. Review of outcome from a Lebanon refugee camp under siege during 1982, showed that amongst 160 deaths, 84 were dead on arrival, despite an evacuation time of minutes. A further 35 died within minutes of arrival before any effective treatment could be started. Of the 76 who arrived alive, 34 died of multiple injuries and uncontrollable haemorrhage despite immediate access to a surgeon, and a further 20 died of central nervous system or high spinal injuries. So survival was not possible for at least 86%.

This is consistent with results from both the United Kingdom and United States military. A 1984 report on United States casualties from Vietnam stated ‘Military trauma is seen to have an all-or-none nature, sustaining a fatal or survivable and frequently minor wound. 80–90% of casualties evacuated from the field have little likelihood of dying regardless of the sophistication of the care’.

Triage

Triage, derived from the French *trier*, to sieve or sort, is the process of assessing the priorities of treatment and is usually applied when the injured (or injuries) exceed the available resources such not everything can be dealt with at the same time.

The principle is to identify the ‘most needy’ patients and prioritize their treatment to reduce overall mortality and morbidity. In times of high casualty flow (mass casualty situation) this may mean that the treatment of the most critically ill may be delayed to allow the most good to be done to the greatest number of casualties.

Triage is a military innovation but has been adopted widely in civilian settings for major incident and disaster medical management. Although the terminology will vary between systems the general principles are the same:

**Priority 1**

These are casualties with life-threatening injuries (for example, catastrophic haemorrhage, airway obstruction, or tension pneumothorax). Treatment can not be delayed.

**Priority 2**

These are casualties with serious injuries that require treatment within 2h. Most of these will result in significant, but not catastrophic, haemorrhage, or spillage of abdominal contents.

**Priority 3**

These are casualties whose injuries can safely wait for 4–6h or so before treatment. This will include fractures and open wounds, when there is no significant haemorrhage or ischaemia.

**Priority 4**

This priority is usually reserved for times of high casualty flow, when the demands exceed the available resources. It is usually reserved for those patients whose injuries are so severe that the prognosis is hopeless, e.g. open head injury with a Glasgow Coma Score of 3. Using resources to treat these patients at times of high demand may place other casualties at risk by delaying their treatment.

Management of military wounds

The initial management of injuries resulting from ballistic mechanisms should be exactly the same as that during peacetime. Life-saving measures take priority; maintaining an airway, and ensuring adequate ventilation and circulation. Unless there is life-threatening haemorrhage from an open wound, it should not be dealt with until the secondary survey.

Surgical treatment
The aim of local surgery is to reduce the risk of infection, one of the most important factors in the morbidity after ballistic injuries. All military bullet wounds should be formally explored to reduce the infection risk, although civilian trauma centres have reported the successful non-operative management of bullet wounds. These were, however, low-energy wounds, evacuated rapidly to a hospital and not associated with the factors discussed earlier.

When small shrapnel wounds, particularly multiple wounds, are present, not all need debridement. If wounds are small, there is no evidence of fracture or joint penetration and they appear to be superficial and low energy, then a conservative approach can be adopted provided regular review is possible.

**Surgical technique**

The principle of debridement is to remove all foreign and non-viable tissue. This must be methodical and thorough as inadequate surgery may be worse than no surgery.

Debridement starts with the skin, and often excision of the skin margins is all that is required; degloving injuries may require more extensive debridement of skin. Although minimal excision is required, the wound should be extended to allow its full extent to be visualized. For high-energy wounds considerable extension may be required. This should be in the long axis of the limb, with the exception of the flexor surface of a joint, when oblique incisions should be used.

Subcutaneous fat should be excised, but additional areas of degloving must not be created by overgenerous debridement.

The deep fascia should be incised along the complete length of the wound, including any extensions. Fasciotomies with complete longitudinal division of the deep fascia along the full length of the compartment should be carried out in most high-energy wounds.

Adequate debridement of muscle is essential, and often a large amount of necrotic muscle may have to be excised. The aim is to remove all non-viable tissue, with the aim of leaving only pink, healthy-looking, contractile muscle; however, it is not necessary to excise the wound track en bloc. Lack of capillary bleeding or contractility, colour and consistency (the 4 Cs) are guides to muscle viability, but experience is the best way of judging (Box 12.6.3). Debridement of muscle may result in considerable bleeding from the wound, and both the surgeon and anaesthetist should be prepared for this.

**Box 12.6.3 Guide to assessing muscle viability**

- Capillary bleeding
- Contractility
- Colour
- Consistency
- Experience

Nerves and patent blood vessels should be left, as can tendons in continuity with muscles. Often, however, the tendons may be become desiccated and may have to be excised at a later date. Divided nerves ends can be marked with a non-absorbable monofilament suture; however, further damage to the nerve, by the marking sutures, must be avoided.

Difficulties can often occur in the debridement of bone, particularly the fate of the many small fragments. Bone fragments without any soft tissue attachments are avascular and should be removed. Often, however, periosteal and other soft tissue attachments are present and the viability of the fragment can be difficult to determine. Experience is probably the most important factor in deciding the viability of a bone fragment or muscle. Experimental work has suggested that there is limited spread of contamination beyond the fracture site and, therefore, exposure of intact bone beyond the fracture site is not necessary. However, the fracture site itself must be well visualized and washed out.

All wounds should be washed with copious amounts of fluid. It has been recommended that 9L are used for open fractures. In a military environment, it may be impossible to use this quantity of sterile fluids, but potable water can be used with a final washout of 1L of sterile saline. With high-energy transfer wounds, contamination can be spread along tissue planes, and these should be thoroughly irrigated.

**Antibiotics**

Although antibiotics are necessary in the treatment of open fractures, they must not be seen as an alternative to surgery. This is particularly true with the military wound that may be highly contaminated, and there may be a considerable time delay before appropriate management can be started. In a report on the United States of America’s invasion of Panama, there was a wound infection rate of 22% in patients operated on in Panama. This compared with an infection rate of 66% when wound debridement was delayed until the patient was evacuated to the United States. The higher infection rate was despite the use of early broad-spectrum antibiotics, and delayed primary closure of the wounds.

**Amputation**

Primary amputation may be required as part of the initial debridement. Although the decision may be easy with a limb that is hanging off and obviously non-viable, the viability of less severe injuries can be difficult to determine.
Although scoring systems have been developed for civilian limb injuries, there is still no reliable predictor of the need for amputation. Even in the military environment, a second opinion should be obtained, if possible, prior to amputation. If the viability of the limb cannot be determined initially, it may be reassessed after 48h. However, with military casualties a return to the operating theatre cannot be guaranteed, as problems with evacuation or mass casualty situations may occur. The decision to perform bilateral or upper limb amputations injuries will often be delayed, but infection may threaten the life of the casualty and this must be considered.

Even with recent advances in medical treatment, amputation remains a commonly performed operation in the military environment with rates up to 19% reported among United States military personnel from recent conflicts, and 22.5% from the Balkans conflict.

In the military environment amputations should initially be carried out at the lowest level possible, rather than creating formal flaps at the time of the initial surgery. This allows for later revision to a definitive level at the time of wound closure. If a definitive stump is created at the initial operation, subsequent infection (of which there is a high risk) may require further shortening and compromise the ultimate result.

No attempt should be made to close the amputation site at the initial operation, despite the perceived advantages. This will lead to oedema, ischaemia, and infection requiring further debridement.

**Closure of the wound**

Delayed primary closure of ballistic wounds is the rule for military injuries; primary closure is associated with an increased risk of infection. Wounds are left open to allow for swelling, and to prevent raised tissue pressures, which will impair microcirculation and lead to further tissue death, predisposing to infection. Although certain injuries, such as wounds to the face or genitals, may never need to be closed primarily, this should be the exception. High-energy transfer wounds, with comminution of the bone should never be closed primarily, and will often require plastic surgical techniques several days after the initial debridement. Delayed primary closure can be carried out between 2–14 days after initial surgery, depending on the nature of the wound, evacuation of the casualty, and available resources and casualty numbers. Heavily contaminated limbs that may require amputation can be reassessed at 48h, but for most wounds 4–5 days is the optimum period until the wound is closed.

Low-energy injuries are associated with small wounds and require minimal debridement. Often they can be left to close by secondary intention, but should not be closed primarily.

Exposed bone or tendon does not have to be covered at the initial operation, but consideration should be given to early closure of these wounds to prevent desiccation. Bone or tendon that is left exposed for long periods will usually require further debridement despite appearing viable at initial surgery.

Wounds can be dressed with plain gauze, which can be fluffed up, but the wound should not be packed. The purpose of the dressing is to allow absorption of fluid, and not to hold the wound open. Packing will increases wound pressure leading to further tissue death. Bandages and tape can be used to secure the dressing but must not be allowed to encircle and constrict the limb.

Delayed primary closure was originally a military practice developed due to the risk of wound complications during casualty evacuation. Wounds were debrided at a forward surgical centre, and then delayed primary closure was carried out at a base hospital when the casualty could be observed more closely. Delayed suture of wounds at an interval of 2–4 days was recommended for the treatment of gunshot wounds during the First World War. The concept of delayed primary closure was defined in 1918 as closure of the wound before ‘granulations’ had formed; suture after this granulation tissue had formed was defined as secondary suture. One of the advantages of the technique was the ability to determine the microbiology of the wound prior to suturing. A high complication rate was noted following the suturing of wounds that were contaminated by haemolytic streptococci. The presence of other organisms was considered less problematic. At the end of the First World War this technique seems to have been neglected.

**Box 12.6.4**

**Primary closure is associated with an increased risk of infection**

In the Second World War, the technique of delayed primary closure of wounds from missile injuries was again described. The wounds were associated with fractures of the long bones, skull, and pelvis in servicemen. The treatment protocol involved careful debridement, lightly packing the wound with a Vaseline gauze dressing, and then encasing the limb in plaster. Delayed primary closure, was then performed, by direct suture or skin grafting at an average of 14 days following wounding. In a report of 2393 patients, complete success was achieved in 66.5%, and partial failure, with a small sinus or stitch abscess or partial loss of skin graft, in 26.8%. Overall, 93.3% of wounds had healed by the time the patient was discharged; complete failure with dehiscence or osteomyelitis occurred in only 6.7%. Unfortunately the healing rates for specific fractures, was not reported. The interval of 14 days was not planned, but was a result of the evacuation time to a base hospital.

**Retained fragments**

Many bullet wounds will be associated with an entrance and exit wound, and the issue of retained fragments will not arise. Most of the remaining fragments will be removed at the time of initial debridement, but some will be left behind, and are often diagnosed on later radiographs.

Retained fragments can usually be left, with only a small risk of subsequent infection. If the wound does develop an infection,
secondary surgery will often be required, and the fragments can be removed at this stage. Consideration must be given, however, to the removal of retained bullets.

Civilian data suggests that intra-articular and intrabursal bullets should be removed due to the risk of lead arthropathy or systemic toxicity. This can, however, be left until the patient has been evacuated back to a base hospital, and arthroscopic techniques can be used. Bullets retained in soft tissues including muscle can be observed, and the current evidence would also suggest that bullets retained in bone can also be treated conservatively.

Management of open fractures

Introduction

A fracture is considered open when a wound causes a direct communication between the fracture and a contaminated environment.

Open fractures frequently occur in the high-energy polytrauma patient. Prioritized treatment is required to manage all injuries efficiently without detriment to non-life- or limb-threatening injury. Open fractures are frequently complex with significant soft tissue, neurological, and vascular damage.

Effective management of open fractures requires a multidisciplinary approach from the early management to the long-term follow-up. The management of open fractures continues to improve and evolve. Consensus documents, such as ‘Standards for the management of open fractures of the lower limb’ produced by the British Orthopaedic Association (BOA) and British Association of Plastic, Reconstructive and Aesthetic Surgeons (BAPRAS) are extremely important. They ensure continued improvement in clinical practice based on current literature and expert opinion.

Aetiology and epidemiology

The severity of soft tissue injury is proportional to the energy transferred to the limb and can be represented by the equation \( E = \frac{1}{2}mv^2 \). The energy \( E \) dissipated is thus proportional to the mass \( m \) and the square of the velocity \( v \). Energies involved in high velocity missile injury (900m/s) are significant due to the logarithmic influence of velocity. However, the energy transfer in relatively low velocity pedestrian road traffic accidents must not be underappreciated due to the significantly greater mass (1500kg, average car vs 3.6g, 5.56-calibre bullet). A 10mph collision with the bumper of a car will have ten times the energy of a high-velocity bullet.

The soft tissues will be damaged directly as result of both the impact and the fractured bone ends. This has the potential to produce a significant quantity of devitalized soft tissue. Subsequent damage can occur as a result of vascular compromise from arterial damage, pressure within the capillary beds, or reduced venous drainage.

Open fractures in the United Kingdom are estimated to occur with a frequency of 23 in 100 000 patients per year. They are more frequent in bones with less soft tissue coverage. Open phalangeal and open tibial fractures account for the majority (approximately 54%) of these fractures.

Classification of open fractures

In 1976, Gustilo and Anderson reviewed 1025 open fractures in long bones and described the first stage of their classification. They identified a prognostic classification system that took into account the energy involved and the degree of soft tissue disruption. The original classification was inadequate for the description of the more severely traumatized limbs. In 1984, Gustilo and colleagues modified their classification of type III injuries based on the degree of contamination, the extent of the periosteal stripping, and the requirement for vascular repair. This is the classification that is now most widely accepted and used (Table 12.7.1).
Table 12.7.1 Combination of original classification (1976) and modification of type III classification (1984) of open fractures

<table>

<td>Open fracture with associated with arterial injury requiring repair&lt;sup&gt;b&lt;/sup&gt;</td>
</tr>
</tbody>
</table>

This classification system has been used to demonstrate the association between the severity of the soft tissue injury and infection: Grade I, 0–2%; Grade II, 2–5%; Grade IIIa, 5–10%; Grade IIIb, 10–50%; and Grade IIIc, 25–50%.

There are several limitations of this classification.

The classification is frequently misquoted in the published literature and with all classifications even relatively subtle changes to the wording can have significant impact.

It is currently accepted practice to classify the wound based on the findings after the initial debridement. Although this provides a more accurate assessment, it has not always been standard practice.

Overall the interobserver agreement for the Gustilo classification has been found to be moderate to poor, with agreement ranging from 42–94% for individual cases. One of the main areas of discrepancy is differentiating between Grade II and IIIa. The other criticism is the association of Grade IIIb fractures with the use of flaps. The classification should not be based on the perceived treatment. Not all Grade IIIb fractures will require a flap to achieve soft tissue coverage.

A number of other classification systems have been developed to describe open fractures (e.g. AO classification, Ganga Hospital Score) and help in decision-making with mangled extremities (MESS, LSI, PSI, NISSSA, HFS-97). The AO classification and Ganga Hospital Score both acknowledge that the different components of the open fracture (bone, musculotendinous units, skin, nerves and blood vessels) will be injured in varying degrees. The GHS, Table 12.7.2, also attempts to take into account systemic components such as age, comorbidity, and polytrauma.

**Rationale for the treatment of open fractures**

The aim of the initial treatment is to limit the effect of the original injury. This is achieved by treating associated injury, preventing extension of the zone of injury, maximizing limb perfusion, and minimizing the bacterial load.

**Antibiotics**

Antibiotics should be administered as soon as possible and they have been shown to reduce infection risk by 59%. The choice of antibiotics should be based on the likely contaminants of the open wound, and the significant pathogens that need to be suppressed. It is important to appreciate that the bacterial flora within the wound changes and is influenced by antibiotics, surgical debridement, and bacteria acquired from the hospital environment. This influences the choice and timing of the antibiotics. Antibiotic requirements will also change with time and geographical location and this should be appreciated by individual hospital’s antibiotic protocols.

**Initial operative treatment**

It is accepted that the biggest factor in the outcome of the injury is the quality of the initial debridement, and therefore this should be performed by an experienced surgeon. Wounds that require repeat debridement are associated with an increased risk of infection.

The aim of the initial operative intervention is to produce a clean healthy wound by removing devitalized tissue, maximizing tissue perfusion, and providing skeletal stability.
Healthy soft tissue can cope with a significant number of bacteria without developing evidence of infection. Civilian wounds with less than 10^5 per gram, at the time of closure, have been shown to heal uneventfully. The presence of nonviable material (devitalized tissue or foreign material) has been shown to reduce, by a factor of 1000, the number of bacteria required to cause infection. Ultimately the body's ability to deal with devitalized, contaminated tissue is dependent on local and systemic factors and the acceptable threshold is variable. It is important to appreciate that surgical devices (implants or sutures) should be considered foreign material and will become colonized and contribute to the risk of infection.

Several studies have looked at whether Grade I and II open fractures and low-energy gunshot wounds can be managed without operative debridement. These studies have reported acceptable results in both the paediatric and adult populations.

Assessing the characteristics of a wound by formal surgical exploration is superior to superficial inspection. Treating an open fracture wound non-operatively requires experienced surgical judgement and there should be a low threshold for surgical exploration and debridement.

In wounds that are heavily contaminated, associated with arterial injury requiring repair, or sustained as a result of crush it is often difficult to determine the adequacy of the debridement and these wounds should have a second look at 48h before planning definitive treatment (Figure 12.7.1).

Maximizing tissue perfusion

For the soft tissues to clear residual bacteria from the wound, they must be well oxygenated and this requires a good blood supply. Pressure within the soft tissues will compromise perfusion and increase the likelihood of infection. Wound debridement originates from the French word meaning to ‘unbridge’ or release. In modern parlance we use the word to describe the removal of devitalized tissue but forget at our peril the importance of decompressing the wound to maximize perfusion. Leaving the wound open not only prevents compressing the soft tissues with closure but also facilitates drainage, further decreasing wound pressure (Box 12.7.1).

Timing of debridement

Based on limited evidence it has been accepted practice to perform surgical debridement of open fractures within 6h. More recent studies have failed to identify any benefit from early debridement and an increase in deep infection rate has not been demonstrated with delays up to 48h. Based on the current evidence, BOA/BAPRAS guidelines for tibial fractures recommend that debridement is performed on a semielective basis within 24h of injury with senior orthopaedic and plastic surgery input. Emergency debridement should still be performed in grossly contaminated wounds (organic material, stagnant or sea water), compartment syndrome, multiply injured and devascularized limbs.

Skeletal stabilization

Skeletal stabilization has been shown to be advantageous in reducing infection rates in open fractures but the scientific basis is limited. However, it is accepted that skeletal stabilization provides stability to the injured soft tissue envelope. This prevents further trauma, oedema, and reduced perfusion at the site of injury. The systemic and local benefits of skeletal stabilization are well established and facilitate early mobilization, nursing, and wound care.

Initial skeletal stabilization is temporary or definitive and the decision to use internal or external fixation will be dependent on the fracture, soft tissue cover, and local and systemic factors. An open wound devoid of devitalized tissue and foreign material will tolerate more contamination than a wound with an exposed implant. The timing of the planned soft tissue cover must be taken into account.
Timing of soft tissue coverage

Following successful debridement of open fracture wounds they remain at risk of infection while the wound remains open. The evidence would suggest that the vast majority of infections in open fractures are due to organisms that are not found in the wound at presentation. Early soft tissue coverage has repeatedly been shown to minimize the risk of infection from hospital-acquired organisms. The aim should be to achieve soft tissue coverage as soon as possible. The method of achieving coverage will be dependent on the soft tissues. Primary suture, delayed primary suture, and split skin grafting can be considered when the contamination is minimal and the soft tissue envelope is adequate to cover the implant. Primary suture has been shown to be safe when performed by experienced surgeons and will be discussed later in this chapter.

In those open fractures that have inadequate soft tissue coverage the best results (infection rate, flap failure, time to union, and function) have been achieved with debridement, fixation, and flap coverage within 72h. The current recommended optimum management involves debridement, fixation, and flap coverage as a single procedure. This technique has been shown to have a 3% deep infection rate in tibial fractures requiring flap coverage.

Involvement of multidisciplinary team

Any facility dealing with open fractures must be able to provide or access all of the relevant specialties. In the early management orthopaedic and plastic surgery input will be required. Vascular surgery will be required for Grade IIIc injuries. Complications are to be expected and the involvement of microbiologists with a specialist interest in bone infection and joint orthoplastic reconstruction clinics are beneficial.

Recognizing host factors

Host factors should be considered in the management of these injuries. Some of these factors have the potential to be optimized, others are indicative of high risk and should be managed accordingly.

Paediatric open fractures are associated with very low rates of infection in both upper and lower limb injury. There is a much higher rate of complications with increasing age.

A delay in neutrophil delivery to wounds in the lower extremity has been identified and this may help explain the higher incidence of infection in comparison to the upper limb.

Increased infection rates, in open long-bone fractures, are seen with systemic and local compromising factors. In the absence of compromising factors an overall infection rate of 4% has been reported. In comparison, open fractures with greater than three risk factors (or an absolute neutrophil count less than 1000; a CD4 count less than 100; intravenous drug abuse; chronic active infection of another site, or dysplasia or a neoplasm of the immune system) have an infection rate of 30%. The use of internal fixation in these high risk groups requires careful consideration.

In open tibial fractures, smoking has been demonstrated to increase the risk of infection (odds ratio 2.2), osteomyelitis (odds ratio 3.7), and non-union (37% less likely to be healed at 2 years). Cessation of smoking improves outcome but does not reduce the risks to non-smoking levels.

Initial management of open fractures (Box 12.7.2)

Open fractures are often high-energy injuries presenting as part of a polytrauma. The initial assessment and management should be carried out according to ATLS® principles. Ideally, prioritized activity can be concurrent rather than sequential. However during the primary survey attention may need to be directed at the open wound to address ongoing bleeding using pressure dressings or occasionally tourniquets.

Assessment of the wound

As a result of the significant deformation that can occur at the time of injury, open wounds may be some distance from the site of fracture. Any bleeding wound in proximity to a fracture should be treated with suspicion and assumed to be open until proven otherwise. The presence of fat globules in blood draining from a wound should be considered pathognomonic. In the case of pelvic fractures, open wounds may not be apparent on external inspection as communication may occur with the rectum or vagina. To avoid missing open fractures the entire limb must be visualized before applying dressings and splints. It is the responsibility of the person involved in this assessment to document clearly whether the injury is either open or closed. If an open injury is identified the characteristics of both the wound (size, location, and contamination) and surrounding soft tissues (degloving, abrasions and burns) also need to be recorded.

Microbiology swabs of the wound have not been found to be useful. In those cases that become infected the admission wound swabs are only representative of the organism involved in 8–18% of cases.

Assessment of vascular status

Pallor, reduced temperature, poor capillary return, and absence of peripheral pulses should alert the surgeon to the possibility of a vascular injury. To facilitate preoperative planning the presence or absence of all peripheral pulses in the affected limb must be documented. When pulses are not palpable it should not be attributed to hypotension. Doppler should be used to detect the presence and, where appropriate, the pressure of the distal pulses. Limbs which are grossly deformed should be manipulated into
anatomical alignment with a vascular assessment both before and after manipulation. Positional ischaemia may resolve with a brisk hyperaemia following reduction. Failure to re-establish the circulation merits consultation with the vascular surgeons and further assessment of the vascular injury. Angiography should be considered, however in most cases the zone of injury and surgical target for reconstruction is clearly identifiable. A lower threshold for angiography should be used in blunt injury where intimal tear is suspected, multilevel injury, or upper limb injuries that may maintain peripheral pulses due to collateral circulation despite arterial injury (see Chapter 12.9).

Neurological assessment

Motor function is difficult to assess in the presence of a severe open fracture due to the pain and loss of muscle function. Light touch sensation is usually sufficient in the lower limb. Two-point discrimination is necessary to detect more subtle lesions, particularly in the upper limb.

Assessment of compartment syndrome

Despite significant soft tissue disruption it is still possible for open fractures to develop compartment syndrome. In the majority of cases this is a clinical diagnosis based on the patient’s pain and evidence of muscle ischaemia on passive stretch. Neurological and vascular signs are late features. In the obtunded patient compartment pressure monitoring may be useful.

Wound cover

During this early phase the aim is to cover the wound as soon as possible and further exposure is to be avoided. The dressing should be sterile, moistened with normal saline, and occlusive. Antiseptic solutions are not recommended. The wound should be photographed and details documented. This should provide sufficient information prior to the next stage of treatment, and avoid the wound being repeatedly exposed. This simple measure has been shown to significantly reduce infection rates from 19% to 4%. Gross contamination should be removed from the wound. Exploration, debridement, and irrigation in the Emergency Department should be avoided as they are counterproductive.

Intravenous antibiotics

The first dose of antibiotics should be given as soon as possible. Current BOA/BAPRAS guidelines for lower limb open fractures recommend co-amoxiclav (1.2g 8-hourly in adults) or cefuroxime (1.5g 8-hourly in adults).

Clindamycin 600mg 6-hourly can be used instead of co-amoxiclav/cephalosporin when there is a history of penicillin-induced anaphylaxis should be administered within 3h and continued 8-hourly.

These antibiotics should be continued until the first debridement.

Tetanus prophylaxis

Tetanus prophylaxis must also be considered. Recommendations for prophylaxis are based on the condition of the wound and the patient’s immunization history.

Splintage

Gross malalignment should be reduced, splintage applied, and the limb elevated. Splintage serves many purposes:

- Reduces bleeding by stabilizing the clot and reducing volume
- Pain relief
- Reduces local effect of displacement on skin, nerves, and blood vessels
- Temporary stabilization of soft tissue envelope reduces development of oedema
- Reduces complications relating to fat emboli.

Following application it is important to recheck distal neurological and vascular status and perform x-rays to check position.

Radiographic assessment

Prior to x-rays the limb should have already been assessed, the wound covered and the limb splinted. Good-quality anteroposterior (AP) and lateral radiographs of the fracture including the joint above and below is the minimum that is required. Significant bone displacement, bone loss and fragmentation indicate the presence of high-energy injury. Air in the soft tissue planes confirms that the fracture is open and indicates the zone of injury. Radio-opaque foreign material can be identified. Where possible, articular fractures should be investigated with computed tomography before the first operative intervention. This provides the surgeon with the best opportunity to reduce the articular surface with minimally invasive techniques.

Communication with other surgical teams

Ideally the wound assessment should be performed by the surgical team involved in the definitive care. Unfortunately this may not always be possible. Early communication will facilitate planning and avoid delays. Repeat assessment by the same team will allow evolving injuries (e.g. vascular and compartment syndrome) to be identified.
Preoperative preparation

The surgery should be adequately planned. In cases where there may be soft tissue coverage problems it should be performed by
the orthopaedic and plastic surgeons as a joint procedure.

Strategy

- The area should be given a ‘social’ wash with warm soapy water
- Further antibiotics should be given at induction. BOA/BAPRAS guidelines recommend co-amoxiclav (1.2g in adults) and
gentamicin (7mg/kg, reduce if renal impairment)
- Following removal of the splint and dressings a further assessment of the limb can be performed
- Prep and drape for one- or two-stage procedure using alcoholic chlorhexidine solution, avoiding direct contact with the open
wound
- Order of procedures, e.g. fasciotomies, vascular reconstruction, skeletal stabilization
- Skin incisions to allow adequate visualization. Where possible, fasciotomy incisions should be used to avoid perforator
vessels. The surgeon should appreciate what secondary operations may be required to avoid compromising these procedures
- Consideration of the zone of injury will influence the necessary extent of the incisions, influence availability of local flaps, and
the placement of fixation
- Debridement must be efficient and thorough. Random ‘picking’ at the wound should be avoided. Proceed in a sequential
ordered fashion (superficial to deep, posterior to anterior, layer by layer). Make use of a second surgeon on the opposite side of
the limb, operating alternately on each layer

Box 12.7.1 Debridement

- Adequate skin incisions:
  - Avoid compromising the next operation
  - Avoid further devascularization by using recommended fasciotomy incisions
- Adequate fascial release
- Excise all contaminated and devitalized tissue (unless articular bone):
  - ‘Surgical steel is the best antibiotic’
- Irrigate
- Stabilize fracture and soft tissue envelope.

- Standardized routine is helpful (especially in the middle of the night with non-specialist staff).

Equipment

- Ensure that all the required equipment is in the room and the theatre staff are aware of your plans. An appropriate quantity of
irrigation fluid can be warmed in preparation
- Tourniquet—where possible a tourniquet should be fitted and can be used intermittently, which minimizes blood loss and
allows the safe identification of nerves and vessels
- Image intensifier—fractures are most amenable to reduction at presentation. A short period of time spent maximizing
alignment with external fixation will greatly facilitate minimally invasive definitive fixation techniques at the next sitting.

Potential problems

Complications will be avoided by preoperative consideration of potential problems. This will influence the choice of strategy and
equipment.

- Patient’s physiology—polytrauma patients may physiologically decompensate requiring the operation to be brought to a swift
conclusion so that the patient can be optimized on the intensive care unit
- High-energy wounds will present with grossly distorted anatomy. A good knowledge of the anatomy will be required.
Extending incisions to allow identification of nerves and blood vessels within normal anatomy is good practice, particularly if a
limb is being perfused by a single vessel!
- Specific problems related to the different methods of stabilization
- Routine postoperative complications, e.g. compartment syndrome, infection, and deep vein thrombosis.

Intraoperative strategy
Vascular injury

Vascular injury that compromises the viability of the limb is a priority and reperfusion of the limb should be achieved within 4h, before irreversible ischaemic muscle damage occurs. The viability of the limb should be considered when the ischaemic time is greater than 4–6h.

Early reperfusion can be temporary or definitive (see Chapter 12.9). Adequate exposure and debridement should be performed rapidly to allow either definitive repair or temporary intraluminal shunting. A coordinated plan must be made with the vascular surgeons. If fasciotomy is likely to be needed it should be performed before the vascular repair. This will facilitate venous drainage and any perfusion provided by intact collateral vessels.

Skin

The size of the traumatic wound does not always reflect the degree of soft tissue damage. Skin wounds must be extended to allow an adequate estimation of the full soft tissue injury (Figure 12.7.2). The wound extensions should be made taking into consideration local fasciotomy incisions. In the tibia this will protect the fasciocutaneous perforator vessels. Consideration must also be given to access for internal fixation. Transverse incisions should be avoided when possible. The skin survives trauma well and routine excision is not appropriate, only non-viable or contaminated skin edges need excision. Usually excision of a few millimetres is the most that is required.

Degloving (Figure 12.7.3), occurs as a result of a shear force resulting in separation between the deep fascia and subcutaneous fat. This damages the perforator vessels that supply the skin and may devascularize large areas of skin.

Subcutaneous fat

Subcutaneous fat often has a poor blood supply and does not tolerate trauma as well as skin. This layer should be freely excised if there is any contamination or there is any question of viability.
Fascia

Any non-viable damaged or contaminated fascia should be removed. The fascia should be incised to decompress the underlying muscle and improve tissue perfusion. The surgeon should have a low threshold for performing complete fasciotomy of all compartments. Even if compartment syndrome is not present at the time of initial surgery it may subsequently develop.

Muscle and tendons

The identity and location of the muscle and tendon injuries need to be clearly documented to facilitate reconstruction at the time of definitive skin cover. It will also help establish if preoperative lack of function was due to a mechanical or neurological cause.

Necrotic muscle is the major medium for bacterial proliferation. All severely injured, ischaemic, and non-viable muscle must be removed. Assessing the viability of muscle may be difficult particularly in the presence of hypovolaemia, respiratory insufficiency, or temporary ischaemia (vascular injury or tourniquet). In general muscle viability can be assessed using the four Cs:

- Consistency
- Contractility—viable muscle will contract when gently pinched with forceps
- Colour—may be difficult to interpret due to blood under the myonesium
- Capacity to bleed—by the very nature of the procedure debridement of muscle must produce bleeding, to limit blood loss the majority of the debridement can be performed under tourniquet.

Nerves

Nerves in continuity should be maintained and cleaned. The epineurium of transected nerves can be tagged with a monofilament suture but care needs to be taken to avoid further damage. Identity and location of the nerve injury needs to be clearly documented.

Bone

Bacteria will colonize dead or ischaemic bone and produce a biofilm, making subsequent eradication very difficult. The tourniquet should be deflated to allow assessment of bleeding bone ends. Bone devoid of soft tissue attachment should be removed. These fragments should, however, be used to help judge fracture reduction before being discarded. An exception is made in the case of large articular fragments. These fragments need to be meticulously cleaned and reattached with absolute stability to facilitate union and revascularization. The viability of bone fragments that have some residual soft tissue attachments, in the absence of an available intraoperative assessment tool, continues to require surgical judgement. If the tissue is insufficient to resist the bone fragment detaching with a gentle pull it should be removed ('tug test'). The vascularity of a soft tissue bridge can be assessed using a hypodermic needle to elicit bleeding.

All fracture surfaces should be directly exposed and cleaned with a combination of nibblers, curettes, and scrubbing brushes.

Irrigation

The main purpose of irrigation is to wash away the loose particulate matter generated from the injury and the debridement. Tissue impregnated with foreign material and bacteria will not be effectively cleaned by washing alone. This should influence the volume of irrigation fluid used. There is no good evidence with regard to volumes required; however it is accepted practice to use large volumes (3–12L). Soap, antiseptics, and antibacterial agents have been investigated and demonstrated to have no additional benefit and in some circumstances are harmful.

Pulse lavage should not be used as this is associated with driving contaminants further into the tissues and increased bacterial seeding. It is also associated with trauma to the soft tissues. Although initially it is effective at reducing bacterial count there is a subsequent significant rebound.

Primary skeletal stabilization

At this stage the wound should be completely clean with all devitalized tissue and foreign material removed. The conditions should be sufficient to allow internal fixation to be considered. In addition to planning the method of fixation the wound should be classified and consideration should be given to how soft tissue coverage will be obtained. Where soft tissue cover is inadequate, involvement of the plastic surgeons is recommended. This is best performed at the time of the initial debridement as it will allow the fixation and soft tissue cover to be optimally planned.

  - X-rays
  - Consider angiography
- Consult other specialists where indicated (e.g. plastic surgeon)
- Consider transfer.

Skeletal stabilization can either be temporary or definitive. Where debridement and soft tissue cover is considered adequate it is appropriate to proceed with definitive fixation. Despite adequate soft tissue coverage, if there is concern about the adequacy of debridement it is appropriate to use temporary stabilization and delay definitive fixation for 48h. Temporary stabilization with an external fixator should be considered when there is a soft tissue defect that would leave the implant exposed. The aim should be to perform definitive fixation at the same time as providing definitive soft tissue cover. Delays in covering exposed metal work are associated with increased infection rates (Box 12.7.3).

Placement of external fixators should avoid placing pins within the zone of injury or in areas of future internal fixation. Although conversion to internal fixation has been successfully reported up to 10–14 days following external fixation, colonization of the intramedullary canal from pin sites occurs rapidly. In general it is beneficial to convert from external to internal fixation as soon as possible.

Closure

There is good evidence to suggest that open fracture wounds can be closed primarily and early closure is associated with lower infection rates. This philosophy is based on the high prevalence of hospital-acquired organisms seen to cause infection in open fractures and the desiccation of exposed soft tissues. Dead space and drainage should be addressed as there will be a significant exudate as part of the inflammatory process. Failure to drain this fluid will further increase soft tissue tension and result in the accumulation of colonized fluid. Skin loss, heavily contaminated wounds, arterial injury, polytrauma, and compromising patient factors should be considered as contraindications to primary closure.

Primary closure requires experience, if in doubt leave the debrided wound and extensions open.

Dressings

The aim of the dressings, used following initial debridement, is to prevent external contamination and allow fluid drainage. The simplest dressing involves physiological saline soaked gauze. Antiseptic solutions should not be used. Several large studies have demonstrated a significant reduction in infective complications by using antibiotic bead pouches. Beads are placed in the wound and covered with strips of non-circumferential adhesive semipermeable membrane and produce high local concentrations with low systemic absorption. In one study of Grade III tibial fractures treated with systemic both antibiotics, the addition of antibiotic beads reduced the rate of infection (39% vs 7.3%) and osteomyelitis (26% vs 6.3%).

Negative pressure wound therapy (NPWT) can also be recommended with a 1.9 times lower infection rate compared to standard dressings. These dressings have been shown to reduce oedema, increase local blood flow, encourage granulation, and reduce the size of the wound. The dressings can remain in situ for 48h and during this time the problems of dressing 'strike through' and contamination are avoided as the wound is sealed and continuously drained. Although NPWT dressings can be used to close open wounds and reduce requirements for flap coverage it is not recommended in the case of open fractures.

Current evidence demonstrates that NPWT and antibiotic bead pouches do not extend the ‘window of opportunity’ and the best results are still achieved with early soft tissue wound coverage (Figure 12.7.4).
Fig. 12.7.4
A) Primary open reduction and internal fixation of Grade IIIb distal tibia fracture. Gentamicin bead pouch dressings. Definitive soft tissue coverage delayed, performed at day 7. B) Complicated by deep sepsis requiring debridement resulting in significant bone defect. C) Treated with circular frame and bone transport. Complicated by further soft tissue problems and re-fracture. D) Union and resolution of sepsis at 2 years postinjury.

Postoperative antibiotics

Antibiotics should be continued postoperatively, however there is no good evidence to guide clinicians on duration.

Current guidelines for open lower limb fractures recommend continuing with co-amoxiclav (1.2g) 8-hourly:

- Gustilo I open fractures should not be treated beyond 24h and certainly not beyond 48h
- Gustilo II and III fractures, prophylaxis should be continued until definitive soft tissue closure or for a maximum of 72h, whichever is shorter. This may have to be modified with regards to timing of debridement.

Secondary operative intervention

When there is uncertainty about the adequacy of primary debridement, further debridement at 24–48h can be considered. However the aim must always be to produce a clean wound with the first debridement.

It must be anticipated that at the time of secondary procedures the wound may be colonized with hospital-acquired organisms. Antibiotics with a different spectrum of activity are appropriate to cover these procedures involving the insertion and soft tissue coverage of internal fixation. Current BOA/BAPRAS guidelines for open lower limb fractures recommend:

When skeletal fixation and definitive soft tissue reconstruction is undertaken, gentamicin (7mg/kg, with appropriate adjustment in the elderly or those with renal impairment) and either vancomycin (1g) or teicoplanin (800mg). Vancomycin infusion will require to be started at least 90min before surgery.

Skeletal stabilization

The method chosen for definitive fixation of the fracture will depend on the fracture pattern. The method used should be optimal for bone healing and avoid further soft tissue trauma. Achieving early coverage of the implant is more important than the implant itself. Open fractures are associated with a higher incidence of non-union and early secondary surgery may be required to facilitate healing (11–58% in Grade III tibial fractures).

External fixation should be considered for definitive treatment of grossly contaminated wounds. Ring fixators provide additional benefit when there is bone loss, complex fracture patterns, and compromised soft tissues.

Intramedullary nailing has been demonstrated to be appropriate in the management of minimally contaminated open tibia and femur fractures. There are also significant benefits in terms of malalignment, subsequent procedures, function, and patient satisfaction. Reaming has not been shown to be detrimental. It has been recommended that if late conversion to intramedullary nailing from external fixation is considered there should be a delay of 7–14 days following removal of the external fixator to minimize the risk of infection.

Cast immobilization is generally not appropriate for either the temporary or definitive management of lower extremity long-bone open fractures in adults. In children Grade I and II open forearm fractures can be successfully treated with debridement and cast immobilization.

Soft tissue coverage
It should be considered best practice to achieve definitive skeletal stabilization and soft tissue coverage within 72h and certainly within 7 days (Figure 12.7.5).

Fig. 12.7.5
A) A 21-year-old motorcyclist treated with debridement and external fixation as an emergency procedure. B) At 48h postinjury he was treated with internal fixation, reconstruction of extensor mechanism (hamstring tendon), gastrocnemius flap, and split skin graft. C) Multifragmentary distal femur and tibia.

In those wounds left open for a second look this should be performed at 48h and at this stage, soft tissue coverage can be achieved with direct skin closure, split skin graft, or flaps. Small residual defects, not involving exposed metal work can be left to heal by secondary intention. A 1cm² defect will take approximately 1 month to heal.

Definitive soft tissue coverage is covered in detail in Chapter 12.8.

Further reading

Summary points

- Soft tissue cover is a complex process
- Soft tissue cover requires specialist skills
- Soft tissue cover should ideally be performed in collaboration with a Plastic & Reconstructive Surgeon.

Introduction

Soft tissue coverage of the extremities following trauma facilitates early wound healing and provides durable cover for exposed structures. Defects have traditionally been closed by using the simplest suitable technique from a reconstructive ladder, ranging from primary closure and skin grafting to flap cover. However, the expanded armamentarium available to the reconstructive surgeon permits the emphasis to shift from simply closing the wound to one providing an optimal functional and aesthetic result.

Outcomes are judged by the extent of restoration of form and function, and also by the donor site morbidity of the reconstruction. Losses should ideally be replaced with like tissue and cover should provide durable protection for underlying structures with minimal donor site morbidity. Attempts should be made to restore sensibility where possible as functional results will be enhanced. This chapter discusses options for soft tissue cover in the upper and lower extremities. Hand and wrist cover are discussed in a separate chapter.

General principles (Box 12.8.1)

Clinical evaluation (Box 12.8.2)

The approach to assessment and reconstruction of a surgical defect is similar in both extremities. The history should include an estimate of the forces causing the injury. The presence of peripheral vascular disease, diabetes mellitus, or a history of heavy smoking may influence the choice of reconstruction and are considered with age, sex, occupation, and pre-injury mobility status.

The limb assessment starts with the general trauma evaluation and continues in the operating theatre during initial debridement. High velocity, severe crush, or degloving injuries have extended zones of damage which are often unrecognized on initial inspection but should be suspected as soon as the details of the accident are known. The limb examination should pay particular attention to the vascular supply, skeletal integrity, and the presence or absence of nerve injury. The wound is examined to determine the extent of soft tissue loss, absence of other structures, and degree of exposure of vulnerable tissues (bone, tendon, nerve, cartilage, and vessels). The quality and availability of adjacent tissue is evaluated for possible use in local flap transfer. Avulsion or degloving mechanisms will further widen the affected area. Marginal tissues may not declare viability at the initial exploration and serial debridements are necessary until the wound is stable.

Box 12.8.1 Principles

- Replace like with like
- Minimal donor site morbidity
- Restore sensation if possible.

Box 12.8.2 Assessment

- Premorbid, e.g. smoking
- Soft tissue/vascular/neurological injury assessment
- Continues during surgery
- Avulsion/degloving will widen injury area.

Investigations such as angiography should be requested if indicated, especially if free tissue transfer is being contemplated. Indications for preoperative angiography include patients with suspected vascular injury who may require acute vascular reconstruction (Gustilo 3C tibial fractures) and patients who have had previous regional surgery with possible alteration of recipient vessel anatomy.
A multidisciplinary approach is commonly necessary for the management of these patients, especially in the lower limb where complex fracture fixation procedures are undertaken prior to soft tissue coverage and early participation of all parties who will be involved in management should be encouraged.

**Early management (Box 12.8.3)**

The foremost principle in the management of any traumatic injury is early, meticulous surgical debridement and wound irrigation. In complex injuries, particularly with heavy contamination, serial debridement may be performed after 48–72h in order to determine more accurately the extent of tissue damage. Conservative initial debridement in wounds with massive tissue loss allows for preservation of tissue which may otherwise be excised using a more radical approach. At the second debridement any obvious residual devitalized tissue can be excised. The wound should then be suitable for cover which can be undertaken at this stage. Alternatively, if free tissue transfer is proposed as a single-stage procedure, it is essential that all devitalized tissues are excised prior to coverage.

**Box 12.8.3 Early management**

- Meticulous debridement
- Serial debridement in complex injuries
- Intravenous antibiotics at outset and until wound closed
- Bacterial swabs from wound.

The bacterial count in the wound increases with time prior to surgery and intravenous antibiotic therapy is therefore commenced on admission and continued until soft tissue cover is achieved. Wound swabs should be taken intraoperatively and antibiotics adjusted according to bacterial sensitivities.

**Indications for soft tissue cover (Box 12.8.4)**

Where skin loss is minimal, wounds can be closed by primary suture following debridement and irrigation under appropriate antibiotic cover. During suturing the margins of the wound should be easily opposed without blanching and allowances made for postoperative swelling to avoid ischaemic skin necrosis (approximate—don’t strangulate!). Wounds should not be closed primarily if under tension. In doubt, sutures should be removed and another method of cover sought. In practice, most wounds can be closed either primarily or with a split skin graft.

Wounds that cannot be closed primarily can generally be closed by applying skin grafts or with flap cover. Skin grafts are also indicated in wounds where grafting would expedite healing in contrast to healing by secondary intention, and also where no advantage can be obtained by using a skin flap. The wound bed should be well vascularized and free from infection, which in practical terms means a wound bed consisting of healthy muscle, fascia, or granulation tissue. The presence of beta-haemolytic streptococci (Lancefield group A) is an absolute contraindication to grafting. Graft will not take on exposed bone, cartilage, or tendon unless the perioistium, perichondrium, or paratenon are intact. Absence of these well vascularized structures, or exposure of nerves or vessels, excludes the use of a skin graft and necessitates flap cover.

Flap cover may be from a local or regional source, or as a free tissue transfer. Flap transfer may be fascial, fasciocutaneous, muscle, or composites depending on the reconstructive requirements. Local random pattern flaps can be transposed, advanced, or rotated to cover small defects where the bed is unsuitable for a skin graft or where a flap would give a better cosmetic result.

The timing and choice of cover depends on the general condition of the patient including associated injuries, site, size, and depth of defect, extent of the zone of injury (macroscopic and microscopic), thickness of tissue required for reconstruction, donor site availability, and the need to perform secondary reconstructive procedures. In general, low-energy injuries unsuitable for primary closure or split skin grafting can be covered with local fasciocutaneous flaps, whereas extensive defects from high energy injuries often require free tissue transfer. Primary reconstruction of damaged tendons and nerves should only be performed if adequate cover can be provided simultaneously. Nerves and tendons that are not suitable for primary repair should be tagged following debridement and bony stabilization in order to facilitate easy identification during secondary reconstruction.

**Box 12.8.4 Soft tissue cover**

- Do not oppose edges with tension
- Split skin graft needs vascularized bed
- Beta-haemolytic Streptococcus contraindication to grafting
- Low-energy injuries local flap.

**Technique of split skin grafting**

Split skin grafts are most commonly harvested from the uninvolved thigh or buttock region under general or local anaesthesia with
either an electrical or air-driven dermatome or a free hand knife. The donor site is prepared and draped in a sterile fashion. An epinephrine (adrenaline) containing local anaesthetic solution may be infiltrated subcutaneously preoperatively or applied topically following harvest to reduce blood loss and provide postoperative pain relief. The dermatome is set to the appropriate thickness, the donor site lubricated with liquid paraffin, and the graft cut by setting the dermatome flat on the skin, turning on the power and advancing it across the donor site using gentle downward pressure. The harvested skin may be meshed using a mechanical device or ‘hand meshed’ using a scalpel. Meshing allows egress of exudate which could otherwise accumulate under the graft lifting it from its bed. The donor site is dressed. A number of donor site dressings are available, including semiocclusive dressing such as calcium alginate (Kaltostat) or Lyoderm. The graft is spread, cut surface upwards, on a sheet of paraffin gauze. It is then placed on the wound and fixed with sutures or tissue glue (Histacryl), and a well-padded dressing is applied. The graft is typically inspected 5 days postoperatively and the donor site inspected 10–14 days postoperatively.

### Principles of flap transfer

Careful planning and execution are of paramount importance for successful flap transfer. Flap design begins with projection of the recipient defect backwards (via a template) onto a suitable donor site. The flap should have a predictable circulation and be larger than the primary defect, allowing for safe single-stage transfer with tension free inset. Donor sites produce a secondary defect which may be closed directly or indirectly, using either skin graft or local flaps. Principles which improve the quality of the reconstruction include: elimination of dead space; atraumatic tissue handling; meticulous haemostasis; and the use of appropriate suture materials.

### Fracture fixation methods and soft tissue cover

Complex injuries involving fractures with varying degrees of soft tissue loss require stabilization prior to coverage. The method of fixation used depends on the fracture site and type, size and characteristics of the wound and to a certain extent the preference of the orthopaedic surgeon. External fixation conveniently splints bone and soft tissues while providing access to the wound and can be applied rapidly with minimal risk of further devascularization of bone fragments and adjacent soft tissues. Internal fixation using plates and screws or intramedullary nails may be used primarily provided soft tissue cover can be achieved simultaneously. If the surgeon performing the external fixation is different from the surgeon providing cover, it is important that placement of fixation pins is discussed to avoid compromise of potential local donor tissues.

### Timing of reconstruction

The timing of reconstruction depends on the mechanism of injury, wound status, condition of the patient and availability of appropriate surgical expertise. Early wound closure (defined by Byrd et al. as the first 6 days from injury and by Godina as the first 72h from injury) of complex lower extremity defects with vascularized muscle following radical debridement was associated with lower wound infection rates, a lower incidence of osteomyelitis and non-union, and lower anastomotic thrombosis rates, than delayed closure. In practice, initial evaluation, debridement, and bone stabilization are performed by the orthopaedic trauma team and the plastic/reconstructive surgeon is asked to provide soft tissue cover days later, thus missing the first ‘window of opportunity’ for reconstruction.

Ideally, all severe injuries are managed on a single site with dedicated orthopaedic and plastic/microsurgical surgeons with an interest in trauma. If the appropriate expertise is not available locally, it is essential that orthopaedic surgeons communicate with their local plastic surgery service or with appropriately trained and experienced orthopaedic colleagues before embarking on the first operative procedure. In cases where cover is delayed, it is important to avoid desiccation of the wound between operations.

### Wound closure with vacuum-assisted devices

Topical negative pressure (TNP) wound care management systems have become increasingly popular over the last decade and their use in the management of limb trauma is continually evolving. Used in the appropriate wounds, TNP can reduce swelling and encourage the growth of granulation tissue allowing wound closure with split skin graft rather than a flap. However, used incorrectly it can delay appropriate radical debridement that may otherwise salvage early infected prostheses and metal work. In the military and acute trauma setting it can allow wound debridement and then sterile wound closure, so that appropriate transfer to a specialist centre can be achieved. Its usage should be regularly reviewed and restricted to those with appropriate training or when used in close collaboration with plastic surgery colleagues and it should not replace adequate surgical debridement.

### Flaps available (Box 12.8.5)

Although numerous flaps have been described, the vast majority of defects can be covered adequately by using one of a limited number of ‘workhorse’ flaps.

**Latissimus dorsi (Figure 12.8.1)**

The latissimus dorsi muscle free flap is the workhorse of lower limb reconstruction, whereas the pedicled latissimus dorsi muscle or musculocutaneous flaps are useful in shoulder and arm reconstruction. The muscle is easily elevated, has a long pedicle enabling microvascular anastomosis outside the zone of injury, and can be folded which aids in dead-space obliteration. Dimensions averaging 25cm × 40cm in adults provide cover for defects extending from the proximal tibia to the ankle. The amount of muscle harvested can be tailored to the defect preserving innervation and function of the remaining muscle. Among the disadvantages of muscle transfer is weakness of upper extremity ‘push-off’, an activity of importance in some athletes and bell
Serratus anterior

The serratus anterior muscle can be transferred as a free flap either alone or combined with the latissimus dorsi muscle for cover of medium to large defects in the distal third of the leg and foot. The upper slips of the muscle should be preserved during harvest in order to reduce winging of the scapula which would result from complete removal of the muscle. Although the donor site is closed directly, lack of an associated skin flap necessitates skin grafting for resurfacing.

Rectus abdominis

The rectus abdominis muscle can be used as a pedicled muscle or musculocutaneous flap for coverage of both groins or as a free muscle flap for coverage of lower limb defects. The blood supply is robust, considerable muscle bulk is available and the skin paddle can be carried anywhere along the muscle. If the skin island is placed at the level of the inframammary fold, a pedicled musculocutaneous flap can provide cover of the groin, trochanter, or anterior thigh as far as the knee. Disadvantages of flap harvest include abdominal weakness that results particularly in the inferior portion of the abdomen below the arcuate line, although hernias are rare and functional morbidity is minimal as the remaining rectus muscle compensates.

Gracilis

The arc of rotation of the pedicled gracilis flap allows for cover of ipsilateral groin defects or defects on the anterior and posterior thigh. The gracilis can also be transferred as a free muscle or musculocutaneous flap for coverage of limb defects. A neuromuscular flap can be used to provide motor input following muscle loss, e.g. for elbow flexion. Muscle harvest causes minimal functional morbidity and the donor site can always be closed primarily. However, long cutaneous skin paddles are unreliable distally and the flap may be difficult to raise in the obese.

Scapula flap

The scapula flap can be used to cover defects in the upper arm and axilla as a pedicled flap and defects in the forearm as a free flap. Composite flaps consisting of skin overlying the scapula, latissimus dorsi, and/or serratus anterior muscle are available for cover of large complex defects. Primary closure of the donor site is usual, although the scar over the scapula will almost always stretch leaving an unattractive donor site.

Groin flap

The groin flap has been popular for cover of hand and forearm defects. It is large enough for most upper extremity defects and can be extended if necessary by delay procedures. The donor site can usually be closed primarily leaving an acceptable ‘‘skini-line’’ scar. The distal portion can be radically thinned to fit hand defects with a more acceptable contour although it may still be bulky in obese patients. As with all staged transfers the delay between stages may lead to stiffness which is compounded by the dependent position the arm is forced to adopt. Early aggressive hand therapy or use of this flap as a free tissue transfer can reduce this problem. Utilizing either method, groin flaps may require thinning procedures to improve contour.

Fig. 12.8.1

Latissimus dorsi flap cover of complex lower-limb injury in 12-year old male patient: A) initial presentation; B) following debridement, external fixation, and cover with a latissimus dorsi free flap; C) application of meshed split skin graft; D) late result showing stable soft-tissue cover.
Radial forearm flap

A large territory of forearm skin can be raised as an axial pedicle flap or as a free flap on the radial artery. Palmaris longus tendon and radial bone can be included for extensor or metacarpal reconstruction respectively if required. Composites of bone and skin can also be used for thumb reconstruction. The pedicled radial forearm flap is often used as a reversed flow distally based fasciocutaneous flap for cover of distal dorsal hand defects or degloved fingers in a mutilated hand. The vascular anatomy is constant and the excellent nerve supply allows its use as a neurovascular flap. The main disadvantages of this flap are the donor site morbidity and the sacrifice of the radial artery. The donor site may require a split skin graft for reconstruction which can be unsightly and should preferably not be used in female patients. Smaller donor sites that are still too wide for direct suture may close with a local sliding transposition flap. An Allen test should always be performed before raising this flap to confirm adequate ulnar artery vascular input to the whole hand.

Lateral arm flap

The lateral arm fasciocutaneous flap can be used as a pedicled flap to cover proximal forearm defects, or as a free flap to cover small to moderate size defects in the lower limb and distal forearm. Flaps with dimensions of 15 cm × 14 cm have been described but if the donor site is to be closed primarily the width should be limited to 6–8cm. The main advantage of the lateral arm flap over the radial forearm flap is that the nutrient artery is not essential to the vascularity of the distal upper extremity.

Adipofascial

For small to medium sized defects of the middle and distal third of the leg, turnover flaps of fat and fascia have been used as a bed for a split skin graft (Figure 12.8.2). They can be designed to incorporate a perforator in the base adjacent to the defect, and hence a more reliable blood supply. Donor sites that have been previously traumatized or degloved are unsuitable due to perforator damage and impaired vascularity. Success with these flaps requires some expertise and they should not be used for coverage of infected wounds. While muscle flaps are relatively resistant to bacterial contamination in contrast to fasciocutaneous flaps, adipofascial flaps have not been shown to have this property. Although donor site morbidity is minimal, the major disadvantage of this flap is the unpredictable take of skin grafts applied to the fascial surface.

Cover in specific anatomical regions

Upper limb (Box 12.8.6)

Where nerve, blood vessels, tendon, or bone are not injured or exposed, e.g. a deep friction burn or a skin avulsion injury, a split thickness skin graft can provide excellent cover. Where grafts cross the elbow joint, splinting and physiotherapy help to prevent the development of skin contractures that may reduce the range of elbow motion. With careful surgical technique, a split skin graft will heal sufficiently to allow mobilization within one week of the procedure. Pressure garments can be worn for 6–18 months to hasten graft maturation and improve the final appearance.

In some avulsion or degloving type injuries the skin flap can be used as a full thickness skin graft following defatting providing the surface of the skin flap is relatively undamaged. This has the advantage of providing skin with a good colour and texture match without donor site morbidity. Defects that are unsuitable for skin grafting require flap cover from local or regional sites or free tissue transfer.

Significant upper limb trauma is often associated with chest injuries and definitive cover may have to be delayed until the patient’s condition is stable. Debridement with dressings or a split thickness skin graft, autogenous or autologous, can be used as a temporary biologic dressing. A pedicled latissimus dorsi flap may then be required to reconstruct defects in the shoulder and arm.
Fasciocutaneous flaps such as the scapula or groin flaps may also be used to cover large forearm defects. For smaller defects, the lateral arm flap can cover defects above and below the elbow.

In more complex defects, free tissue transfer may be the method of choice for soft tissue cover. Other indications for free tissue transfers in the upper limb are as follows:

- Where simpler techniques are not suitable because of trauma to local donor sites or previous failures with use of adjacent tissues
- Where a one-stage procedure will allow for early mobilization and restoration of function

### Upper limb

- Early movement to avoid contractures
- Pressure garments useful
- Local flap may be used
- Latissimus dorsi or myocutaneous flaps may be required.

- Composite tissue transfers can be performed if required for reconstruction
- Staged pedicle transfers may be uncertain due to dubious vascularity of the recipient bed.

### Lower limb (Box 12.8.7 and Figure 12.8.3)

Significant lower limb trauma is often associated with other injuries and while management of life-threatening conditions takes precedence over limb injuries, decisions regarding treatment of the injured limb need not be delayed. Prerequisites for reconstruction are vascular patency and tibial nerve integrity.

#### Groin and thigh

The circumferential muscle layer surrounding the femur in the proximal third of the thigh allows for most defects to be closed with split thickness skin grafts. When vessels or nerves are exposed following post-traumatic vascular reconstruction or occasionally with exposure of orthopaedic metalwork, a number of local pedicled flaps are available including: rectus abdominis, tensor fascia lata, gracilis, sartorius, vastus medialis, and vastus lateralis. When suitable local tissue is not available or composite tissue is needed, free tissue transfer should be considered.

#### Knee and proximal third of leg

Traumatic defects or exposure of orthopaedic metalwork following wound dehiscence in this region frequently require flap cover. Choices for coverage include proximally based fasciocutaneous flaps, local muscle flaps, and free tissue transfer. The gastrocnemius muscle is the most useful source of cover in this area. Based on proximal pedicles, the medial or lateral head of this muscle can be harvested for cover of medium sized defects from the proximal patella as far caudal as the junction of the upper and middle thirds of the tibia. Functional morbidity is minimal and split skin grafting of the muscle produces good surface contour.

#### Middle third of leg

Defects in the middle third of the leg can be covered with a soleus muscle flap. Based proximally, muscle vascularity is reliable to a point 5cm above its tendinous insertion. No functional deficit is noted following transfer although the long term effects on the venous pump mechanism have not been reported. High energy injuries with comminuted tibial fractures can result in soleus laceration and contusion excluding its use. In these cases, free tissue transfer of muscle from outside the zone of injury is indicated. For coverage of smaller defects the tibialis anterior muscle can be split longitudinally and flipped through 180 degrees to cover the tibial shaft. This technique preserves the innervation to the muscle and there is no functional deficit.

### Box 12.8.7 Lower limb

- Need intact vascular supply and tibial nerve integrity
- Groin/upper thigh SSG or local flap
- Knee and upper leg—gastrocnemius local flap
- Middle third of lower leg soleus flap
- Distal lower leg and ankle fasciocutaneous flaps or free graft.
Distal third of leg and ankle

Defects in the distal third of the leg cannot easily be replaced with skin grafts as muscle cover is limited. Choices for cover include fasciocutaneous and free flaps. The axis of rotation of distally based fasciocutaneous flaps is designed with the base including one of two vascular perforators located 6cm and 12cm superior to the medial malleolus. These can be identified preoperatively using handheld Doppler. Fasciocutaneous flaps cannot be used when there has been extensive degloving as perforators will have been avulsed. Under such circumstances, in infected wounds, or where there is segmental bone loss, a free muscle transfer with a split skin graft is more appropriate.

Foot (Box 12.8.8)

Soft tissue cover in the foot can present a challenging prospect to the reconstructive surgeon with different requirements for dorsal and plantar surfaces. Dorsal skin is thin and pliable and provides a smooth undersurface to allow for tendon gliding whereas the weight bearing plantar skin is glabrous and able to withstand the shearing stresses of ambulation due to its dense soft tissue attachments to bone. Reconstructive goals include the restoration of sensibility, cover of bones and tendons, to minimize bulk and provide resistance to tangential shearing movement. The ability to perceive deep pressure is essential for weight bearing, ambulation and long-term stability of coverage.

Box 12.8.8 Foot

- Sensation important
- Dorsum—local or free fasciocutaneous flaps
- Plantar—local transposition or simple skin graft
- Free flap may be required in severe plantar injury.

Skin grafts on the dorsum of the foot are susceptible to trauma from footwear and need protection until they are mature. Small defects unsuitable for grafts can be covered by local fasciocutaneous or muscle flaps (dorsalis pedis, lateral calcaneal, extensor digitorum brevis, abductor hallucis, or abductor digiti minimi). For more extensive defects, free fascial transfers (lateral arm, radial forearm, or temporalis) can be used with a skin graft. Free fascial flaps lack bulk and produce an excellent contour to the dorsum of the foot while permitting tendon gliding. Free fasciocutaneous or muscle flaps should be used for contaminated wounds or deeper defects.

The specialized plantar skin is best replaced with like tissue. Heel or forefoot defects with an adequate pad of subcutaneous tissue do well with a split or full thickness graft. Delayed application of skin grafts can reduce the severity of hyperkeratosis seen at the junction of plantar skin and skin graft. In wounds where the subcutaneous padding has been lost, the non-weight bearing skin of the medial instep can often be used for transposition to adjacent weight-bearing areas, i.e. lateral instep and heel. Axial flaps such as the medial planatar artery instep flap are useful for heel cover as they contain cutaneous nerves and are sensate. The toe fillet flap provides the best cover for forefoot defects with innervated skin, and minimal donor site morbidity. If the medial and lateral plantar nerves are intact, deep pressure sensation will be preserved offering protection from pressure necrosis to free flap cover. Muscle flaps, e.g. latissimus dorsi, provide bulk for padding of bony prominences and ambulation will be restored in most cases with appropriate rehabilitation. Rehabilitation of these patients is especially important with provision of custom-made shoes and instruction on foot care.

Chronic osteomyelitis (Box 12.8.9)
Chronic osteomyelitis has been defined as ‘one or more foci in bone that contain pus, infected granulation tissue, sequestra, a draining sinus and resistant cellulites’. Treatment involves radical debridement of all devascularized bone, poorly vascularized soft tissue, and infected granulations. The wound is then left to heal by secondary intention, skin grafted, or covered with a flap. In cases where there is segmental bone loss skeletal reconstruction should be delayed and closure is best accomplished using free or pedicled muscle flaps. Reconstructive options once primary healing has occurred depend on the size of the defect and include: cancellous bone grafting; the use of vascularized iliac crest or fibula grafts; and the use of bone transport techniques.

**Indications for amputation**

The decision to amputate is made on a case by case basis, considering the injured extremity, the patient’s age, associated injuries, and socioeconomic situation. While recovery and rehabilitation following complex lower limb reconstruction can often be a lengthy process, amputation often hastens recovery and return to work and with a suitable prosthesis can often provide a functional extremity. Disruption of the posterior tibial nerve is generally considered an indication for amputation because of the importance of plantar sensibility. Amputation should also be considered in massive degloving injuries of the foot as reconstruction will not recreate a normal foot.

**Box 12.8.9 Osteomyelitis**

- Radical debridement
- Then healing by secondary intention/SSG/free flap.

**Results and complications**

Valid comparisons of the results of soft tissue cover are difficult to make for the following reasons:

- There has been a lack of uniformity in the description of the soft tissue injuries
- Associated fractures have not been specified
- Criteria for wound closure have not been completely documented
- There has been variation in timing of cover in different published series.

Fasciocutaneous flaps provide reliable soft tissue cover in the extremities with a reported 97% success rate, as measured by wound healing and limb preservation. Free tissue transfer for cover of Gustillo grade III lower limb injuries has resulted in limb salvage rates of greater than 90%. In all series the highest success rate with the least complications occurred when patients were treated in the acute period. A major factor in obtaining better outcomes was the surgeon’s learning curve with results improving with experience.

Long-term follow-up of 72 patients with Gustillo grade IIIB open fractures treated with free tissue transfer revealed a limb salvage rate of 93%, with 96% patient satisfaction. However, only 26% of these patients returned to long-term employment within 2 years in contrast to 68% of patients who underwent amputation for lower extremity trauma during the same period. This puts into perspective the fact that despite the technical ability to achieve salvage in a severely injured limb the surgeon must bear in mind the long-term goals of occupational rehabilitation before selecting patients for this treatment.

**Further reading**

Combined vascular and orthopaedic injuries

Summary points

- Early diagnosis of an arterial injury is critical in reducing the risk of limb loss
- Don’t assume that missing pulses are due to arterial ‘spasm’
- Don’t assume that presence of distal pulses rules out a proximal vascular injury – arterial intimal tears can occlude the vessel many hours after the initial injury
- After an arterial repair has been completed there is still a risk of subsequent compartment syndrome from reperfusion
- Arterial shunts can procure some time for skeletal fixation prior to definitive arterial repair or grafting.

Introduction

Severe fractures and dislocations commonly cause injury to adjacent vascular structures. Certain patterns of injury such as femoral shaft fractures injuring the superficial femoral artery, popliteal artery injury after knee dislocation, and brachial artery injury after supracondylar fracture of the humerus are frequent because of the close anatomical relationship between certain blood vessels and bones or joints.

The major determinant of outcome following arterial injury is the early recognition of the possibility of vascular damage and its prompt investigation. This can be difficult as some arterial injuries can be caused to the intima of the artery alone with no obvious external bleeding or haematoma. Initially the perfusion of the limb can appear to be normal (even pulses can be intact) with thrombosis of the artery occurring several hours after presentation of the patient. Frequent reassessment of the distal vasculature in patients with fracture patterns that often injure blood vessels is necessary to prevent late diagnosis and the risk of limb loss or loss of function.

Major veins can also be damaged either in tandem with an arterial injury or as an isolated event. Venous injury rarely requires operative intervention but does raise the risk of later deep vein thrombosis (DVT) and subsequent ongoing morbidity from post-thrombotic limb syndrome.

Mechanisms of vascular injury (Box 12.9.1)

Penetrating trauma

Penetrating injuries causing both vascular and orthopaedic injuries usually result from gunshot wounds. A low-energy transfer missile ordinarily damages a vessel lying directly in its path and bony injury may be no more than the equivalent of a ‘drill hole’ (Figure 12.9.1). On the other hand, a high-energy transfer wound with a bullet striking bone will have an impact velocity which shatters bone into fragments producing secondary missiles which cause further injury (Figure 12.9.2). A cluster of pellets from a shotgun fired at close range will produce a concentrated ‘spread’ causing large defects in soft tissue and severe comminution of bone, as well as contamination from the wadding and clothing, features which are often underestimated on superficial inspection. The vascular and bony injuries caused by shrapnel and secondary missiles in bomb explosions may be further complicated by crush injury from falling masonry.
Bullet created a 'drill hole' in lower femur, fracturing the anterior cortex, leaving the bone essentially intact, and transecting popliteal artery and veins. Reproduced from Barros D'Sa (1992).

Fig. 12.9.2

Blunt trauma

The severity of vascular injury resulting from blunt trauma—as observed following sudden deceleration in road traffic collisions, in falls, and in rail, air, and mining disasters—often exceeds that caused by penetrating agents. The shearing forces generated by violent angulation of fractures may cause sharp bony fragments to lacerate or sever adjacent vessels (Figure 12.9.3) and indirectly stretch vessel segments at points of relative fixity, causing thrombosis. In posterior dislocations of the knee, the avulsive forces involved may result in tearing of tissues and in the process the layers of the popliteal artery, beginning with the intima, disrupt progressively. The dislocated knee has a tendency to reduce spontaneously, and notoriously the vascular injury may remain unsuspected and unrecognized on examination. In such cases, damage to the collateral system around the knee joint heightens the effects of ischaemia caused by popliteal artery injury. Fractures of the tibia associated with dislocation of the knee carry a vascular injury rate approaching 40% with a high risk of subsequent amputation if the injury is not recognized immediately.

Box 12.9.1 Mechanism of vascular injury

♦ Penetrating:
  • Low velocity—vessel directly in path
  • High velocity—injury may occur from secondary fragmentation or cavitation

♦ Blunt—shear forces resulting from:
  • Dislocations
  • Fractures.
In severe type Ilc open tibial fractures a constellation of factors inevitably combine to thwart success and are responsible for quite high amputation rates. In these cases, not only is there comminution of the fracture with bone defects and periosteal stripping but also severe muscle and skin loss, nerve trauma, and contamination compounded by injury to long segments of popliteal and crural vessels as well as collateral systems.

All these features may be found in blunt arterial trauma of the upper limb. In axillary vessel traction injuries the brachial plexus is also commonly affected.

**Morphology of vascular injury (Box 12.9.2)**

A variety of vascular injuries may occur in association with fractures and dislocations. These may be injuries in continuity, partial tears, or complete tears. True traumatic spasm is quite rare and ought not to be presumed, with at least some intimal damage present in most instances of ‘spasm’, in some cases permitting flow transiently before progressing to thrombotic occlusion (Figure 12.9.4). An intimal fracture may develop into an intimal flap, which in turn may lead to dissection and intramural bleeding, and in cases where the intimal tear is circumferential, thrombosis is common. The key message for the orthopaedic clinician is never to assume that loss of a pulse distal to a major fracture is due to ‘arterial spasm’, nor to assume that if a pulse is present on initial presentation that vascular damage is completely ruled out.

**Box 12.9.2 Injury morphology**

- Partial lacerations more commonly result in exsanguination
- Complete division allows retraction and thrombosis
- Blunt venous injuries are difficult to repair
- Elderly arteriopathies are most vulnerable to complications.
A lacerated artery, is usually unable to contract and in open injuries may cause rapid exsanguination. If it seals, a false aneurysm may develop which may present with later rupture (Figures 12.9.5 and 12.9.6). Concomitant injury to the adjacent artery and vein may produce an arteriovenous fistula (Figure 12.9.7), with or without an adjacent false aneurysm. On occasions fistulae can compromise flow to a limb; or in the long-term a proximal fistula may provoke a high-output cardiac state.
When a vessel is completely transected by a missile or a shard of metal, the free ends tend to constrict, retract, and become sealed by a plug of thrombus. This process is also seen in traction injuries, such as posterior dislocations of the knee, in which the avulsive forces stretch the intima until it fractures and curls back on itself, the media and adventitia disrupt, the ends constrict, and thrombosis ensues. This does not occur in partial lacerations and can be associated with greater blood loss.

Venous injuries generally remain unrecognized until surgical exposure of an arterial injury. Those vein injuries sustained in blunt trauma do not easily lend themselves to repair.

**Pathophysiology of vascular injury**

**Ischaemia**

Arrest of arterial flow causes tissue hypoperfusion and hypoxia which, in some cases, is further compounded by hypovolaemic shock and vasoconstriction. Striated muscle has a low tolerance for continuing warm ischaemia and after 6–8h, depending on the degree of injury and availability of collateral flow, muscle death occurs.

**Ischaemia–reperfusion**

The restoration of blood flow after a period of ischaemia may cause the complex biochemical and cellular pathophysiological changes of ischaemia–reperfusion injury. Clamping or ligation of an adjacent injured main vein aggravates this process, as will the presence of associated bone and soft tissue damage (Figure 12.9.8). The extent of ischaemia–reperfusion injury is directly proportional to the severity and duration of striated muscle ischaemia. Ischaemia–reperfusion injury of a large mass of skeletal muscle has systemic implications, provoking multiple organ failure. An unrelieved rise in pressure may result in the development of compartment syndrome and ischaemic nerve damage. Again, the key point for the clinicians is not to assume that once the vascular reconstruction has been completed that everything will be fine—there is still the possibility of complications developing—particularly compartment syndrome and DVT.
Management

Initial measures

In the multiply injured patient, resuscitative measures are taken to ensure an adequate airway, satisfactory ventilation, and correction of hypovolaemic shock. In many cases the orthopaedic team may be leading a resuscitation team and will therefore need to manage arterial or venous injuries in the acute phase until a vascular surgeon arrives. Many of these complex limb injuries are obscured by splints and bandages on first arrival. External bleeding should be controlled digitally and then by means of a pad and bandage. If arterial forceps or clamps are applied incorrectly they are likely to damage both vessels and nerves in the vicinity. Tourniquets tend to be poorly applied, often in a manner which accelerates the rate of bleeding, and if left unreleased will cause irreversible tissue and nerve damage. Information from bystanders as to the nature of the wounding agent, the amount of blood lost, and the time interval since injury will help in further decision making. Tetanus toxoid, prophylactic antibiotics, as well as appropriate analgesia, should be routinely administered.

Diagnosis and assessment (Box 12.9.3)

Clinical

A number of questions have to be answered in assessing the location, degree, and extent of vascular injury accompanying orthopaedic trauma:

♦ If bleeding is continuous, is it clearly arterial or venous, or of both types?
♦ If a haematoma is present, is it expanding or pulsatile?
♦ Is there evidence of a thrill or audible bruit indicative of arterial compression or arteriovenous fistula?
♦ Are there identifiable 'hard' signs of ischaemia, namely absent distal pulses, mottling, pallor, coolness, and numbness?
♦ If there are not, are 'soft' signs detectable, namely transient ischaemia, mild neurological deficit, or a small nonexpanding haematoma? The deficit caused by coincidental nerve injury cannot be evaluated with certainty in cases of profound ischaemia

Box 12.9.3 Diagnosis

♦ Clinical:
  • Bleeding, haematoma, bruits
  • Absent pulses, ischaemia, and failure to recover following reduction

♦ Investigation:
  • Ankle–brachial index (indicates need for angiography if <0.9)
  • Duplex scans
  • Angiography
  • Standard
  • One shot on table
  • Computed tomography (CT)/magnetic resonance imaging (MRI).

♦ When signs of arterial injury are obscured in the shocked multiply injured patient, does circulatory recovery in the fractured limb lag behind its partner following resuscitation?
♦ Does reduction of the fracture or dislocation fail to restore distal flow?
♦ Even in the absence of signs of bleeding within the tissues around the knee, is there any evidence that a dislocated knee has reduced spontaneously and, if so, is there incontrovertible evidence that arterial injury is not present?

If the answers to these questions are neither clear nor unequivocal, further investigation is required.

Ultrasound

Doppler ultrasound pulse waveforms, segmental pressures, and ankle–brachial pressure indices may provide an early assessment of the presence of vascular injuries particularly in cases of blunt trauma, but should not be relied upon to definitively exclude injuries. In open injuries ultrasound is usually impractical.

Angiography
Angiography either delineates an arterial injury or excludes its presence (Figures 12.9.9 and 12.9.10). In the latter case it gives the surgeon the confidence not to intervene, preventing unnecessary exploration. When clinical signs are equivocal, angiography is advisable. The medico-legal consequences of missing an arterial injury leading to subsequent limb loss are obvious. Angiography is of particular importance in blunt injuries which cause instability or dislocation of the knee, sometimes in association with displacement of a fracture close to the knee. Even when distal pulses are palpable, the chance of an occult arterial injury going on to occlusion and loss of the limb remains, and therefore this condition demands a policy of routine angiography.

**Fig. 12.9.9**
Angiogram reveals some spasm in an otherwise intact brachial artery in relation to a midhumeral fracture.

**Fig. 12.9.10**
Blunt injury with fractures of upper tibia and fibula with consequent distortion and spasm of the anterior tibial artery, high-grade stenosis of the tibioperoneal trunk (upper arrow), virtual occlusion of peroneal artery at its origin (lower arrow), and a patent posterior tibial artery. Reproduced from Barros D’Sa (1992).

If angiography is likely to be delayed and an arterial injury is suspected clinically, it may be preferable to take the patient to the operating room and perform a one-shot single-plate on-table angiogram followed by urgent repair of the arterial injury. Timely angiography may also prevent disaster in cases of persistent ischaemia after reduction of a fracture, especially in the elderly atherosclerotic patient. Many hospitals now have facilities for CT or MRI angiography. The advantage of these modalities is that, particularly CT angiography, may be obtained quickly and allow for some visualization of the bone and surrounding soft tissue. If clinical doubt exists despite imaging that does not show an injury then meticulous and repeated clinical examination should be performed and, if necessary, surgical exploration to resolve any doubt of arterial injury.

**The critical importance of time**

In injuries involving fractures and vascular trauma it is important to abbreviate the period of ischaemia and minimize ischaemia–reperfusion injury following arterial repair. Control of bleeding, resuscitation, and surgical treatment should be overlapping rather than sequential stages of management. Life-threatening injuries of the head, chest, and abdomen naturally deserve priority, but delay in dealing with limb vessel trauma may result in a poor outcome. Even if the complex vascular injury is isolated to a leg, surgical intervention still requires adequate time for exposure, wound care, bone fixation, and repair of artery and vein.

Time pressure, should not progress to rushed surgical practice. Wound care and cleaning should be performed correctly and all
repairs, be that of the vessels or damaged bones carried out meticulously. Stabilization of a fracture prior to repair of injured vessels deserves consideration. Some of the pain is relieved, movement of loose bone fragments ceases to injure the vessels and soft tissues, optimal lengths of graft are used to repair the vessels, and confidence is instilled by the knowledge that artery and vein repair will remain secure from disruption. However, this sequence of surgical action delays restoration of flow and correspondingly has an impact on the degree of ischaemia–reperfusion injury.

This time pressure may be relieved by using shunts for both artery and vein on exploration of the wound. The arterial shunt restores perfusion, minimizes ischaemia–reperfusion injury, and reduces compartment pressure. The venous shunt re-establishes drainage and further helps to prevent a rise in compartment pressure.

Initial operative steps

Standard longitudinal incisions are employed for access to vessels of the upper and lower limb. A posterior gentle S-shaped incisional approach to the midpopliteal artery is acceptable in some penetrating injuries. In the case of blunt trauma associated with instability of the knee, a medial approach, accepting some compromise to the integrity of the knee, is preferable. The injured vessel is controlled first by digital pressure and then by suitable vascular clamps applied to segments exposed on either side of an artery and vein injury. The damaged vessel must be adequately excised to leave pristine ends for suture. The proximal artery is released to flush out thrombus and a balloon catheter is used to retrieve clot from the distal vessel, a process which can be assisted by milking the limb upwards, especially when surgery is delayed. Heparinized saline (20IU/mL) is then perfused into the distal limb.

Operative discipline centred around shunting

Arterial and venous shunting

An indwelling shunt in a transected femoral or popliteal artery (Figure 2.9.11) immediately restores flow, buying valuable time for precise operative work. An outlying shunt should be considered for an extensive wound within which lengthy segments of vessel have been destroyed (Figure 2.9.12). An indwelling venous shunt in a severed adjacent vein (Figure 12.9.11) re-establishes venous drainage and will also discourage thrombosis. If the vein is simply clamped, an acute and unacceptable rise in compartment pressure will occur, invariably necessitating fasciotomy. In some multiply injured patients, the vascular surgeon, working alongside other specialists involved in life-saving surgery in the head or torso, may be able to place shunts in vessels in wounds of a lower limb, assuring its survival until definitive vascular repair some time later. A range of shunts are available and the surgeon should choose one which with they are familiar.

Fig. 12.9.11
Intravascular shunts: Brener shunt in torn popliteal artery (above) and Javid shunt in transected popliteal vein (below) preparatory to vein graft replacement of each vessel. (Reproduced from Barros D’sa (1988).)
Wound care

The placement of shunts allows for ample time to survey the wound, identify nerve injury, remove debris, and irrigate the tissues. Restored arterial and venous flow provides sharper and more reliable demarcation between dead and viable tissue. Meticulous excision of nonviable tissues and debridement is especially essential in high-energy injuries. Free bone fragments and foreign bodies are removed, followed by copious irrigation, particularly in open contaminated wounds, a process which is of value in significantly lowering the concentration of the bacterial inoculum.

In the critically injured but neurologically intact limb (Figure 12.9.13A) restoration of flow by means of shunts (Figure 12.9.13B) will assist the surgeon in coming to a decision as to whether primary amputation may be more sensible than an attempt at major reconstruction.

Bone fixation

The use of long intravascular shunts in artery and vein (Figure 12.9.13B) will provide the necessary slack for the liberal manipulation of the bone fragments. At this stage the orthopaedic surgeon proceeds to restore skeletal integrity. He is under no pressure to compromise technique and will be guided solely by a desire to achieve the best possible orthopaedic outcome.

Arterial repair

Minor arterial injuries identified preoperatively may be amenable to treatment by endovascular means allowing the orthopaedic surgeons to proceed with bone stabilization in the presence of treated vascular injuries. Most injuries will not be suitable for endovascular repair in the trauma environment and will require open surgical repair. A variety of techniques may be employed by the vascular surgeon with the guiding principle of restoring both arterial and venous integrity in as many cases as possible. In lower limb injuries vein for repair should be harvested from the contralateral limb, particularly if there is damage to the deep venous system of the affected limb. If concomitantly injured artery and vein have not been shunted, the artery should be repaired first. If both vessels have been shunted, the order of repair is entirely immaterial.

Vein repair

It is worth remembering that repair of a damaged vein not only renews free venous drainage but also enhances the patency of an adjacent arterial repair. Moreover, the likelihood of thrombosis, oedema, and chronic venous insufficiency is minimized. In a very small number of cases the development of limb-threatening venous gangrene is averted.

Wound closure

Vessel cover

The success of a vascular repair is dependent on achieving satisfactory vessel cover and the elimination of dead space by viable adjacent soft tissue and muscle. As shunting will have provided ample time for proper wound care at an earlier stage, some reliance can be placed on the quality and viability of tissue surrounding a completed vascular repair. If adequate soft tissue is not preserved to enable the repaired vessels to be covered then a superficial muscle such as the sartorius or gracilis may be freed with its blood supply intact and swung over to ensheathe the repaired vessels. If that is not possible, then the skills of a plastic surgeon
may have to be sought and free vascularized musculocutaneous flaps used to cover artery and vein repair and exposed bone. The construction of an extra-anatomic vein bypass through clean viable tissue may eliminate the need for these measures in some cases.

**Fasciotomy**

The adjunctive use of shunts in injured artery and vein limits the extent of ischaemia–reperfusion injury and its consequences, and reduces the necessity for fasciotomy.

Certain compartments are particularly vulnerable to short periods of raised compartment pressure; these include the muscle compartments of the forearm and hand in the upper limb, and the anterior compartment in the lower leg which lies within rigid osseous and fascial boundaries.

When shunts are used in managing complex vascular injuries the need for fasciotomy is reduced. There will of course be a percentage of patients who will require fasciotomy even when shunts have been used. If restoration of blood flow is delayed or fasciotomies are deemed necessary, then the procedure should be performed early as this will be beneficial to the residual collateral circulation. There may be occasions when this should be considered prior to the definitive vascular repair. If fasciotomy is delayed and tissue of tenuous viability (due to the ischaemia or trauma) is exposed, the chances of infection are high.

<tr>
<td>♦ If fasciotomy necessary, perform early.</td>
</tr>
</tbody>
</table>

The clinician must repeatedly evaluate the need for fasciotomy before, during and after the vascular repair. Assessment should be based on clinical findings and, where necessary, compartment pressure monitoring.

**Postoperative care**

Early haemorrhage after surgery usually arises from debrided tissues or from a gap in vascular repair. Thrombotic occlusion and secondary haemorrhage are the two most common complications of vascular repair (Box 12.9.5). The latter is likely to occur as a sequel to a scenario of insufficient vessel cover and infection within inadequately debrided tissue. An extra-anatomic vein graft should be considered in this situation.

<table>
<thead>
<tr>
<th>Box 12.9.5 Postoperative problems</th>

<tr>
<td>♦ Suture line</td>
</tr>
<tr>
<td>♦ Graft too short</td>
</tr>
<tr>
<td>♦ Graft kinked.</td>
</tr>
</tbody>
</table>

Close monitoring of pulses, Doppler ultrasound pulse waveforms, and pressures will provide warning of deterioration in arterial flow. Vigilance is required in anticipating complete thrombotic occlusion of a vessel repair. If flow is impaired and graft failure is suspected, angiography must be undertaken urgently and the vascular repair revised. The defects which can be expected to lead to graft failure include constriction at the site of lateral suture, purse-string constriction of a direct anastomosis, inadequate excision of damaged vessel, anastomotic tension when the vein graft is too short, or slackness and kinking when it is too long. These last
two problems are more likely to occur when vessel repair precedes bone fixation.

In isolated limb injuries, low-dose heparin may be of value in aiding graft patency and also in preventing DVT. It may be contraindicated in the multiply injured patient.

**Summary**

The challenge of combined vascular and orthopaedic injury must be faced in the knowledge that a number of complications including amputation may occur, but these can be minimized by prompt intervention. Diverse factors play a role in achieving good results, namely early recognition of arterial injury, if necessary defined by angiography, a methodical approach to operative technique, often best formulated around the use of indwelling shunts in both injured artery and vein, diligent care of the wound, stabilization of bone before vascular repair, liberal use of interposition vein grafts including compound vein grafts of suitable calibre when necessary, timely and effective fasciotomy, and a willingness to revise repair in the event of failure.

Chapter: Limb salvage versus amputation

Author(s): Gregory M. Georgiadis

DOI: 10.1093/med/9780199550647.003.012010

Summary points

♦ The decision to attempt limb salvage or amputate is difficult and depends on many factors
♦ Scoring systems provide guidelines only and not absolute treatment mandates
♦ Severe limb trauma results in a high degree of self reported disability regardless of treatment
♦ These injuries are best managed by a multidisciplinary approach.

Introduction

In the modern era there has been an increase in the incidence of severely traumatized extremities, often associated with open fracture and/or vascular injury. These injuries are now a leading cause of hospitalization among young adults. Most are due to motor vehicle related or industrial accidents or falls from heights. Military injuries are also increasing as well with recent conflicts in Iraq, Afghanistan, and other locations. With advances in surgical principles and techniques, many severely injured limbs that could previously be treated only by amputation can now be saved. However, these salvaged limbs are never normal. Almost all patients have some element of chronic pain. Others may have deformity, chronic infection, and many have a non-functional extremity or even require a late amputation. Financial, medical, social, and psychological problems due to prolonged and extensive treatments can also occur. Thus there is great interest in defining which injuries should have attempted limb salvage.

Recently the Lower Extremity Assessment Project (LEAP) completed a multicentre, prospective outcome study of 601 patients in the civilian population of the United States of America with high-energy lower extremity trauma (Box 12.10.1). This study group followed patients for as long as 7 years.

Box 12.10.1 Leap project

♦ The Lower Extremity Assessment Project (LEAP) was a recent large prospective outcome study of patients with high-energy lower extremity trauma
♦ Patients were followed up to seven years
♦ Multiple published studies were generated.

The severely damaged limb: defining the injury

The initial assessment of a severely injured extremity is based on a description and subsequent classification of the associated open wound. This is not an exact science, and clinical descriptions of open wounds may not always be accurate or reproducible. The Gustilo grading system is the most widely used method for describing open fractures in North America. However, studies have shown that the interobserver reliability of this system is only moderate, and that it alone may be inadequate for treatment decisions or comparison of published results.

The soft tissue injury is a key component of any high-energy extremity fractures (Box 12.10.2). However, the true nature and extent of the soft tissue injury after high-energy trauma is often not readily apparent from the outset. Frequently serial debridement over 2 or 3 days reveal the true extent of the injury (Figure 12.10.1). Despite the recognition that the nature and extent of the soft tissue injury has the greatest impact on the decision to attempt limb salvage or amputation, it still remains one of the most difficult aspects to reliability assess.
Surgeons can encounter lower extremities where the bone and soft tissues are so injured that the prognosis for salvage becomes questionable. The term ‘mangled extremity’ has been used to describe these limbs (Figure 12.10.2).

The mangled extremity is defined as one in which three of the four organ systems (skin, bone, vessels, muscle) have been severely injured. Further expansion of this definition is presented in Table 12.10.1.

<table>
<thead>
<tr>
<th>Table 12.10.1 Definition of the mangled lower extremity</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 Severe injury to three of four major organ systems (skin, bone, nerve, vessel) in the same extremity</td>

<tr>
<td>2 Severe injury to two of four organ systems in an extremity, when the area of skin and muscle loss is greater than the circumference of the extremity and requires a free tissue transfer</td>
</tr>
<tr>
<td>3 Severe injury to two, and minor injury to the other two, organ systems in an extremity, requiring surgical intervention</td>
</tr>
<tr>
<td>4 Severe injury in two of four organ systems in an extremity, with greater than 5cm of bone loss and periosteal stripping</td>
</tr>
</tbody>
</table>

The prototype for the mangled lower extremity is the Gustilo type III open tibia fracture. During treatment these injuries have numerous complications and problems. Rates of secondary amputation, deep infection, and non-union of 17%, 29%, and 43%, respectively, for grade IIIB open tibia fractures have been reported. For type IIIC injuries, these same figures increase to 78%, 57%, and 100%.

Severe open tibia fracture with vascular injury requiring revascularization may be an indication for an early amputation. However, modern surgical techniques now allow many severely damaged limbs to be saved. For example a 93% salvage of type IIIC open fractures has been achieved in one study.

Box 12.10.2 Soft tissue injury

- The soft tissue injury to the damaged extremity remains one of the most difficult aspects to reliably assess
- Gustilo grading system not reliable
- The true nature of the soft tissues may not be initially apparent.

Indications for amputation after lower extremity fractures

In a patient with severe lower extremity trauma, the physician strives to restore the following:

- A painless leg
- Bony union
- No infection
- Equal limb lengths
- Protective sensation.

Frequently, however, in the mangled extremity all these goals cannot be attained. Prolonged warm ischaemia time, irreparable nerve injury resulting in an insensate limb, extensive crush injury, entrapment, limb avulsion or traumatic amputation, and multiple trauma with other life-threatening injuries are all indications for acute amputation (Box 12.10.3).

Extensive comminution and bone loss of more than 6-8cm, especially when combined with soft tissue loss, has also been considered an indication for amputation. Although a difficult and tedious procedure, local bone transport using distraction histogenesis is now being increasingly used to salvage these extremities. This technique not only restores bone loss, but helps unite non-unions, equalizes limb-length discrepancies, corrects angulatory deformities, and increases vascularity which is helpful in controlling osteomyelitis. Using these methods successful salvage of 11 of 12 patients with an average bone deficit of 12.5cm has been reported in one clinical study.

Precise indications for amputation or attempted salvage are difficult to define. Indications for primary amputation after open tibia fractures with vascular injury are as follows:

- Absolute indications: includes anatomical transection of the posterior tibial nerve and prolonged warm ischaemia time of over 6h
- Relative indications: include serious polytrauma, severe ipsilateral foot trauma, or an anticipated prolonged soft tissue or bony reconstruction.

Although these recommendations are generally accepted, there have been no follow-up studies to specifically verify them. The insensate foot was previously considered a major factor in considering whether to proceed with amputation or reconstruction. However, the LEAP study group have shown that initial plantar sensation is not prognostic of long-term outcomes. At 2-year follow-up after limb salvage, most patients initially reported as having insensate feet regained sensation (Box 12.10.4). The extent of the injury to the posterior tibial nerve can therefore not be reliably assessed at the time of injury. Nerve exploration is usually not indicated as it further damages the soft tissues.

Several clinical scoring systems have since been developed (Box 12.10.5). Their aim is to aid in the early decision-making on whether to proceed with attempts at limb salvage or to amputate the severely injured lower extremity.

Clinical scoring systems

A number of different scoring systems have been developed. One of the first was the Mangled Extremity Syndrome Index (MESI). All these systems have resulted from retrospective reviews of relatively small numbers of patients. Others include the Predictive Salvage Index, the Mangled Extremity Severity Score (MESS), the Limb Salvage Index (LSI), and a modification of the MESS score, the NISSSA (for nerve injury, ischaemia, soft tissue injury, skeletal injury, shock, and age of patient). Recently, the Ganza Hospital Score (GHS) has been developed in India.

Each predictive scale attempts to quantitate the injury to the various organ systems of the extremity (skin, bone, nerve, vessel) by assigning a numerical score depending on the severity of the trauma. Some also include other factors like age, shock, and comorbid conditions.
Box 12.10.3 Amputation indications

- Long warm ischaemia time
- Irreparable nerve injury
- Extensive crush
- Limb avulsion or traumatic amputation
- Multiple traumas
- Severe ipsilateral limb trauma.

The MESI was developed from a retrospective review of five patients with upper-extremity injuries and 12 patients with lower-extremity injuries. It was recommended that a score of below 20 should have limb salvage attempted. The MESI requires a thorough knowledge of the patient's history and injuries.

Box 12.10.4 The insensate foot

- An insensate foot on initial examination is not an indication for amputation
- Many patients without plantar sensation at presentation regain sensation and have satisfactory limb salvage.

The LSI was developed from a retrospective review of 67 patients. An LSI of 6 or less was associated with successful limb salvage in 51 patients.

Both the PSI and the MESS scoring systems are less complicated than the MESI or LSI. In a retrospective review of 21 patients with pelvic and lower-extremity trauma, a PSI of less than 8 was compatible with a successful limb salvage.

The MESS score is perhaps one of the most referenced scoring systems. A MESS score of less than 7 was highly predictive of a successful limb salvage in a retrospective review of 26 patients.

The MESS score was used retrospectively to review 152 patients with 164 severely injured lower limbs. All cases with a MESS of 7 or more required amputation. A MESS of less than 7 was present for all salvaged limbs. However, many patients with a MESS of less than 7 also required amputation. Robertson felt the MESS was specific, but not sensitive, in predicting the need for a lower-extremity amputation after trauma.

In a retrospective study of 43 upper-extremity injuries, the MESS was found to have a 100% specificity, sensitivity, and positive and negative predictive value. This system was felt to be an early and accurate predictor of which upper extremity should be treated by amputation. The MESS was recently used in a combat setting and found to be useful.

The MESS score was modified to produce the NISSSA. In a retrospective review of 24 patients the NISSSA was more sensitive and specific in predicting amputation than the MESS.

The MESI, MESS, PSI, and LSI were analysed in a retrospective review of 58 limb salvage attempts over a 10-year period at a single institution. None of these four indices had the sensitivity or specificity required to predict limb salvage. The exact time to utilize a limb salvage index is unclear. The initial evaluation in the emergency department may be different from that in the operating room. Some information (patient age, comorbid conditions, exact time of injury, the true nature of the neurovascular injury, and many other pertinent factors) may only be available postoperatively. In addition, the degree of crush injury to the limb may be more apparent after several days than at the initial evaluation. It has been suggested that limb salvage scores may be most useful in early postoperative decision making.

The LEAP study group performed a prospective study to evaluate the use of clinical scoring systems to assist in the decision makeup process for limb salvage or amputation. The MESS, LSI, PSI, NISSA and Hannover Fracture Scale 97 (HFS 97) were studied in 556 lower extremity fractures. The study did not validate the utility of any of the lower extremity injury scores as absolute predictors of amputation.

Box 12.10.5 Clinical scoring systems

- Both retrospective and prospective studies fail to support the validity of any scoring system as an absolute predictor of amputation or salvage
- Scoring system are best used as helpful guidelines, not a mandate.

In summary, despite persistent interest, scoring systems provide only helpful guidelines, not absolute mandates. The final decision for salvage versus amputation still rests with the clinical impression of the treating surgeon.
The timing of a traumatic extremity amputation

The initial decision to proceed with amputation or limb salvage is based on the surgeon’s experience and available resources. The injured patient is often not able to make an informed decision and the extent of the injury may not be readily apparent.

Retaining an obviously necrotic or gangrenous limb can lead to higher morbidity and mortality. In one study forty-three patients with amputations after grade III open tibia fractures were reviewed; delayed amputations had increased incidence of sepsis, death, disability, operative procedures, and costs.

Earlier amputation and prosthetic fitting can be expected to result in shorter hospital stays, fewer surgical procedures, lower infection rates, and lower initial costs. Better rehabilitation and return to work occurs in patients who have amputations within 1 month of injury than those who had delayed procedures.

Emergency amputations have a higher incidence of anatomical stump problems than delayed amputations (57% versus 37%), and secondary amputation after limb salvage attempts probably does not compromise the final outcome.

If the initial decision to proceed with limb salvage is made, but the viability of the extremity remains questionable, the use of limb salvage scales has been useful for some authors. Rates of secondary amputation after initial attempts at limb salvage have been reported to be as low as 4% in series of 177 microsurgical free tissues transfers. Reported failure rates in other studies have ranged from 9–40%.

Timing of reconstructive procedures for limb salvage

Reconstruction begins after the initial debridement. The precise timing and type of procedures can vary widely. In general, early soft tissue coverage decreases infection rates. Subsequent staged procedures to achieve bony union are typically needed (Box 12.10.6).

Microsurgical free tissue transfers have lead to high rates of soft tissue coverage of open wounds. For the most severe injuries there may even be less wound complications using free flaps than rotational flaps. Nevertheless, these procedures are very labour intensive, and require close cooperation with microvascular surgeons.

There has been a renewed interest in local fasciocutaneous flaps for lower extremity trauma. In addition, negative pressure therapy (vacuum-assisted wound closure) has now begun to be used for high-energy soft tissue injuries. Both these developments have lead to a decreased need for microvascular free tissue transfer in some patients with large traumatic wounds.

Box 12.10.6 Limb reconstruction strategies

- Immediate internal or external fixation and early soft tissue coverage
- Increased use of local flaps, negative pressure therapy in addition to free flaps
- Staged procedures to achieve bony union likely.

In a polytrauma situation, provisional external fixation (‘damage control’) may be appropriate. Staged reconstruction can then follow once the patient’s condition stabilizes. Prolonged used of external fixation, however, may be associated with increased complications.

The ‘fix and flap’ concept has been developed for treatment of severe open tibia fractures. This involves radical debridement followed by immediate internal fixation and soft tissue coverage. The final limb salvage rate in one series was 95%.

Outcome measures

In the past, outcomes were often measured by specific physician defined parameters: bony union, absence of infection, and final salvage of the extremity. Today patient perceived outcome parameters are just as important. This has lead to increased interest in health status and quality of life assessments.

Specific evaluation scales can either be disease specific or general measures of overall health. The SF–36 Health Status Profile takes about 10min to complete and is a popular health status questionnaire. The Musculoskeletal Functional Assessment (MFA) has been specifically developed for patients with musculoskeletal disorders. The Sickness Impact Profile (SIP) involves 136 statements about functional status in 12 categories. The SIP has been extensively used in outcome studies for lower extremity fractures, including all of the studies in the LEAP project.

Current challenges include selecting and evaluating outcome measures so that research and clinical studies can be adequately compared. There is no consensus on the best outcome studies to use; over 200 general orthopaedic musculoskeletal outcome measures are currently in use.

Outcomes of amputation versus limb salvage
Young adults after a traumatic amputation below the knee can be expected to be functional when fit with a prosthesis. Employment rates of 50% have been noted in several studies.

How do these patients compare long term with a severely damaged limb that has been salvaged? Some small, retrospective studies found no significant differences, and in fact noted that amputees seemed to fair slightly better. Other series reported opposite results. Patients with foot and ankle injuries can be expected to have poorer salvage outcomes.

A major advance in our understanding of the outcomes of limb salvage or amputation has come from the LEAP study. This was a large, multicentre, prospective study of 569 patients in the United States of America. At 2 years there were no significant differences between the amputation and reconstruction groups. These results were maintained at 7 years. The SIP was the major outcome measure in this study. Outcomes did not improve over time. In fact physical and psychosocial function tended to deteriorate. Significantly poor outcomes were seen in patients who were older, female, non-white, as well as those who smoked cigarettes, had low self efficacy, lived in a poor household, had a lower education level, or were involved in litigation.

Rehospitalization for major complications, foot amputation and severe soft tissue trauma were also poor prognostic factors. Using different outcome measures for quality of life, similar results were noted in a group of patients from the Netherlands. Successful limb salvage patients in this series had more complications and required more operative intervention. Complications were most commonly related to problems with bone healing.

The LEAP study also provided information on outcomes after lower extremity amputations at different levels above the ankle. As expected, below the knee amputees had better timed walking speeds than above the knee amputees. However, there were no significant differences in the SIP scores between these two groups. Patients with an amputation through the knee however had significantly worse SIP scores.

In a meta-analysis of the recent literature, it was found that limb salvage and amputation patients had roughly similar lengths of initial hospital stay. However, limb salvage was associated with much longer rehabilitation and increased early cost. Limb salvage has higher rates of rehospitalization, more surgical procedures, and higher complication rates.

Lifetime costs of reconstructing a limb may be less than amputation. The long-term costs of an amputation in the Swiss healthcare system are nearly twice that of reconstruction if the financial impact of pensions and prostheses were considered. The costs of limb salvage using Ilizarov techniques were compared with amputation. The projected costs of a lifetime supply of prosthetic equipment exceeded the estimated cost of the Ilizarov reconstruction. The costs at 2 years between amputees and limb reconstruction are about equal, but lifetime cost for amputees are projected to be three times higher.

Reports of pain after limb salvage or amputation are difficult to interpret. Some studies show no significant differences between the groups. Others have noted more pain in limb salvage patients, while a number note more pain in amputees. So although many amputees can have chronic phantom and stump pain, limb reconstruction patients also appear to have a significant issues with chronic pain.

Employment rates appear to be similar in both groups. About half of the injured patients can be expected to return to work regardless of which treatment method was chosen. In the LEAP study, 53% of patients with an amputation and 49% with limb reconstruction return to work at 2 years.

**Box 12.10.7 Outcomes**

- Both amputees and limb salvage patients have a much higher incidence of self-reported disability than age matched controls.
- Rates of pain, employment, and many outcome measures are similar in both groups.

**Traumatic upper-extremity amputation and replantation**

A patient’s response to a unilateral upper-extremity amputation can be quite variable, and can depend on societal influences.

However, the loss of a significant part of the upper extremity is generally considered more disabling than loss of a lower limb. A sensate salvaged upper extremity can be expected to function better than a prosthesis. Therefore the revascularization or replantation of an upper-extremity injury is usually desirable.

The best indications for replantation include sharp or guillotine amputations of the arm, forearm, or hand. Limb salvage rates of greater than 80% have consistently been reported in these situations. Mangled or crushed extremities can be expected to have much lower salvage rates. Single-digit replantation remains controversial, but thumb, multiple digit, or mid-palm amputations are indications for replantation.

The first successful replantations of digits, hands, and upper extremities were reported in the 1960s. Since then there has been an increasing realization that a viable but non-functioning limb may often be unsatisfactory to many patients. To date, however, there are no standardized methods to measure outcomes.

Functional recovery has been divided into one of four groups which included criteria on ability to work, range of motion, sensory recovery, and muscle power: An overall good to excellent functional recovery can be achieved in 60% of cases.

A very detailed 100-point grading system has been developed which includes range of motion, activities of daily living, sensory recovery, subjective symptoms, cosmesis, subjective satisfaction, and employment status. Good to excellent results were reported.
in 72% of the patients. Using a modified Tamai grading system, Ipsen et al. had a 47% rate of good to excellent results in long-term follow-up of their upper-extremity replantations and revascularizations.

**Summary**

The severely injured extremity cannot be expected to ever recover normal function. Modern techniques of vascular repair, local tissue transfers, negative pressure therapy, and free tissue transfer can provide reliable soft tissue coverage in many cases. Staged procedures to restore bony continuity are typically needed. Many severely damaged limbs can now be saved. Deciding which extremities should have attempted salvage remains extremely difficult. Predictive scoring scales can be very helpful in this area, but do not represent absolute mandates or replace the clinical judgement of the surgeon.

These injuries are best managed by a team approach. Close supervision of the entire treatment process, including surgery and subsequent rehabilitation, which can be expected to improve the final result. A salvaged extremity in and of itself does not necessarily yield a successful result. Much more emphasis is now being placed on final long-term function, patient satisfaction and quality of life, and return to useful employment.

In summary, patients with limb threatening lower extremity injuries have a high incidence of self reported disability no matter how they are treated. Long-term functional results of up to 7 years show no significant differences between lower extremity limb salvage and amputation. Reports of pain as well as rates of employment are similar. Certain clinical (rehospitalization for complications, associated foot and ankle trauma, severe soft tissue injury) and psychosocial factors (poor education, poverty, older age, female sex, lack of insurance, smoking, litigation, low self efficacy) can negatively effect outcomes.

Thus, amputation may remain the best solution for some mangled limbs despite modern reconstructive advances. It should not be considered a failure, but rather another treatment option.

Functional bracing

Summary points

- Inexpensive
- Avoids complications of internal fixation
- Allows mobilization of joints
- Weight bearing and movement as tolerated, guided by pain.

Introduction

During the past five decades, considerable progress has been made in the surgical treatment of a number of fractures, so much that many non-surgical modalities have been rendered obsolete and replaced by more effective surgical approaches. The most obvious examples are the fractures of the hip, and the femoral shaft. Rarely, are these fractures treated non-surgically.

Despite such progress, surgical treatments have their limitations and the potential for anatomical reduction is not necessarily synonymous with excellent clinical results. In some instances, complications such as infection are difficult to overcome. Plate and external fixators that rigidly immobilize fracture fragments can delay healing, because the osteogenic stimulus of interfragmentary motion is absent. In addition, the cost of surgical treatment is in many cases a great deal higher than that of conservative treatment.

It must be concluded that a rational balance between the two therapeutic approaches is essential for the best way to deal with specific clinical conditions.

Functional casting or bracing of certain long-bone fractures is a relatively new approach to care. It is a philosophy of management predicated on the premise that immobilization of fractured long bones and their adjacent joints is unphysiological and detrimental to healing, and that physiologically induced motion at the fracture site enhances osteogenesis. This premise does not fail to recognize that immobilization of fractures is often desirable, and in many instances the best means to achieve healing, while providing final acceptable cosmesis and limb function.

Our initial techniques for functional casting and bracing of fractures have undergone major change over the years, and have proven to be inappropriate in the care of many fractures such as metaphyseal and diaphyseal femoral fractures where internal fixation is more appropriate. Bracing of fractures of both bones of the forearm was practically abandoned because the implementation of the technique was difficult and the maintenance of reduction was often impossible. However, some profitable lessons were learned in the process, such as the realization that closed oblique or comminuted fractures of both bones if simply appropriately aligned, maintain the initial, usually acceptable, shortening without synostosis, while permitting unencumbered motion of the elbow and wrist. In addition it provided information regarding the ultimate limitation of motion that accompanies various degrees of angular deformity.

Bracing of diaphyseal tibial, humeral, and isolated ulnar fractures has been proven highly successful in most instances.

The diaphyseal tibial fracture (Box 12.11.1)

Functional casting and bracing offers good results in the vast majority of closed axially unstable diaphyseal tibial fractures that experience, at the time of the injury, an acceptable degree of shortening and an easily correctable angular deformity. Transverse fractures can also be managed in this way when a stable reduction can be manually obtained. These criteria were established upon recognition that the vast majority of closed fractures initially suffer less than 0.5cm of shortening. This degree of final shortening is inconsequential from the physiological, functional, and aesthetic point of view. Through clinical and laboratory investigations we have proven that the initial shortening does not increase with the introduction of graduated weight-bearing ambulation. Beyond those criteria, tibial fractures with intact fibula that demonstrate initial varus angulation should not be braced because of the likelihood of increased deformity.

Diaphyseal tibial fractures that are to be treated by non-surgical means are best stabilized initially with a well-padded above-the-knee cast that extends from below the groin to the base of the toes. The knee joint is flexed to approximately 7–10 degrees. Further knee flexion to prevent weight bearing is not necessary as additional shortening does not increase in the case of closed tibias. If there is significant swelling at the time of the first evaluation of the patient, or additional swelling is anticipated because of the severity of the injury, a circular cast is not advisable. A posterior splint may be used or the posterior half of the bivalved above-the-knee cast. The ankle joint is best held at 90 degrees of flexion. Forceful dorsiflexion should be avoided in order to prevent the development of recurvatum deformity at the fracture site. The limb should be elevated at rest and observed for compartment syndrome. The functional cast may be applied as soon as the acute symptoms subside, which in most instances occurs within the first 2 post-injury weeks. To apply it while the leg is still painful is an unwarranted and unnecessary experience. On the other hand, postponing its application until ‘early callus’ is seen on radiographs is also a misguided and erroneous practice. By the time callus is seen on the tibia, the faster healing fibula is likely to be solidly healed, creating a situation similar to that of an acute tibial fracture with an intact fibula, leading to the development of angular varus deformity.
If the cast is to be used in preference to the brace, it is best to postpone its application until the swelling has decreased to a greater degree, simply because the circular cast lacks the adjustable features to accommodate the reduction of swelling and limb atrophy that the brace possesses.

### The application of the below-the-knee functional cast

The functional cast, mistakenly called a PTB (patellar tendon bearing) cast because it resembles the moulding of the PTB prosthesis worn by the amputee, is applied in three stages.

1) **First stage**: following the removal of the above-the-knee cast the patient must sit on a high table with the hip, knee, and ankle joints at 90 degrees. Both legs are exposed to facilitate reproduction of alignment. Stockinette and a thin layer of cotton wadding are applied. The cast can be applied without padding, but requires greater care during its removal. Plaster of Paris or synthetic material is used. The cast is moulded around the ankle which is held at 90 degrees of dorsiflexion. A recurvatum deformity at the fracture site can develop with excessive dorsiflexion (Figure 12.11.1A). It is not necessary at this time to pay attention to alignment or rotation of the fragments.

2) **Second stage**: when the casting material begins to set it is firmly wrapped over the leg overlapping the portion of the cast over the ankle and extending to just below the tibial tuberosity. It is during this time that exposure of the normal leg is essential in order for the surgeon to duplicate the shape of the normal leg in the fractured one. The surgeon corrects any angulation or rotation seen during the above-the-knee cast stage. The soft tissues of the extremity are firmly moulded with particular attention being paid to the compression of the sub-popliteal space and the medial tibial condyle (Figure 12.11.1B).

3) **Third stage**: the cast is then extended over the femoral condyles with the knee at approximately 45 degrees of flexion and heel resting on the surgeons lap. This allows the quadriceps to relax in order that the patellar tendon can be firmly compressed as the material begins to set. The compression of the patellar tendon is not done in expectation that this soft tissue structure will become a weighty bearing area. The compression is performed only to facilitate posterior counter pressure of the subpopliteal calf (Figure 12.11.1C).

### Box 12.11.1 Diaphyseal tibial functional casting/bracing

- Suitable for transverse fractures
- Suitable for axially stable fractures
- Suitable when there is an acceptable degree of shortening on the initial x-rays
- Not suitable when fibula is intact with varus angulation
- Convert to functional cast/brace when swelling and acute symptoms subside (usually within 2 weeks)
- Benefit of motion at the tibial fracture site before ulna unites.

3) **Third stage**: the cast is then extended over the femoral condyles with the knee at approximately 45 degrees of flexion and heel resting on the surgeons lap. This allows the quadriceps to relax in order that the patellar tendon can be firmly compressed as the material begins to set. The compression of the patellar tendon is not done in expectation that this soft tissue structure will become a weighty bearing area. The compression is performed only to facilitate posterior counter pressure of the sub-popliteal calf (Figure 12.11.1C).

The freedom of the knee joint is made possible by trimming the proximal cast (Figure 12.11.1D). Anteriorly, to just above the proximal pole of the patella; laterally, as far posteriorly as possible without impinging on the hamstring tendons; posteriorly, at a point opposite the tibial tubercle. The completed trimming should make possible full flexion and extension of the knee (Figure 12.11.1D).
Once the casting material has dried, ambulation with the aid of a walker or crutches may begin. Symptoms should dictate the degree of weight bearing. It is increased gradually.

**Application of the below-the-knee functional brace**

The surgeon might prefer to askew the functional cast, and go directly to the functional brace. The appropriate timing for its application is the same used for the application of the functional cast. That is, evidence of subsidence of acute pain and disappearance of significant swelling distally. If applied before these criteria are met, undesirable discomfort and persistence of distal oedema will result.

The brace can be custom-made or prefabricated. It extends from the level of the proximal pole of the patella and extends to just above the ankle. It must be held firmly in place against the soft tissue with Velcro straps (Figure 12.11.3A,B).

---

**Fig. 12.11.3**
A) The prefabricate brace illustrating the attached and removable distal ankle insert. B) The brace has two shells, which are held in place in order to permit their separation and to slide the components over the ankle without creating pain. C) Brace should allow full flexion and extension of the knee and ankle.

The brace is applied with the patient sitting on a high table, holding the hip and knee at 90 degrees of flexion. The functional brace is fitted over a layer of stockinette. The completed brace should allow full flexion and extension of the knee and ankle. If this is not possible because the brace is too long, the proximal or distal ends of the shells can be trimmed down with scissors (Figure 12.11.3C).

Instructions to the patient should consist of avoidance, during the first few days, of prolonged sitting with the knee flexed. Elevation of the leg and frequent active flexion and extension of the ankle expedite the subsidence of swelling and the restoration of motion. Ambulation can begin from the outset with the use of crutches. The degree of weight bearing is determined by the degrees of discomfort. There is nothing to be gained from forcing patients to bear weight if such an action is painful. The straps must be adjusted frequently several times during the first few days, and twice a day afterwards, in order to accommodate the new geometry of the limb created by the reduction of swelling. It is this firm compression that controls angular deformities.

The brace should not be removed for approximately 1 week, at which time the surgeon removes the brace and inspects the extremity. New x-rays are taken at this time. If clinically and radiographically there appear to be no problem, the patient is taught how to apply and remove the brace without assistance (Figure 12.11.4).

**Fig. 12.11.2**
A) Radiograph of closed comminuted fracture of the proximal tibia and fibula. Notice the acceptable shortening seen at the time of the initial insult. B) Radiograph obtained after completion of healing. Notice that the initial shortening remained essentially unchanged.
Fig. 12.11.4
A) Radiograph of closed oblique fracture of the distal third of the tibia and proximal fibula. Notice the acceptable initial shortening. B) Radiograph obtained after application of the brace. C) Radiograph taken after completion of healing. Notice that the initial shortening and alignment were maintained.

**The humeral shaft fracture (Box 12.11.2)**

Non-surgical functional treatment of diaphyseal humeral fractures has been highly successful, with a very low incidence of non-union and acceptable functional and cosmetic results.

**Initial management**

Patients with diaphyseal humeral fractures who are selected for non-surgical functional management are usually those with closed fractures that do not suggest extreme degrees of soft tissue damage, which is usually depicted by major axial separation between the major fragments. In order to provide comfort during the early acute stage of the process, an above the elbow cast or a coaptation splint is applied (Figure 12.11.5). The elbow should be held at approximately 90 degrees of flexion. A sling is essential, and must be attached while the shoulder is in a relaxed position; otherwise an angular deformity is likely to develop when the shrugged shoulder relaxes (Figure 12.11.6).

**Box 12.11.2 Humeral shaft functional bracing**

- Suitable for closed fractures without evidence of significant soft tissue damage (fracture gap)
- Initial treatment in cast or coaptation splint
- Apply brace from day 2, when pain and swelling settled
- Avoid applying sling with shoulder elevated, ‘shrugged’.

Fig. 12.11.5
A) Illustration of an above-the-elbow cast holding the elbow at 90 degrees of flexion. B) Illustration of a coaptation splint.

Fig. 12.11.6
A) A shrugged shoulder is a commonly seen problem at the time of application of the sling. B) As the shoulder relaxes a varus deformity readily occurs. It is important therefore to ascertain that when the sling is applied the shoulder is a relaxed position.
Circumduction (pendulum) exercises, in the sling, should begin within the first couple of days following the initial injury. Under no circumstances should the patient be encouraged to actively abduct or elevate the shoulder. These active exercises readily lead to angular deformity and increase the likelihood of non-union.

The application of the functional brace

In most patients with diaphyseal humeral fractures sustained from relatively low energy injuries, the functional brace may be applied within the first week of injury. However, if the extremity is still very painful and significant swelling is present at that time, it is best to postpone the application of the brace by a few more days.

The brace is applied while the patient is sitting in a high chair with the arm in a relaxed position. Since it is likely that the elbow will be limited in flexion because of the preceding days of immobilization, the arm should be supported by the patient’s normal hand (Figure 12.11.7). A layer of stockinette is rolled over the upper arm, extending from the acromioclavicular level to below the elbow.

The prefabricated brace, which is made of two separate shelves, is slipped over the arm until it reaches a point below the axilla. Once this has been accomplished, the Velcro straps are firmly adjusted.

Braces that extend over the acromium do more harm than good. They have been allegedly designed to prevent their distal slippage. Although it is possible that in some stances this is accomplished, the necessary soft tissue compression is lost and pain or discomfort ensues.

Following the application of the brace, circumduction exercises, in sling, should be reinitiated. A few days later, in accordance with the degree of symptoms, the patient is instructed to start passive flexion and extension of the elbow. These exercises are then combined with active contractions of the flexors and extensors of the elbow. These exercises might favourably correct any rotary deformity that may have developed at the time of the injury. Once the elbow reaches full extension, and the acute symptoms have disappeared, circumduction exercises in extension may be started. These exercises must be conducted gingerly and without pain. During rest, the arm is best held in the sling until clinical evidence of early intrinsic healing has been demonstrated (Figure 12.11.8). Active flexion and abduction should be postponed until the fracture shows early callus formation in order to avoid angular deformities.

The isolated ulnar fracture (Box 12.11.3)

Plating of isolated ulnar fractures is a popular method of treatment. Postoperative infection is low and non-union and implant failure do not occur with great frequency. However, refracture following plate removal is not uncommon and the costs of surgical treatment remain high.
The popularity of surgical plating came as a result of observing that non-union was not infrequently encountered when the limb was
immobilized in a cast that extended from the head of the metacarpals to above the elbow. Such a cast had been used as it was
believed that the joint above and below a fracture required immobilization. Today, the theory of rigid immobilization has been proven
flawed, and replaced with evidence-supported data that freedom of motion of joints and physiologically induced motion at the
fracture site are conducive to diaphyseal fracture healing. The high rate of success with functional bracing of isolated ulnar fractures
makes it difficult to justify the routine plating of these fractures. There are, however, instances when open surgery is the treatment
of choice, such as in the case of open fractures with severe soft tissue damage or major displacement of the fragments.

Box 12.11.3 Ulnar shaft functional bracing

♦ Usually the result of a direct blow
♦ Fracture is usually axially stable and supported by interosseous membrane
♦ Mild angular deformity correctable
♦ When the forearm is placed in a relaxed attitude of supination, the angular deformity usually improves
♦ Contraindicated in Monteggia fracture.

Since isolated ulnar fractures are usually the result of direct blows over the forearm, the most common displacement of the
fragments is in a radial direction. Since the injury produces minimal to moderate damage to the interosseous membrane, its
stabilizing role is rarely compromised. Shortening is not possible, since the intact radius prevents such a development. When the
forearm is placed in a relaxed attitude of supination, the angular deformity usually improves. In any event, the common residual
angulation does not result in a noticeable loss of pronosupination. It is our view that the surgical trauma produced at the time of
plate fixation is more likely to create a greater degree of limitation of motion. A synostosis between the two bones is a
complication we have not observed with the use of functional braces.

Initial angular deformity in a volar direction is usually of a mild degree and the clinical consequences are rarely of any significance.
This type of angulation is easily correct by gently, steady pressure at the apex of the fracture for a few minutes. Major angular
defority may be seen in severe open fractures associated with significant amount of soft tissue damage. These fractures require
stabilization with internal or external fixation. Low-grade open fractures can be treated with functional bracing following appropriate
debridement of the injured soft tissues.

These observations suggest that the majority of isolated ulnar fractures can be successfully treated with functional braces that
permit early use of the extremity without the need for complete prevention of pronosupination of the forearm and flexion and
extension of the elbow and wrist.

We recognize that the functional brace does not immobilize the fractured fragments. This is a desirable feature, since
immobilization retards healing. This is true for all other types of braces used in the care of tibial or humeral fractures. In the case of
the ulna, the brace simply provides comfort and holds the forearm in the desirable relaxed attitude of supination, which assists in
maintaining the two bones as far apart as possible.

Successful results have been achieved treating isolated ulnar fractures with the simply use of an elastic bandage. However, the
brace provides a degree of comfort the bandage does not accomplish.

Instructions

Patients are encouraged to use the extremity to the maximum degree allowed by pain. In most instances the pain present at the
time of application of the brace is only moderate. It is our opinion that the early introduction of function results in a more rapid
disappearance of acute symptoms and faster healing. The brace should be short enough to make possible free motion of the wrist
and elbow, regardless of the location of the fracture (Figure 12.11.9).

Flexion and extension of the elbow are rapidly regained. Pronation and supination required a longer period of time because such
motions are more painful. In a few instances we have treated with functional braces patients who had sustained bilateral isolated
ulnar fractures. Their recovery was rapid and uneventful.

The brace should be adjusted on a frequent basis during the first few days in order to maintain the desirable compression of the
soft tissues and to prevent the distal displacement of the sleeve over the wrist. The brace may be removed for hygienic purposes as
often as necessary and the collar-and-cuff permanently discontinued as soon as the symptoms subside.
Obviously, rigid immobilization of fragments is not necessary. All the brace accomplishes is probably nothing more than provision of comfort and protection to the arm from inadvertent forceful contact with hard objects (Figure 12.11.10).

Summary points

- Fixation using plates and screws requires an understanding of basic principles rather than simple pattern recognition.
- Although plates and screws are simple mechanical devices, their correct application requires good technique.

Screws—basic concepts (Box 12.1.1)

General principles of screw fixation

Screws have several components:

- **Head**
- **Shaft**—the shaft is comprised of a threaded section and in partially threaded screws, there is also a non-threaded section. **Shaft diameter** is used to describe the diameter of any non-threaded sections. Threaded sections have both a **core diameter** and a **thread diameter**.
- The screw thread has a **pitch** which defines the relationship between rotation and axial displacement of the screw (Figure 12.12.1). This is directly related to the inclination of the thread, which determines the axial displacement that occurs with rotation.
- **Tip.**

![Fig. 12.12.1](pitch_of_a_screw_h_axial_displacement_with_360_degree_rotation_omega_inclination_the_spherical_under_surface_maximizes_the_contact_surface_area_when_placed_at_an_angle_and_when_used_with_plates)

As a ‘conventional’ screw is tightened, a load is generated between the bottom of the screw head and the upper surface of the screw threads. As the axial load increases, so does the friction generated between the screw and bone. It is this friction that prevents the screw backing out, and this is dependent on the thread pitch. The steeper the pitch, the less friction and vice versa. Further tightening has the potential to generate load in excess of the ultimate strength of the bone. At this point, failure occurs at the interface between the screw and bone. The strength of this interface can be improved by using larger threads and washers, both of which reduce pressure on the bone.

Box 12.12.1

A screw is a mechanical device that converts a rotational movement (torque) into a linear movement (translation).

The corresponding drill for a screw accommodates the core diameter. In cortical bone, tapping is recommended to create a channel for the threads. In addition to cutting the threads, the tap has flutes that allow the bone cuttings to be cleared. Conventional screw threads are not designed to ‘cut’ channels and there is a risk of the screw jamming, breaking, or stripping the threads.
Screw head

Head undersurface

Screw heads are required to interface with both bone and plates. Ideally this interface involves a large surface area and allows the screw to be angled. To accommodate these features a spherical undersurface is desirable (Figure 12.12.1). When screws are placed at an angle in cortical bone a counter sink can be used to increase the contact surface area and reduce pressure and the subsequent risk of failure of the underlying bone.

Head recesses

Recesses within the head accommodate the screwdriver. Different designs are available that aim to provide an effective coupling which is easy to use and resistant to damage on insertion and extraction. Hexagonal and 'star' recesses are the most frequently used in fracture fixation (Figure 12.12.2).

Threaded screw head

Many manufacturers of trauma implants have now utilized a threaded-head screw design, this allows the head of the screw to be ‘locked’ into the plate (Figure 12.12.3). The screw-plate construct acts as a fixed angle device and will be discussed later in the chapter.

Screw thread

Symmetrical threads

Thread symmetry refers to the profile of the thread. The upper and lower surfaces of symmetrical threads are the same. This design is easier to manufacture and is used in cancellous bone (Figure 12.12.4A).
Asymmetrical threads

This design is used for cortical bone screws (Figure 12.12.4B). The upper surface of the thread is flatter than the lower thread surface. The upper surface is more or less orthogonal to the axis of the screw increasing frictional resistance. The friction generated during insertion is minimized by the rounded undersurface.

Screw tips

Conventional cortical bone screws have a blunt tip and are designed to be used in a pre-drilled and pre-tapped hole. Self-tapping screws have a cutting flute on the tip that allows the screw to cut its own thread through a pre-drilled hole (Figure 12.12.5). Self-drilling/self-tapping screws incorporate a drill tip and cut their own hole and thread (Figure 12.12.6). Self-drilling screws should only be used for monocortical fixation. When used to achieve bicortical fixation there is a risk of stripping the thread in the proximal cortex. If bicortical fixation is required it is advisable to pre-drill and not use a self-drilling screw.

Methods of screw fixation

Lag screw (Box 12.12.2)

A lag screw generates displacement of one fracture fragment relative to another, generating compression at the fracture site.
Interfragmentary compression helps create the stability that is required for direct bone healing. Lag screws should be placed at 90 degrees to the fracture site to maximize compression and avoid the risk of displacement.

Both partially and fully threaded screws can be used as lag screws. To generate compression at the fracture site the threads must only engage the distal fragment. When using a fully threaded screw a glide hole must be drilled in the proximal fragment to accommodate the outer diameter of the screw. A threaded hole is drilled in the distal fragment.

**Box 12.12.2**

A lag screw technique is used to generate compression between fracture fragments.

**Box 12.12.3**

A positioning screw maintains the correct anatomical alignment without exerting compression.

**Positioning screw (Box 12.12.3)**

Under circumstances involving bone loss or syndesmotic disruption, positioning screws can be used (Figure 12.12.7). Generation of compression under these circumstances would be undesirable as it would generate malalignment. As the screw is tightened the threads must engaged both fragments so that there is no relative displacement.

A positional screw placed across a fracture line can be used to maintain the compression generated by the prior application of reduction clamps or a compression device.

**Plate screw**

**Plate fixing screw**

The stability of a conventional plate screw construct is dependent on the friction generated at the bone–plate interface. For friction to be generated it relies on compression by the screws at the bone–plate interface and contact between the bone and plate.

**Plate lag screw**

The plate lag screw hole is prepared in a similar fashion to when a lag screw is placed in isolation. By placing the screw through the plate it achieves compression at both the bone plate interface and the fracture site (Figure 12.12.8).
Plate locking screw

The most common method involves a threaded screw head within a threaded plate hole (see Figure 12.12.3). With these implants the screw direction is fixed. Polyaxial locking plates allow the screw to lock to the plate at variable angles.

Plate fixation—basic concepts (Box 12.12.4)

Plate design may have evolved considerably from strips of metal, with simple circular screw holes, but they continue to function as temporary internal splints. The mechanical properties of the plate will influence the mechanical environment experienced at the fracture site and this will be dependent on the size and shape of the material used. Most orthopaedic trauma implants are made from stainless steel or titanium. Titanium has approximately 50% of the stiffness of stainless steel; however it is the dimensions rather than the elastic modulus that has the greatest effect on the mechanical properties of plates. Doubling the thickness of the plate has the potential to increase the stiffness by a factor of 16.

Box 12.12.4

A plate is a mechanical device that can temporarily take over the mechanical function of the bone to which it is applied.

The strength of the fracture fixation construct is dependent on the mechanical interfaces between all the components. The strength of all plate-screw constructs is dependent on the bone–screw interface and this has been discussed in the previous section. The development of locking plates has resulted in improved biology and mechanics at the plate–screw and bone–plate interfaces.

Non-locking plate-screw fixation

In conventional non-locking plates, fixation strength is dependent on friction at the bone–plate and plate–screw interfaces. As the plate screw is tightened the plate is pulled against the bone increasing the friction between both of these interfaces. Loss of friction at the bone–plate interface will result in loosening of the construct. It can be expected that with the inevitable relaxation, of the relatively high application force generated by the screws, there will be loss of fixation. In screws that have been inserted with good technique this process will take months and this will be sufficient time to allow fracture healing. Screw tightening can cause high stresses at the interface between the undersurface of the screw head and the floor of the plate hole, causing incongruency as a result of the elastic and plastic deformation of the plate holes. Micromotion at this interface causes fretting corrosion and decreased friction between plate and bone. Any loosening will result in micromotion, bone resorption, and further loosening.

Another limitation of using high tensile force and friction is the detrimental effect to blood flow in the ‘footprint’ of the plate. This can result in necrosis and the potential for reduced bone healing, re-fracture with plate removal, and infection. Low contact plates have been developed to minimize this problem by reducing the surface area affected by bone necrosis without affecting friction. These plates allow soft tissue ingrowth and avoid creating large volumes of dead space.

Locking plate–screw fixation

Screw heads lock into the locking plate forming a construct with axial and angular stability. The plate does not need to be contoured precisely to the bone as it relies on the strength of the plate–screw interface rather than friction at the bone–plate interface for stability. It therefore functions as an internal fixator. This has a beneficial effect on the perfusion at the bone–plate interface. Relaxation is minimal at the plate–screw interface and the screws are subject to bending forces as opposed to the tensile loads experienced by non-locking screws. This allows the creation of stronger fracture fixation constructs in the presence of bone loss. For failure to occur at the bone–screw interface it must be accompanied by failure of all the screws on one side of the construct.

Methods of plate fixation

Plates can be considered load bearing when used to support the entire physiologic load in the absence of inherent fracture stability. When the reduced fracture contributes to stability the plate can be considered load sharing. The choice of plate will be
dependent on the load to which it will be subjected and this is dependent on the anatomical position and the method of application.

The method used to apply a plate should be chosen according to the fracture pattern, soft tissues, and available reduction techniques. The methods of plate application are independent of whether a locked or non-locked plate is used (Box 12.12.5).

**Box 12.12.5 Methods of plate application**

- Neutralization
- Compression
- Buttress
- Antiglide
- Tension-band
- Bridge plate.

### Neutralization

Simple fractures may be amenable to anatomical reduction and interfragmentary compression using lag screws. Fixation by this method alone is seldom sufficient as the fixation is likely to fail as a result of twisting and bending forces. The addition of a plate helps to neutralize these forces.

### Compression

Plates can be used in compression mode by using the following methods:

- Dynamic compression plate holes
- Removable compression devices
- Pre-bending
- Plate lag screw.

### Dynamic compression plates

Compression plates have oval holes that, viewed in longitudinal cross-section, have an inclined plane at one end (Figure 12.12.9). When a screw is inserted at this end of the plate the head slides down the incline resulting in axial translation of the plate and compression at the fracture site. This mode of usage relies on one end of the plate being rigidly fixed to the other fragment. The axial translation is small and the fracture needs to be anatomically reduced before application of the compression screw. The compression hole has been incorporated into plate designs that also accommodate locking screws (Figure 12.12.10).

![Click to view larger](Fig. 12.12.9)

Dynamic compression hole used to achieve interfragmentary compression.
Removable compression devices

These devices can generate compression once the plate has been firmly anchored to one side of the fracture (Figure 12.12.11). This technique requires a greater exposure but can generate more axial translation than can be achieved with dynamic compression holes. These devices can also be used in reverse to distract the fracture when performing indirect reduction techniques.

Pre-bending

When simple transverse fractures are fixed with compression applied through the plate there is a tendency for the fracture to gap on the opposite side. Placing a small bend in the plate with the apex at the level of the fracture causes the plate to sit off the bone. When the plate is then compressed down to the bone the elasticity of the plate results in compression of the bone on the opposite side.

Buttress and antiglide

Plates can be applied to resist specific deforming forces. Metaphyseal fracture fragments have characteristic fracture patterns and displacement can be prevented by using plates in a buttress or antiglide mode. Lag screw fixation alone is unlikely to provide sufficient stability to allow early range of motion. Buttress plates prevent displacement away from the axis of the limb in the same way as a buttress used in architecture prevents walls from falling outwards. Antiglide refers to plates used predominantly to prevent displacement in the axis of the limb. Antiglide plates can be used to hold the apex of the fracture as part of a minimally invasive technique that allows both reduction and stabilization using the plate (Figure 12.12.12).
Tension band

Plates can be applied in tension band mode and work in a similar manner to tension band wire constructs by converting tension within the construct into compression at the fracture site. For this method to be effective it requires bony continuity at the fracture site and a predominantly asymmetric load. This is best illustrated in the femur where the lateral cortex is in tension and the medial cortex is in compression. A plate applied to the lateral side will resist tension and facilitate compression of the fracture site.

Bridge plate

In complex multifragmentary fractures it may be impossible or undesirable to attempt to reconstruct the multifragmentary region of the fracture. Direct reduction, anatomical fixation, and absolute stability would necessitate further soft tissue stripping and runs the risk of de-vitalizing bone fragments and infection. An alternative method is to use indirect reduction techniques to restore length, axial alignment, and rotation without anatomical reduction at the fracture site. The plate functions as a load-bearing device until sufficient fracture healing has occurred.

Rationale of plate and screw fixation

When using a plate, consideration must be given to the mechanical environment that is being created at the fracture site. Bone healing is a complex process involving a multitude of biological and mechanical factors. Following the inflammatory phase, granulation tissue is formed within the fracture site, later this is then accompanied by the differentiation of cells into chondroblasts and osteoblasts producing hyaline cartilage and woven bone respectively. Lamellar bone eventually replaces hyaline cartilage by endochondral ossification and woven bone by bone substitution.

The tissue that forms within a fracture site is dependent on the mechanical environment, and in particular strain. Strain is a measurement of deformation and is reported as a percentage derived from the change in length divided by the original length (strain = ΔL/L). Although not definitive, Perren's interfragmentary strain theory helps to explain the mechanics of fracture healing and how strain relates to plate fixation. Interfragmentary strain is influenced by both dynamic fracture displacement and fracture gap. The theory states that the strain experienced at the fracture gap determines the tissue that can form within the fracture gap. This is dependent on both the induction and tolerance of tissue within the fracture gap. The optimum strain range lies between that which is capable of inducing tissue formation, but below the threshold resulting in tissue disruption. Elongation strain below 2% is tolerated by lamellar bone and elongation strain below 10% is tolerated by cartilage and woven bone. Granulation tissue is more resilient and can tolerate elongation strains up to 100%. When strain is greater than 10% bone cannot form and resorption is the predominant process.

The strain experienced within an intact bone under physiological loading is very small (<1%). This is the optimum mechanical environment for the formation of lamellar bone and is seen to occur continuously as part of the remodelling process. Haversian osteones travel along the axis of the bone with osteoclast ‘cutting cones’ removing bone and osteoblasts laying down bone. The stability achieved by fixation using interfragmentary compression produces a strain environment, at the fracture site, which approximates bone. No resorption occurs and the ‘cutting cones’ are seen to cross the fracture (Figure 12.12.13). Small defects within the fracture that are supported by neighbouring contact areas do not compromise stability and therefore will experience similar low interfragmentary strain allowing direct bone healing. This process is described as primary bone healing without callus but may be more accurately described as bone healing by remodelling.
A residual fracture gap associated with instability will experience higher levels of interfragmentary strain. The strain experienced will be dependent on many factors: physiological load, mechanical properties of fixation, fracture gap, and the position within the fracture relative to the fixation and fracture gap.

Small fracture gaps subjected to even small amounts of displacement will experience very high levels of strain preventing the formation of bone or cartilage and potentially resulting in bone resorption. This is the mechanism for resorption around loose implants. Poor technique will fail to provide a tight interface between the bone and screw, micromotion will create high strain environment within the interface resulting in resorption and further loosening. The proximal cortex is particularly important in non-locked constructs as movement perpendicular to the axis of the screw will cause the screw to ‘toggle’ around a fulcrum provided by the screw’s fixation in the distal cortex. When the drill holes are being prepared care should be taken to avoid thermal necrosis as this will both compromise the bone-screw interface and increase the risk of infection. Thermal necrosis can be avoided by the use of a sharp, clean drill bit operating at the ideal speed and without undue pressure. The drill bit should be cleaned after drilling each hole.

Larger fracture gaps subjected to the same displacement will experience lower levels of strain and have the potential to facilitate the formation of hyaline cartilage and woven bone. Very low strain levels will not induce callus formation. Peripheral tissue will experience less strain as deformation is distributed over a greater volume of tissue. Fractures treated with non-rigid stabilization first form callus peripherally, in an area of optimum strain, resulting in a characteristic fusiform appearance. This is also seen to occur frequently in bridge plate constructs (Figure 12.12.14).

The strain environment within the fracture site changes with time depending on the stiffness of the new tissue. Granulation tissue has little stiffness, contributes little to stability, and has little influence on the strain environment of the surrounding tissues. In contrast, cartilage and bone have much greater stiffness and as they form they will reduce the strain experienced by the surrounding tissues. The reduction in strain has the potential to allow more cartilage and woven bone to form in a centripetal direction. Once the fracture is stabilized with mature callus it can then be replaced and remodelled by lamellar bone.

The orthopaedic trauma surgeon must harness these processes to successfully treat fractures with plates. Both the biology of the fracture and the strain environment must be optimized using a fixation technique that will maintain mechanical integrity until fracture healing is achieved. The technique will fail if the optimum strain lies outside the fracture haematoma, there is insufficient...
vascularity or the fixation fails prematurely.

The construct stiffness is one of the few factors that is directly controllable by the surgeon. Stiffer constructs can be created by fracture reduction, using larger implants and shorter working lengths. The physiologic loading can be controlled to a limited extent by the post operative regime.

Secondary bone healing with callus occurs with fixation that achieves relative stability. The effect of both the injury and open reduction on the soft tissues of complex diaphyseal fractures makes indirect restoration of mechanical alignment and fixation using relative stability techniques appealing. The strain is kept low as displacement is shared across multiple fracture lines with significant fracture gaps. It is not uncommon for these complex fractures to unite and consolidate resulting in a residual non-union of a simple fracture pattern. This problem can then be relatively easily resolved by revising the plate construct to create absolute stability at this residual fracture site.

When a fracture is reduced and fixed anatomically with interfragmentary compression, the rigid construct created is mechanically similar to an intact bone and is described as having absolute stability. Absolute stability is desirable for treatment of both articular fragments and simple diaphyseal fracture configurations (Type A). In both cases restoration of alignment, to achieve a congruent joint surface or a mechanically aligned limb may result in a small fracture gap with the potential for high strain at the fracture site unless absolute stability is achieved. This is best accomplished with interfragmentary compression. Simple diaphyseal fractures can be managed with relative stability only if a sufficient fracture gap is maintained and elastic fixation techniques are used.

With early osteosynthesis techniques, emphasis was placed on anatomical reduction with open techniques, direct reduction, and absolute stability. This had the potential to adversely affect the biology by devascularizing bone fragments. Minimally invasive plate osteosynthesis (MIPO) techniques have been developed to minimize disruption of the soft tissues and fracture site. These techniques use image intensification and specific implants that allow restoration of alignment, relative stability, and bone healing through callus formation. These implants are designed to produce a more elastic fracture fixation construct that can be used for bridging and optimizes induction of callus. Consideration should be given to leaving a long enough working length between the screws on either side of the fracture to minimize the risk of plate breakage.

It is important to appreciate that, although technically more challenging, the advantages of MIPO techniques and implants can also be used to achieve anatomical reduction and absolute stability. Under these circumstances the plate can be used to utilize other modes of plate fixation (neutralization, compression, buttress, antiglide) in combination or isolation. It is the fracture configuration and soft tissues that determine the plate fixation technique, not the implant.

### Complications specifically related to plate-screw fixation

- **Infection:**
  - Thermonecrosis
  - Necrosis under plate
  - Soft tissue stripping
- **Screw failure:**
  - Stripped threads—poor technique
  - Thermonecrosis
- **Plate breakage:**
  - Stress risers (e.g. short working length)
  - Poor choice of technique
  - Inadequate implant size
  - Non-union
- **Non-union:**
  - Mechanical—poor choice of technique
  - Biological—devascularization.

Principles of intramedullary nailing

Summary points

- Intramedullary nailing provides the trauma surgeon with a biologic solution to the stabilization of both simple and complex long bone fractures
- An appreciation of the biomechanics and the technical difficulties is essential.

Introduction

The term intramedullary nail is used to describe a group of implants that are placed within the medullary canal of a long bone. Intramedullary nails form a construct with the bone and act to resist deformity. Nails may be used to prevent fractures, control fractures acutely, or in post-trauma reconstruction. Intramedullary nailing is the treatment of choice for many diaphyseal fractures and modern nail design has extended their application to include some metaphyseal fractures.

It is over a century since the first descriptions of intramedullary nailing. The technique was refined and popularized by the German surgeon Kuntscher who inserted his first femoral nail in 1939. He also introduced intramedullary reaming and, shortly before his death, described an implant that was the forerunner of the interlocking nail. It was Herzog who, in 1950, first introduced tibial nailing after bending the proximal part of a nail. Intramedullary nailing was further popularized through the 1970s and 1980s and has now become an indispensable tool for the orthopaedic surgeon.

Today, various flexible nailing systems are available with a wide range of applications, especially in the immature skeleton.

Definitions

Nails may be either solid or hollow. The latter are designed to be introduced over a guide wire. Hollow nails were traditionally open section (slotted) but are now more commonly closed section. Both solid and hollow nails have holes proximal and distal to allow the insertion of interlocking bolts. These bolts greatly increase construct stability by resisting torsional and axial forces. In the proximal femur, many nails provide an option to interlock by inserting a screw obliquely into the femoral head. These so-called ‘cephalomedullary’ nails are useful in the treatment of subtrochanteric fractures or ipsilateral neck and shaft fractures.

Interlocking may either be static or dynamic. Static locking provides a fixed relationship between the nail and the proximal and distal portions of the bone. Dynamic locking is produced via an elongated interlocking hole within the nail that allows axial compression while maintaining torsional stability.

Basic science

Biomechanics

The intramedullary nail and bone form a composite structure that is subject to load. The mechanical characteristics of this composite depend on the characteristics of the nail as well as the quality and integrity of the bone. The implant is central in the bone, close to the mechanical axis of the limb, which means it is optimally positioned to resist bending forces.

Intramedullary nails do not, nor are they intended to, abolish movement at the fracture site. This motion stimulates callus formation that bridges the fracture, gradually assuming more of the load and reducing stress upon the implant. The nail and interlocking bolts must be sufficiently durable to survive until fracture healing occurs. If, however, they are excessively rigid they will inhibit the stimuli required for fracture healing.

The strength of an intramedullary nail is a property of its cross-sectional geometry and the implant material. The rigidity of a cylindrical intramedullary nail in bending and torsion is proportional to the fourth power of the radius. Therefore, for a given amount of material, the further the material is distributed from the bending or torsional axis, the stiffer the structure becomes.

Producing a slot in a hollow nail reduces torsional strength by two-thirds, with little effect on the bending stiffness. The slot provides the nail with some radial flexibility, which decreases hoop stresses during insertion and increases contact area between the bone and implant after insertion.

Intramedullary nails are usually made of stainless steel or titanium alloys. The lower modulus of elasticity of titanium alloys has the theoretical advantage of less stress shielding of the bone, but no differences in healing or complication rates have been demonstrated. The geometry of the nail, specifically the diameter and wall thickness, are more significant factors for fracture healing.

The working length of a nail is the distance between the proximal and distal points of secure fixation to bone. With small-diameter interlocking nails without diaphyseal fit, this is usually the distance between the interlocking screws (Figure 12.13.1). The torsional rigidity of an implant is inversely proportional to the working length, and the bending rigidity is inversely proportional to the square of...
the working length.

Fig. 12.13.1
(A) The working length of a tight-fitting nail is between points of secure cortical contact in the proximal and distal fragment. (B) In a small-diameter loose-fitting nail the working length is between the proximal and distal interlocking screws. Both the torsional and bending stiffness of the nail bone composite are inversely related to the working length.

Fatigue fracture is the usual mode of failure for intramedullary nails. Failure is usually associated with delayed or non-union, particularly in unstable fracture patterns where the bone contributes little to the overall construct. Nail design is an important factor that relates to the frequency of nail breakage. Defects in fabrication may also contribute to breakage. Smaller interlocking bolts used with smaller nails are more prone to fatigue failure. In studies examining interlocking intramedullary nailing in tibial fractures, smaller nails inserted without reaming had a higher rate of interlocking bolt failure. This problem is attributed to the size of locking bolt, and is not exclusive to unreamed tibial nails. Locking bolts used in 8- or 9-mm tibial nails are significantly weaker than the bolts used in femoral nails and larger tibial nails (≥10mm). Laboratory testing has shown that the number of cycles to fatigue failure of a 5-mm bolt would be expected to be more than 20 times greater than for a 4-mm bolt.

Box 12.13.1 Positive influences upon nail–bone construct strength and durability

- Simple fracture pattern—reduced
- Implant close to mechanical axis of bone
- Larger diameter nail
- Short working length
- Non-slotted nail
- Larger locking bolts (5mm).

Reaming

Reaming of the medullary canal was first employed by Kuntscher to provide a better contact area between the nail and bone, thus improving the construct’s stability. Interlocking bolts and smaller diameter nails can now provide much of this stability, but there are several other advantages to reaming. After reaming, a larger diameter nail can be passed with less chance of nail incarceration, fracture propagation, and implant failure. The morselized bone formed by reaming may also stimulate fracture healing.

Concerns about both the systemic and local effects of reaming have led some to advocate the use of unreamed nails. The pressure and abrasion from a reamer destroys medullary contents and acts as a piston, displacing medullary contents both locally and systemically. Reaming has, therefore, been implicated in fat embolism syndrome, respiratory distress syndrome, and multisystem organ failure. Recent studies have failed to confirm this link. Locally, reaming damages the endosteal blood supply, but, compared to unreamed nailing, no ill effects have been demonstrated.

The arterial supply to the diaphyses of long bones is from the nutrient, metaphyseal, and periosteal arteries. The venous drainage of bone consists of thin-walled vessels running in the centre of the medullary cavity. The central two-thirds of the diaphyseal cortex receives its blood supply from the high-pressure endosteal circulation, and the outer third of the cortex is supplied by the low-pressure periosteal system. Cortical blood flow is, therefore, centrifugal. The direction of blood flow is reversed after a fracture, resulting from suppression of the intramedullary flow and increased vascularity of the periosteum.

Reaming damages the nutrient arterial circulation, but the clinical significance of this damage is uncertain. The periosteal circulation is only able to supply only the outer one-third of the cortex. Necrosis of the inner two-thirds of the cortex has been demonstrated in animals following reaming. A rapid regeneration of the nutrient system has been demonstrated with loose-fitting
Where the nail directly contacts the cortex, osteoclasts must remove necrotic bone to create a channel for vessels. At 12 weeks, the restoration of endosteal circulation is complete. The extent of revascularization varies and is influenced by the extent of original damage. Revascularization is facilitated by vessels, originating from the surrounding soft tissues, which traverse the external callus to reach the necrotic cortex. After reaming, there is an early periosteal vascular proliferation and hyperaemia, which is associated with periosteal new bone formation.

In an effort to reduce problems associated with reaming, some thought has gone into designing a new generation of reamer. The RIA (Reamer Irrigator Aspirator, Synthes) is a tool that irrigates while reaming, simultaneously aspirating the resulting mix of reamings and fluid. The RIA is a single-use instrument, with a steep cutting angle, designed to ream to the required diameter in a single pass, thus reducing operative time. The intramedullary pressures while reaming are significantly reduced, and throughout much of the process are negative. A reduction in local heat generation has also been demonstrated. Overall the RIA seeks to reduce the physiological impact of reaming both locally and systemically. The RIA is also useful for canal debridement after infected nail removal and harvesting bone graft from the femoral canal.

### Box 12.13.2 Advantages and disadvantages of reaming

**Advantages:**
- Increased contact area between nail and bone:
  - Shorter working length
  - More rigid construct
- Allows the use of larger diameter nails
- Morselized bone acts as autograft

**Disadvantages:**
- Detrimental effects on endosteal blood supply
- Concerns regarding systemic effects of displaced marrow contents.

### Indications

Intramedullary nailing is ideally suited to treating diaphyseal fractures, particularly in the femur and tibia. Nailing provides good stability via a minimally invasive technique, minimizing soft tissue disruption in the zone of injury. Avoiding further damage to the tissues surrounding the fracture site enhances revascularization and aids early bridging callus formation. The strength of the bone–nail construct will often allow for early weight bearing, accelerating rehabilitation.

Statically locked reamed intramedullary nailing is the treatment of choice for diaphyseal fractures of the femur. Reamed intramedullary nailing is the treatment of choice for displaced tibial shaft fractures and can safely be performed in all but the most severe open fractures. Locked intramedullary nailing of the humerus is indicated in patients with pathological fractures, otherwise open reduction and plate fixation is the preferable operative fracture treatment.

Other indications for intramedullary nailing include fixation of subtrochanteric, pertrochanteric, or supracondylar femur fractures, stabilization of arthrodeses, and as a guide for bone transport. Intramedullary nails are also indicated for fracture prophylaxis with metastatic bone tumours, and for tumour-like conditions, e.g. fibrous dysplasia.

### Flexible nailing

Small diameter devices such as Ender’s nails were traditionally used multiply to fill the medullary canal or were pre-bent to provide three-point fixation. These devices did not perform well in adult long bones, especially the femur and tibia, as they did not provide sufficient stability for healing.

Elastic or flexible nailing systems are now very much the preserve of paediatric long-bone fractures. These nails are bent prior to their insertion and are used in opposing pairs. When appropriately placed, the elastic recoil of these nails provides adequate internal splintage to permit fracture healing in the aforementioned bones.

This technique is further discussed in the Paediatric Trauma section (Section 14).

### Operative technique

**Patient positioning**

In order to successfully place an intramedullary nail, patient positioning in the operating room is vitally important. Starting and interlocking points must be accessible, fractures reducible, and importantly all parts of the bone exposable to image intensifier.

The starting point is the where the nail first enters the bone and must be considered when positioning the patient. The point may be
on-axis, such as the piriformis fossa for many anterograde femoral nails. Alternatively an off-axis starting point may be necessary, e.g. tibial nail, or desirable, e.g. trochanteric starting point femoral nail. Off-axis starting points increase forces required for insertion and may deform the fracture particularly if it is close to the starting point.

Limbs may be placed on traction or left free; both techniques have their pros and cons. The obese patient may provide difficulties; particularly with anterograde femoral nail insertion. Preoperative planning, appropriate implant selection and attention to the previously mentioned points will contribute greatly to the overall success of the procedure.

Fracture reduction techniques

It is desirable to reduce the fracture by closed means before passing a guide wire or solid nail across the fracture under image guidance. Sometimes fracture reduction is impossible by closed means and open nailing is indicated. There are several methods that may assist in closed reduction.

Tibial fractures can usually be reduced by closed manipulation and held, if necessary, with percutaneously applied reduction clamps. The use of the traction table is often sufficient to reduce femoral fractures, particularly with a fresh injury. Alternatively the femoral distractor may be used to provide traction and maintain reduction. The seldom-used F-tool applies indirect two-point forces, in the plane of deformity, and can be helpful in completing reduction. Shanz screws may be inserted temporarily to aid fracture reduction. They should be placed close to the fracture site and be unicortical on the side of nail insertion. Attachment of a universal chuck and T-handle aids manipulation.

Angulation control

Intramedullary nails are only well suited to reducing diaphyseal fractures. Diaphyseal-metaphyseal junction fractures are prone to predictable angular deformity with nailing. There is a tendency for oblique fractures to displace giving the appearance of the nail exiting the proximal fragment early and entering the distal fragment late. For successful fixation of these fractures the nail must be centralized within the short segment, using the correct entry point and ensuring appropriate nail tip position. Transmedullary blocking or 'Poller' screws may be used in conjunction with intramedullary nails to control this deformity. These screws can effectively extend the tight fit of the diaphysis and control the relationship between bone and nail. A single screw placed in the metaphyseal segment on the concave side of the deformity will allow the nail to reduce that deformity (Figure 12.13.2). The screw forms a third point of fixation together with the nail tip or entry point, and the point of diaphyseal contact. If there is insufficient anchorage of the nail tip then a second blocking screw is inserted contralaterally to the first.

![Fig. 12.13.2](image)

The placement of a single blocking screw on the concave side of the deformity allows the nail to reduce the metaphyseal fragment (B). If the nail tip is not secure, a second contralateral blocking screw, in combination with diaphyseal fit, produces three-point fixation (C).

Malreduction

Rotational malreduction is one of the most common problems to go undetected in the operating room. In one study 28% of patients who had undergone femoral nailing, in a high volume trauma unit, had a residual rotational deformity of greater than 15 degrees as determined by computed tomography scan. These patients were also more likely to have ongoing functional problems.

Clinical assessment or 'eyeballing' is not particularly sensitive and other techniques may need to be employed. Accurate assessment of rotation requires direct comparison with the normal limb. When performing intramedullary nailing without a traction table, it may be useful to prepare, and leave uncovered, the unaffected limb to allow this comparison. In the femur, radiological signs can be used to avoid malrotation. A comparison of lesser trochanter profiles with the patella facing anteriorly can be used before final locking. A less sensitive sign of malrotation is a sudden change of shaft diameter or cortical thickness on fluoroscopy. Changes may, however, be quite subtle, particularly in areas with a more rounded cross-section.

Box 12.13.3 Adjuncts for fracture reduction when nailing
Traction:
• Whole limb—traction table or manual
• Segmental, e.g. femoral distractor

Externally applied pressure:
• F-tool
• Assistant

Indirect invasive, e.g. Shanz pins
• Open reduction
• Image intensifier, e.g. avoiding rotational malreduction.

Summary points

- The ideal frame should be versatile, stable during load bearing and allow joint movement, correction of deformity and closed application
- Circular fixators consist of rings, connecting rods, fine wires and special parts
- Meticulous preoperative planning with the patient and radiographs is essential
- Recovery of limb function is the primary goal of fracture care; the patient must be fully involved in the rehabilitation
- Fixator removal once union is complete should be performed under general anaesthetic for children or with sedation and analgesia in adults

Introduction

The use of circular external fixators with fine tensioned wires has been extensively developed at the Scientific Centre of Reconstructive Orthopaedics and Traumatology in Kurgan, Russia and is now widely practised around the world.

Circular external fixation is not new. Dickson and Diveley presented their fixator of two arches connected by threaded rods and fixed by tensioned K-wires in 1932. Versatile tensioned-wire fixators were developed in Russia by Florensky, Rodin, and Gudushauri in the 1950s. Ilizarov explored the biomechanical and biologic effects of fine-wire fixation and designed a system of closed ring fixators which allowed dynamic, stable constructs in all planes. It is the ability to vary and control the mechanical properties of the construct which distinguishes circular external fixators from many other bone holding devices.

The ‘ideal external fixation system’ (Box 12.15.1) should allow:

- Varied frame design from simple interchangeable components
- Stable fixation of bone fragments, retaining mobility at neighbouring joints
- Maintenance of fracture stability under conditions of full weight bearing
- Controlled movement, in any direction, at any time during the treatment period, to enhance fracture healing, correct malalignment, or restore limb length
- Application with minimal soft tissue or osseus damage and without the need for open reduction of the fracture.

Box 12.15.1 The ideal external fixator

Circular frames allow control of the mechanical properties of fixation. The ideal frame should:

- Be versatile
- Be stable during load bearing
- Allow joint movement
- Allow correction of deformity
- Allow closed application.

These ‘ideals’ are difficult to achieve with a monolateral fixator but can be produced to varying degrees with even simple circular frame designs. With proper planning a circular frame can allow rehabilitation of the joints with full weight bearing and manipulation of the fracture fragments. Restoration of bone loss can progress within a stable limb segment with little effect on limb function.

Indications for circular external fixation in acute fractures (Box 12.15.2)

The Ilizarov method is established in the management of non-union, limb deformity, and leg lengthening. Primary circular fixation in acute fractures remains controversial. Outcomes of treatment are now clearer with recent studies comparing the Ilizarov method with other techniques.

It is helpful to divide indications into absolute and relative, separating those situations where circular external fixation has major advantages over other treatments and those where it may offer some additional benefits. The following indications are derived from the extensive experience in fracture care at our two institutions.
Articular fractures usually require ORIF
External fixation best in non-articular fractures
Combined approach reduces tissue injury around fracture
Gradual reduction possible
Apply Ilizarov Method, not just the fixator.

Absolute indications

- Fractures with bone loss (bone transport and bifocal compression-distraction)(see Chapter 12.57)
- Infected fractures (see Chapter 12.15)
- Non-articular metaphysodiaphyseal junction fractures
- Highly fragmented diaphyseal fractures
- Schatzker V bicondylar tibial fractures
- Fractures with pre-existing bony deformity or limb length discrepancy
- Delayed presentation with difficulty restoring alignment.

It should be remembered that articular fractures require accurate joint reduction and rigid fixation to allow healing, early movement, and functional recovery. Early weight bearing is rarely a prerequisite in treatment. External fixation works best when it can be applied without opening the fracture and where good limb alignment and early weight bearing is required. For these reasons, it is advisable to apply internal fixation to articular fractures and reserve the Ilizarov method for non-articular injuries. However, the two techniques can be used together, particularly in the proximal tibia with open reduction and limited internal fixation of the joint surface, combined with stabilization of the ‘reconstructed joint fragments’ on the tibial diaphysis using a circular fixator. This combination reduces soft tissue stripping around the fracture and allows adjustments to limb alignment after fixation.

A new fracture in a bone with a pre-existing deformity (especially shortening) gives an opportunity to treat the fracture with correction of the deformity. Ilizarov fixators allow placement of hinges at the CORA (centre of rotation of angulation) of the deformity with stabilization around the fracture. A corticotomy may be performed if the fracture is distant from the CORA.

When patients present late after fracture it may be difficult to reduce the fracture acutely to an acceptable position. Circular fixation can allow gradual reduction over several days. Similarly, some open injuries can have primary closure of the wound with the fracture shortened or angulated. The length and alignment can be restored gradually after wound healing with a circular frame.

The Taylor Spatial Frame (TSF) has been advocated in this mode. This computer-assisted frame allows multiplanar correction but must be used with all the principles of the Ilizarov method. The computer cannot compensate for poor planning, application, or understanding of the method.

Relative indications

- Schatzker VI articular fractures of proximal tibia
- Pilon fractures
- Fractures with severe joint destruction (allowing primary arthrodesis)
- Segmental fractures
- Articular fractures with instability of adjacent joints
- Midfoot and calcaneal injuries
- Open fractures in children.

There may be many more relative indications for circular external fixation. The following sections deal with fixation in specific fracture groups.

Upper limb fractures

Few acute upper limb injuries require circular fixators. In the humerus, severe bone loss, infected fractures, extensive highly fragmented fractures, and distal fractures with elbow instability may be relative indications. The Compass Hinge fixator allows protection of elbow ligament reconstructions and complex fracture fixations with a large range of motion. However, it should be noted that the application of a circular frame to the humerus is difficult, requiring extensive knowledge of cross-sectional anatomy.

In our experience there is almost no indication for ring frames in acute fracture of the clavicle, radius, or ulna. The principles of rigid internal fixation with early recovery of joint motion are perhaps best applied to these fractures.

Femoral fractures (Box 12.15.3)

Most diaphyseal femoral fractures can be treated by intramedullary nailing. External fixation has been advocated in those patients who have concomitant severe chest injury, contaminated open fractures, or multiligamentous fractures of the distal segment (knee bridging fixation). The hybrid advanced system of frame application allows stable fixation of the proximal femur without transosseous wires. This has extended the use of circular frames in this region.
Circular frames are useful in the upper femur in bone loss fractures of more than 2cm. We have applied frames to such fractures with extensive soft tissue injury, allowing stable bone fixation with full weight bearing within a few days. Compression-distraction or bone transport may progress in parallel with limb rehabilitation.

**Box 12.15.3 Femoral fractures**

- **Indications:**
  - Bone loss >2cm
  - Fractures which cannot be nailed
  - Fracture below deformity (e.g. old fracture)
  - Osteoporotic articular fractures
  - Primary arthrodesis after fracture

- Circular frames may have lower non-union and malunion rates than monolateral fixators.

Circular fixation may also be employed where intramedullary nailing of a shaft fracture is technically impossible. Fractures occurring below an area of deformity in the proximal femur or adjacent to an implant may be well fixed with a ring frame.

In complete articular fractures of the distal femur, rigid fixation of the articular fragments will give the best joint surface for mobilization. In the elderly, osteoporotic bone stock and deficient soft tissues may make extensive open reduction and internal fixation (ORIF) inappropriate, risking high infection rates and fixation failure. Minimal internal fixation of the femoral condyles combined with circular fixation of complex metaphyseal fractures offers advantages of secure fixation of the joint surface with minimal disruption of the soft tissue envelope around the distal femur.

Infrequently, destruction of the joint surface is such that it is impossible to reconstruct any useful joint. Circular external fixation is perhaps the method of choice for primary arthrodesis of the knee in this situation (Figure 12.15.1). If necessary this may be combined with restoration of limb length via a proximal corticotomy and distraction.

**Box 12.15.4 Indications in tibial fractures**

- Significant bone loss
- Non-articular metaphyseal fractures
- Significant fracture comminution
- Associated soft tissue loss
- Combined with minimal ORIF in complex articular fractures
- Pilon fractures—fixator may cross the ankle joint for first few weeks.

**Fig. 12.15.1**
A) A severe open fracture of the distal femur with loss of the joint surface and gross instability; B) a four-ring frame has been applied to allow primary fusion; C) complete fusion after frame removal.
Tibial fractures (Box 12.15.4)

The tibia is unique in that it is easily accessible and has poor subcutaneous tissue cover over much of its length. Open operations may risk deep infection, wound breakdown, and non-union. Most closed and many open diaphyseal fractures are best treated with intramedullary nails but there remains a range of patients and fracture types in which these implants are suboptimal.

Circular fixators are best applied for non-articular fractures at the upper or lower metaphyso-diaphyseal junctions. These can be reduced closed with the fixator. They can be aligned easily and frames allow immediate weight bearing and short times to union. These fractures are often too proximal or distal to nail and plate fixation risks soft tissue complications, even with minimally invasive techniques.

In diaphyseal fractures with extensive fragmentation, circular frames allow excellent stabilization without further soft tissue injury around the tibia (Figure 12.15.2). In open fractures with soft tissue loss and a high-energy fracture pattern a circular frame may be applied with shortening of the limb to allow skin closure followed by gradual distraction after wound healing to restore limb length.

Segmental or complex open tibial fractures in children present fixation challenges. Intramedullary devices are contraindicated with active physes. Circular frame fixation may be used in these cases (Figure 12.15.3). Healing times are short in children, and frames can often be removed within a few weeks.
frame removal with fracture union, good alignment, and correct leg length. The physes were unaffected by the injury or fixation. F), G), and H) Functional outcome 12 months after injury. Active ankle dorsiflexion remains reduced due to loss of muscle power.

As stated previously, intra-articular fractures without dissociation from the tibial shaft (Schatzker I–IV) and similar ankle fractures (AO Muller Type B) require reduction and internal fixation. A few undisplaced articular fractures may benefit from circular fixation alone, particularly with poor skin cover.

Bicondylar fractures without joint surface damage (Schatzker V) can be well treated with circular frames applied in a closed manner. Careful reduction in the frontal and sagittal plane is needed. Schatzker VI injuries will usually need open reduction of the joint surface with internal fixation. The circular fixator provides excellent control of the shaft fracture.

Pilon fractures are characterized by comminution of the joint surface including coronal splitting of the plafond (Figure 12.15.4A, B). They require open reduction of the joint surface. Circular external fixation combined with minimal internal fixation provides adequate stabilization for sound bony union (Figure 12.15.4C). In many cases, the ankle joint is bridged with the fixator, distracting the joint, protecting the cartilage and preventing equinus contracture. Once the articular element of the fracture is uniting, the foot extension can be removed and ankle motion started (Figure 12.14.4D).

Fig. 12.15.4
A) Anteroposterior radiograph of an open Type C3 pilon fracture. B) Lateral radiograph demonstrates the metaphyseal destruction and coronal split of the joint surface. C) A three-ring frame is applied with minimal approach internal fixation to secure the joint surface. D) At 6 weeks the foot frame is removed and gentle ankle movement begins. Touch weight bearing is encouraged up to 10 weeks with increased weight bearing thereafter. E) Fracture union and frame removal at 19 weeks. The ankle mortise has been restored and alignment is good. F), G) Functional outcome at 28 weeks. The patient sustained a minor injury to a toe while jogging!

The components of circular external fixators (Box 12.15.5)

Circular fixators may look complex but they consist of simple parts which fall into four groups:

- Rings can be partial (1/2 or 5/8) or full. Carbon-fibre rings are lighter and radiolucent, allowing visualization of bone regenerate or fracture callus
- Connecting rods are usually threaded, providing gradual compression or distraction between rings but telescopic rods are also available. Four rods are normally required between each ring. The TSF uses six oblique extendable rods attached via universal joints
- Fine wires: flexible 1.5-mm and 1.8-mm wires provide transosseous fixation of the rings to bone. These are tensioned using a calibrated tensioning device. Olive or stopper wires are available with a bead one-third along the length of the wire to allow compression across oblique fracture lines or to move bone segments during treatment
  - Steel or titanium threaded half-pins may be used with fine wires, particularly in the humerus or proximal femur
  - Special parts include plates, hinges, supports, slotted rods, arches, pin clamps, universal joints, and translation–rotation blocks. They allow fixators to move bone segments during osteogenesis.

General principles of circular fixator application (Box 12.15.6)

Meticulous preoperative planning with the patient and the radiographs is essential. Patients may spend many months in a frame and must fully understand the commitment that is required for a good outcome. If possible, patients should see a typical frame before surgery, appreciate the problems that may arise during treatment, and have access to information and help when problems occur.
It is usually inadvisable to apply a circular fixator for multiple lower-bone fractures or multisystem trauma during the initial surgery for open fractures and life-saving procedures. If a circular frame is indicated, the limb may be temporarily stabilized with a bridging monolateral fixator with later conversion.

A sound knowledge of the cross-sectional anatomy of the limbs is necessary for safe wire placement. Variations in neurovascular anatomy and displacement of structures by fracture must be sought to avoid nerve or vessel injury.

Frame application begins with the insertion of reference wires, usually at the ends of the long bones, under radiographic control. An understanding of the anatomical and biomechanical axes of the limbs allows correct frame orientation on these wires and prevents secondary deformities. Where possible, transosseous wires should be passed far enough away from joints to avoid an intra-articular passage, reducing the chance of septic arthritis.

### Box 12.15.5 Components

- Rings
- Rods
- Fine wires/half-pins
- ‘Special parts’.

### Box 12.15.6 General principles

- Preoperative planning essential
- Consider delayed frame application in polytrauma patients
- Knowledge of cross-sectional anatomy essential
- At least 2 cm between ring and skin
- Avoid soft tissue tethering to protect joint motion
- Usually two rings above and below the fracture.

Rings should be chosen that allow at least 2cm of clearance all around the limb. Very large rings are avoided as they reduce the stability of the frame and are inconvenient.

It is important to tension all fine wires around a circular frame. In general, tensions of 100–130kg are recommended to provide sufficient stability and axial loading.

### Application of specific circular fixators

These constructs are based on the hybrid advanced system (HA system) devised predominantly in Lecco, Italy. It provides variations on the traditional ‘all-wire’ Ilizarov designs, making fixation easier and is better tolerated by patients.

### Fractures of the humerus

In practice, different frame constructs are used for fractures in the upper, middle, and lower segments of the humerus. The four-ring frame described for middle-third injuries can be modified for specific fractures throughout the bone.

The preassembled frame is composed of a 5/8 ring distally, two intermediate rings and a proximal arch (Figure 12.15.5). One reference wire is inserted distally and one half-pin proximally to align the frame to the humerus. The frame is applied to these and middle-third wires are added avoiding the neurovascular structures as Additional distal wires and half-pins are placed. A modification of this frame may be used for bone segment transport in the treatment of humeral bone loss.
In some fracture patterns, or in obese patients, a variation of this system can be applied using two arches proximally, one intermediate ring, and the distal 5/8 ring (Figure 12.15.6). This frame, although less stable to angular motion, is tolerated better by patients.

**Femoral fractures**

The standard assembly incorporates a full ring distally, an arch proximally at the subtrochanteric level and one or two intermediate rings depending on the type and level of the fracture. Fixation distally includes a transverse reference wire and two half-pins. Proximal fixation is achieved by attaching two half-pins to the arch as shown. At the intermediate ring or rings, olive wires have traditionally been used to reduce and hold the fracture fragments in alignment. Transosseous wires in the mid-thigh are poorly tolerated by patients for the duration of treatment. Half-pins may be substituted, entering the thigh posterior to the iliotibial band.

**Proximal segment**

The proximal section consists of one 90-degree and one 120-degree arch. It should be secured to the two-ring distal section by oblique support connectors. The proximal arch should be at the greater trochanter and the distal arch is at least 2.5cm proximal to the fracture. The distal ring is located at the base of the femoral condyles and the proximal ring is 2.5cm distal to the fracture (Figure 12.15.7).
Fig. 12.15.7
Hybrid frame construct for proximal femoral fractures and non-unions.

The first reference wire is inserted at the base of the condyles in a transcondylar manner from lateral to medial and perpendicular to the anatomical axis of the femur. After placement of this wire, rotation must be checked. The proximal half-pin is inserted from posterolateral, at the level of the greater trochanter. During attachment of the half-pin to the arch, the frame must remain centred on the thigh. Wires and/or olive wires are then utilized to reduce the fracture. Reduction is confirmed with the aid of a C-arm image intensifier in both planes. After reduction, the remaining half-pins and wires are inserted as shown (Figure 12.15.7). Wires used for reduction, which are in a position which might cause irritation or pain, should now be removed.

Diaphyseal segment

This frame consists of four levels constructed to allow 5–6cm between the upper and lower sections, giving an unobstructed radiographic view of the fracture (Figure 12.15.8).

Fig. 12.15.8
Four-level frame for diaphyseal femoral fractures.

The frame is aligned as before. The proximal arch and distal ring are secured as before. The two central rings are fixed with lateral half-pins and tensioned wires passing from posterolateral to anteromedial, exiting anterior to the femoral artery.

Distal segment

A similar frame can be used for the distal segment, concentrating the three rings around the fracture (Figure 12.15.9). The two distal rings are connected with hexagonal sockets measuring 2, 3, or 4 cm, depending on the length of the distal fragment.
Fig. 12.15.9
Four-ring frame for distal femoral fractures. This frame can be used for intra-articular fractures with or without additional internal fixation.

A variation is needed when the distal fragment is small and there is not enough space for two rings below the fracture. In this case a single distal ring is used, fixed as before but the frame is continued across the knee to include a ring at the proximal and distal tibial metaphysis. The femoral and tibial sections can be connected with hinges to allow some knee motion.

Tibial fractures

There are many variations in frame design for complex tibial fractures or intra-articular fractures but the following description provides a basic system for the commonest indications.

Complex proximal intra-articular fractures with dissociation of the tibial shaft (Schatzker types V and VI)

The preassembled frame consists of one ring above and below the metaphyseal fracture and a single ring on the distal tibia (Figure 12.15.10). The intra-articular component of the injury must be reduced anatomically. When there is no displacement, the frame can be applied without open reduction. Periarticular fragments may be secured with screws or olive wires.

Fig. 12.15.10
Three-ring frame for proximal tibial articular fractures. Note the olive wires in the condylar fragments.

After joint reduction, two reference wires are passed transversely through the proximal and distal tibia perpendicular to the anatomical axis of the bone. The frame is aligned and further fixation is achieved with a second wire distally, passing through the fibula and tibia. The central ring is fixed with a single wire passing from anterolateral to posteromedial, avoiding the bulk of the muscles and a half-pin perpendicular to the subcutaneous surface of the tibia. Fixation on the proximal ring is completed with two olive wires on either side of the reference wire. The position of these wires can be varied depending on the fracture configuration. A similar frame may be used for metaphyseal fractures without joint involvement, especially in those with osteoporotic bone.

Complex fractures of the tibial diaphysis

A four- or five-ring frame will be needed depending on the fragmentation of the fracture (Figure 12.15.11).
Two reference wires are inserted as before and frame alignment is checked. Tibial length is then restored with gentle distraction, aiding reduction. Olive wires may be inserted to reduce the central fragments. After complete reduction, stability is improved with anteromedial half-pins and perpendicular wires where possible and a distal fibular wire.

Distal tibial fractures involving the ankle joint

Circular external fixation provides stabilization of the metaphyseal component of the injury after open reduction of the joint. The preconstructed frame consists of two rings for the tibia, connected to a foot frame with threaded rods, and an intermediate ring at the level of the tibiofibular syndesmosis (Figure 12.15.12). The proximal section is fixed to the tibia as described earlier. The foot frame is fixed with two olive wires in the heel and two wires in the forefoot. Distraction is performed between the tibial section and the foot frame, causing ligamentotaxis (Figure 12.15.13). The fracture is openly reduced, restoring the joint anatomy perfectly. The fracture fragments are further stabilized with bone grafts, olive wires, or screws. After wound closure, the intermediate ring and wires are applied at the level of the fracture for further stabilization (Figure 12.15.12). Distraction is maintained between the foot and tibia, off-loading the articular cartilage. Distraction is removed after 1 month and the connecting rods are substituted with hinges, allowing ankle motion. At 6 weeks, the foot frame is removed and progressive weight bearing is begun until fracture union.
Initial frame application with joint distraction can aid reduction of the joint surface. Additional internal fixation is often advisable in these fractures, particularly for coronal fractures.

Postoperative care of circular external fixators (Box 12.15.7)

Recovery of limb function is the primary goal of fracture care. The patient must be fully involved in the rehabilitation with education and encouragement. Passive and active joint motion begins on the day after surgery. This will require adequate analgesia and supervision with a physiotherapist. Resting splints for neighbouring joints (especially the ankle) will prevent contractures.

For intra-articular fractures, weight bearing may be delayed for several weeks but otherwise early loading will enhance fracture healing and reduce the time spent in the fixator.

Box 12.15.7 Postoperative care

- Engage the patient in all aspects of care
- Encourage early movement with physiotherapy
- Encourage early weight bearing in non-articular fractures
- Regular check for wire tension/fracture malalignment
- Pin-site care essential.

The fixator must be regularly checked (initially weekly) to detect loss of wire tension or deformation of rods. Loose or broken wires will become painful and predispose to pin-site infection. If adjustments are being made for compression, lengthening, or angular corrections then patients should be encouraged to make the adjustments themselves. This promotes acceptance of the frame and integration into the normal activities of daily living.

Pin-site care is mandatory. Minor problems with wires and half-pins are common but major pin sepsis can be avoided with good care. The Oxford protocol is available at: http://www.noc.nhs.uk/limbreconstruction/information/pin-site-care.aspx

When union is complete, the fixator can be removed. In children this should be done with a brief general anaesthetic, but in adults sedation and analgesia will suffice. It is not recommended to transfer limbs from a circular frame to a cast in order to shorten the fixator time as this negates the benefits of early joint rehabilitation. After removal the patient must be reviewed with radiographs of the region as late deformity or refracture may occur with premature frame removal.

Further reading

Monolateral external fixation is a system for the stabilization, reduction, and manipulation of bone segments by means of bone anchorage consisting of pins fastened to an external frame. Monolateral external fixators in their various forms have the advantage that they allow the use of half-pins (bicortical pins that do not penetrate both sides of the soft tissue envelope), thereby avoiding major damage to the neurovascular structures contralateral to the insertion point. The simple structure of monolateral systems permits rapid application and simplified preoperative planning, both of which are features particularly appreciated in traumatology.

The external construct may present different configurations according to the type of fixator used or the application for which it is designed (Box 12.14.1).

**Box 12.14.1 Types of monolateral external fixation**

- One plane versus two plane
- Simple versus clamp
- Static versus dynamic.

We can distinguish between two major types of monolateral fixators: **one-plane monolateral fixators** (Figure 12.14.1) in which clusters of pins are placed practically in the same plane, and **two-plane monolateral fixators** (Figure 12.14.2) in which pin clusters are placed in different planes and joined by the frame in two planes.
Monolateral fixators can also be differentiated on the basis of how the pins are connected to the frame. Simple fixators (Figure 12.14.3) have independent articulations which connect each pin with a rigid longitudinal rod, and clamp fixators (Figure 12.14.4) have pin clusters connected to a clamp which introduces the option of adjustments between the clamp and fixator body.
In addition, external fixators can be subdivided into static fixators and dynamic fixators on the basis of their intrinsic dynamization capability. This characteristic will be considered in the section on the biology of healing.

Simple fixators have the distinct advantage that each pin can be placed at a different angle in relation to the fixator rod, and that the distance between two pins in a bony fragment can be freely chosen in relation to the soft tissue lesion and depending on the mechanical needs of the frame bone construct. A disadvantage is the need for reduction of the fracture prior to fixator application and the fact that external manipulation manoeuvres, particularly rotation, can only be performed by replacing one or more pins.

Advantages of clamp fixators are that they allow fracture reduction after the fixator has been applied and that subsequent adjustments can be performed fairly easily by loosening the universal articulations between the fixator body and the clamps. Disadvantages are the need to resort to supplementary external systems whenever gradual multiplanar adjustments are required; pin cluster placement and spread are strictly dictated by the clamp configuration.

**Mechanics (Box 12.14.2)**

The basic elements to be considered in the mechanics of a monolateral fixation system are as follows:

- Pins
- Wires
- Bone–fixator distance
- Stability of the bone–fixator fastening system
- Frame geometry. Nowadays, the barrier between monolateral and circular fixator is no more so rigid, due to the use of so-called hybrid fixators that combine pins and transfixing wires joined by monolateral and circular frame. These are particularly useful in periarticular fractures in order to take advantage of the transfixing wires in the metaphysis and of the pins in the diaphysis.
- Frame material. Radiolucent materials improve visualization of fracture reduction and healing. The mechanical properties have been tested mechanically and clinically and have shown stiffness characteristics comparable to the fixators currently employed.

The pins play the most important role in the stability of the entire system. When assessing the ideal type of pin, the following parameters must be considered:

- Pin diameter
- Number of pins
- Type of thread
- Pin insertion technique
- Pin material
- Pin coating.

The **pin diameter** must be such as to minimize the risk of breakage at the pin entry point. At the same time the pin must possess a sufficient degree of stiffness to ensure adequate implant stability. A pin hole greater than 30% of the diameter of the bone results in a 45% reduction in the torsional strength of the bone. The bending stiffness of the pin increases as a function of its radius by the power of four. If we know the diameter of the bone, the thickness of the cortex, the elastic modulus of the bone, the number of pins to be applied, the elastic modulus of the pin material, and the load applied, we can calculate the minimum pin diameter allowed in order to obtain a stable implant in relation to different bone–fixator distances.

**Box 12.14.2 Mechanics of monolateral external fixation**

- **Screws:**
  - Larger screws are stronger but weaken bone
  - Tapered conical screws gradually increase preload
  - Number of screws increases stability
  - Predrill screw holes to reduce thermal necrosis
  - Hydroxyapatite may enhance bone purchase

- **Bone fixation distance**—increased bone–fixator distance reduces stability
- **Stability bone and fixator fastener**—screw–body junction is weak point
- **Geometry of frame**—stability may enhance healing but too much rigidity may inhibit it.

In adult bone, a pin of diameter 6mm enables this requirement to be satisfied for bone–fixator distances up to 6cm, while maintaining the specific pressure at the entry cortex below one-third of the tensile strength of the bone tissue.
The load distribution in a monolateral implant is asymmetric, being greater at the entry cortex than at the exit cortex. For this reason a tapered conical pin can be employed and proves particularly useful. The taper ratio produces a gradual increase in radial preload. Pin–bone contact is optimized and the micromovements typical of a straight cylindrical pin inserted in a predrilled hole are avoided.

Increasing the number of pins leads to an increase in implant stability, as does spreading the pins across the bony segment. Maximal stability for a construct with two pins per segment occurs when one pin is close to the fracture site and one is as far away as possible. With a sufficiently rigid frame two or, at most, three pins per fracture segment will be enough to ensure adequate stability regardless of their spread.

The type of pin thread is determined by the shape, pitch, and pitch height. Various types of pins with different morphological characteristics are commercially available. The pin design must make allowance for the quality of the bone to which the pin is applied, with different designs being necessary for cancellous and cortical bone. The pitch vertex angle and the curvature radius at the base of the pin will have an effect on the insertion torque and thus on the temperature generated during pin insertion.

The pin insertion technique influences the bone–pin interface and thus the stability of the entire system over time. The use of self-drilling pins is associated with microfractures (particularly in cortical bone) and with the development of temperatures above 50°C which may cause thermal necrosis. Pre-drilling using very sharp drills minimizes thermal necrosis and bone damage, allowing the use of self-tapping conical pins which afford optimal bone purchase in that each thread cuts its own path as the pin advances. The advantage of such pins consists in their easy removal, often in the outpatient clinic, while the disadvantage is related to the fact that they cannot be backed out, even partially, without complete loss of bone purchase.

The pins must be made of biocompatible material and have substantial stiffness, making the use of stainless steel preferable. Titanium pins have been shown to be more elastic and this reduces pin loosening.

Pin coating with hydroxyapatite improves bone purchase by providing a better pin–bone interface. This reduces pin loosening and pin tract infection. They are recommended in implants applied for a long time and osteoporotic bone.

As the bone–fixator distance increases, implant stability decreases. This must always be borne in mind when deciding on the number of pins to be used and the initial weight-bearing load that the patient is to be allowed. In particular, in applications at the femoral level, the number of pins applied per fracture segment needs to be increased and the patient allowed to bear only a partial load for the first 2–4 weeks.

The weakest part of any system is the junction between the fixator body and the clamp, or directly between the fixator body and the pins. Here, one needs to know the mechanical yield characteristics of these elements through adequate information which should be provided by the manufacturers. In order to avoid secondary fracture displacements, the yield point of each system must be established in relation to the clinical bone–fixator distance, the load applied, and the fracture conditions.

The stability of simple and/or clamp fixators can be enhanced by increasing the number of pins or external rods. An example of this may be the delta or triangular configurations that can be created. In practice, increasing the number of components is less effective and clinically less desirable than increasing the size of the individual components, which increases the bending stiffness to the power of 4 and resistance to torsion to the power of 3. A greater pin diameter, particularly in the entry cortex, is also known to enhance implant stability in monolateral fixation. For these reasons, the latest types of monolateral systems tend to have larger pin diameters and to use conical pins and fixator bodies of fairly large size compared with the rods used in the past.

However, stability must not be confused with rigidity, which is a condition which causes delays in consolidation, pseudoarthrosis, increased screw loosening, and pin-tract infections. Excessively rigid constructs should be avoided and the latest generation of stable fixators should incorporate fracture-stimulation systems such as dynamization.

### Biology (Box 12.14.3)

The natural healing of a fracture proceeds through the well-known phases of inflammation, repair by periosteal callus formation, and remodelling, which depend on numerous variables such as the degree of soft tissue involvement, the reduction obtained, the type of fracture and the stability of the fixation. The type of healing obtainable with external fixation depends on the mechanical characteristics of the device used and the stability of the implant.

In a transverse fracture anatomically reduced and fixed with a rigid external fixation device in such a way that the weight-bearing forces are fully absorbed by the fixation system, healing is of the direct type, without callus formation, via a biological process akin to that associated with the use of rigid compression plates. Direct-type or contact healing requires lengthy time periods to restore the mechanical stability of the bony segment.

When an external fixator has been applied it is always necessary to consider the behaviour of the pin–bone interface, which deteriorates over time, in relation to the healing process. Thus the type of healing that should be achieved by external fixation must be of the periosteal type, as occurs without rigid fixation, which is quicker and stronger. It is only in this way that consolidation can be achieved in a relatively short period of time, which is essential for minimizing the most feared complications of external fixation such as pin loosening and pin-tract infection which in turn result in instability of the bone frame construct and may be a possible cause of pseudoarthrosis.
The conditions necessary for achieving periosteal healing with external fixation are as follows:

- Sparing of the soft tissues at the fracture site
- Adequate reduction
- Transmitting controlled micromovements to the fracture site.

Sparing fracture site can be achieved by placing the pins at an adequate distance from the fracture site (at least 1.5 cm) and by seeking preferably a closed reduction solely by means of external manipulation of the segments. It has been demonstrated that the combination of external fixation with internal fixation with interfragmentary lag screws at diaphyseal levels to contain and reduce segmental fractures leads to an increased incidence of pseudoarthrosis. This is related to the different types of repair biology which the two systems create: interfragmentary—direct healing; external fixation—periosteal healing.

The reduction must be adequate and avoid large gaps which may indicate interposition of soft tissues, and axial alignment must be accurate. However, the reduction does not have to be anatomical where interfragmentary movements might be inhibited.

Micromovements are of fundamental importance for the development of the periosteal callus and distinctions need to be made in terms of quality, extent, and time of application. In this sense we can distinguish between static and dynamic fixators.

Lastly, from the biological standpoint, external fixation allows formation of new bone starting from an osteotomy or fracture site, when a gradual progressive distraction force of varying proportions depending to the bone response is applied. Distraction induces bone formation with an intramembranous-type ossification when the frame is stable; the newly formed bone eventually becomes mature and normally corticalized. This characteristic of bone repair under distraction can be exploited to remedy limb discrepancies and loss of bony substance as well as to perform gradual angular adjustments.

**Dynamization (Box 12.14.4)**

The term dynamization indicates converting a static fixation into a fixation which allows the passage of forces and/or the possibility of stimulating the fracture site with controlled micro movements. In a monolateral fixation, dynamization may be of three types:

- Passive
- Active
- Induced.

Passive dynamization is achieved when the fixator is placed in a static configuration and the patient applies a load to the limb in such a way as to exert a significant force (usually above 200N). In this case the micro movements are cyclic and are applied in an asymmetric manner on the fracture callus through the bending of the pins, which, in modern monolateral fixators, are the most elastic elements in the entire frame. In the long run, this type of dynamization will lead to asymmetric callus formation, thereby facilitating pseudoarthrosis (Figure 12.14.5).

**Box 12.14.4 Dynamization of fixator**

- Passive— asymmetrical by screw bending
- Active— telescopic slides
- Induced— manual or mechanical.
Active dynamization is achieved by releasing the telescopic slides on the bodies of fixators possessing these features, hence the term dynamic fixators (Figure 12.14.6). When bearing weight or applying a load, the patient brings about the progressive closure of the fracture gap; tissue stimulation is of the concentric type and is conducted mainly along the longitudinal axis of the telescopic element, which at the time of assembly must lie parallel to the main axis of the bony segment. This kind of dynamization may be of the free or controlled type. In the latter case, the fixator is equipped with systems which limit the excursion capability of the telesystem and at the same time provide for an elastic recoil after the loading phase.

It has been demonstrated that when all of the fixator joints were allowed to adjust simultaneously during dynamization, exact axial movement or uniform compression at a complicated fracture site was achievable. This study revealed that significant non-axial movements may occur during dynamization, and that such a deficiency can be corrected by relaxing certain fixator joints in addition to the sliding mechanism. The same modelling technique can also be applied in bone lengthening application to assure desirable limb alignment during the distraction process. These analysis results can aid the performance assessment of an external fixator and facilitate appropriate application of such a device to achieve either active or controlled axial movement.

Induced dynamization may be manual or mechanical and is applied according to known quantities and frequencies via external actuators. Kenwright and colleagues applied this type of controlled mechanical stimulation to tibial fractures, starting with a 1-mm movement at 0.5Hz for 30min daily a week after application of the fixator until a load of at least 200N was reached by ambulation. The patient group submitted to dynamization healed earlier than a control group treated with static fixation.

Induced dynamization can also be applied manually, with micromovements induced from the first week after surgery with the purpose of achieving early stimulation of callus formation even in bedbound patients or patients incapable of bearing weight on the limb.

The biological effects of dynamization have been demonstrated in a number of studies.
From the anatomical standpoint monolateral fixation presents no limitations and as a result of the versatility and apparent simplicity of application it may be regarded as indicated for most traumatic or orthopaedic injuries. In practice, however, it is necessary to define the limitations related to considerations of a mechanical nature, such as the stability of the fixation construct, the durability of the pin–bone interface, complications directly associated with external fixation, biological and clinical considerations, such as patient tolerance and the quality of the bone tissue or of the adjacent soft tissues, and the feasibility of adequate patient surveillance in the outpatient setting.

Therefore it is useful to define relative contraindications to external fixation (Box 12.14.5):

- Obesity
- Pronounced osteoporosis
- Psychological and emotional instability
- Impossibility of obtaining satisfactory patient compliance, particularly in terms of adequate scrupulous attention to loading rules, pin care, and regular attendance of scheduled ambulatory checkups.

<table>

<tbody>
<tr>
<td>♦ Obesity</td>
</tr>
<tr>
<td>♦ Osteoporosis</td>
</tr>
<tr>
<td>♦ Psychological or emotional instability</td>
</tr>
<tr>
<td>♦ Poor compliance.</td>
</tr>
</tbody>
</table>

There are also a number of relative contraindications related to the bony segment treated. Application of a fixator to the femur entails crossing soft tissues of such thickness as to create a bone–fixator distance which makes the fixation construct comparatively less stable than in other segments and leads to more serious extension–flexion disorders of the knee.

The indications for external fixation in traumatology are as follows:

- Open fractures
- Complex closed fractures
- Fractures in multiply traumatized patients
- Pelvic fractures
- Complex joint fractures.

In orthopaedic surgery, monolateral fixation is used in the following cases:

- Lengthening
- Pseudoarthrosis
- Corrective osteotomies
- Reconstruction surgery for substance loss.

Open fractures (Box 12.14.6)

Monolateral fixation affords definitive treatment of open fractures. The systems currently employed achieve optimal stability, and frame stiffness can be adjusted over time to adapt to biological needs.

The prognosis of an open fracture depends mainly on the degree of soft tissue injury, the extent of the bone comminution, and the degree of bacterial contamination. Immediate stabilization of the bone lesion, administration of adequate broad-spectrum antibiotic prophylaxis (it is mandatory to perform a bacteriology specimen at the beginning of the debridement and at the end of the procedure in order to assess the pathogenic flora and adjust the antibiotic therapy), elimination of necrotic tissue with repeated debridements, and subsequent coverage of bone by replacing soft tissue substance losses as quickly as possible are necessary to optimize results. These manoeuvres are facilitated by the use of monolateral external fixators. Stability is achieved without interference at the fracture site. In particular, it is of paramount importance that the fracture be adequately reduced. A partial load is permitted as soon as the patient’s general condition allows and the soft tissue lesions are healing. Further fracture callus stimulation is subsequently applied by dynamization. A stable dynamizable monolateral external fixation should be generally regarded as a definitive form of treatment and not merely as a form of temporary stabilization.

Reports have demonstrated the possibility of achieving a healing rate of more than 90% with a malunion rate of less than 5% by the use of monolateral fixators. One study reported the outcomes of 101 open tibial fractures treated with axial dynamic fixators, including 63 grade III fractures, with pseudoarthrosis occurring in five cases and infection in six.

Recently there is a tendency to perform a temporary stabilization by external fixation in deep soft tissues lesions. After thorough care of the local damage, when there is evidence of recovery of the external mantle and absence of contamination, the external fixation, used for bony stabilization, can be substituted by internal synthesis as a definitive treatment. This is used following the
principles of 'local damage orthopaedics' and it is intended to minimize the incidence of osteomyelitis and infected non-union. For this reason, the conversion must be performed only when the earlier mentioned conditions are contemporarily present, unless external fixation can be used as a definitive method of treatment.

Box 12.14.6 Open fractures

- Monolateral fixations allow stabilization, repeated debridement, and soft tissue coverage
- Healing rate >90%
- Malunion rate <5%
- 5% pseudoarthrosis.

Complex closed fractures

In diaphyseal open fractures of the lower extremity, an alternative treatment to monolateral external fixation is intramedullary nailing, which has a decreased rate of angular malunion. External fixation should be favoured when there is greater contamination or more severe soft tissue injury (Figure 12.14.7).

Fig. 12.14.7
Bifocal subtrochanteric metadiaphyseal fracture of the femur in a polytraumatized patient undergoing emergency treatment with open external synthesis. The clinical course was favourable with good callus formation and the possibility of removing the external fixator 18 months postoperatively.

A monolateral external fixator allows rapid closed reduction which enables the surgeon to limit operative time and blood loss. This is useful in those patients with multiple trauma or at anaesthetic risk. Therefore this group of patients can be treated with external fixation even if the type of fracture would lend itself to other methods.

Femoral fractures in patients during growth, especially in multiple trauma, may be treated with external fixation. Other indications include unstable fractures, such as proximal-third fractures, and complex metaphyseal fractures, particularly those associated with a high-grade soft tissue injury.

Box 12.14.7 The use of monolateral external fixation in multiple trauma

- Minimal blood loss and operating time
- Conversion to internal fixation only in first 2 weeks
- Early micromovement is essential.

Fractures in multiply traumatized patients (Box 12.14.7)

The multiply traumatized patient, particularly when simultaneously presenting with a thoracic or cranial trauma, requires early stabilization of the long bones in order to reduce the risk of acute respiratory distress syndrome (ARDS), to decrease time in the intensive care unit, and to decrease the period of ventilatory support.

If the stabilization is performed within 24h, the incidence of ARDS is 7%, compared with 39% if more than 24h has elapsed. However, certain injury combinations may preclude lengthy internal fixation procedures.

External fixation in its monolateral form allows early stabilization with closed reduction, minimal blood loss, and short operative times compatible with the severity of the associated lesions. The benefits of early stabilization are achieved with minimal surgical result.

If external fixation is chosen in the acute period for long-bone stabilization, it is necessary to decide whether the external fixation needs to be kept in place until healing is achieved or whether there is scope for replacement with intramedullary nailing so as to reduce pin-tract problems, increase fixation stability, and afford a better range of movement. Replacement operations must be decided on the basis of the type of fracture (periarticular fractures prove difficult to treat with intramedullary nailing) and the patient’s general condition. Conversion from external to internal fixation should be done within 2 weeks of frame application to reduce the
risk of osteomyelitis.

A definitive stable monolateral external fixator with a system for micromovement and subsequent dynamization is an alternative to internal fixation. Micromovement is necessary in the non-ambulant patient to ensure an adequate healing rate.

**Pelvic fractures (Box 12.14.8)**

The stabilization of unstable pelvic fractures in both the horizontal and vertical planes by external fixation is part of the surgeon’s resuscitative armamentarium. Continuous blood loss and the resulting difficult haemodynamic compensation can be decreased by means of early stabilization with external fixation (Figure 12.14.8).

![Fig. 12.14.8](image)

Click to view larger

Fig. 12.14.8
Horizontally and vertically unstable pelvic lesion. The first manoeuvre is to stabilize the pelvis with an anterior assembly. This assembly is unable to ensure stability at the level of the left sacroiliac articulation, which is stabilized later when the patient’s general condition allows. Radiological findings 3 months after surgery show stability of the pelvic girdle.

The retroperitoneal space can contain as much as 900–1000mL of blood which can collect in a very short period of time. External fixation can decrease pelvic volume and control motion which results in a reduction in mortality rates.

Pin insertion is possible either at the iliac crest level or below the anterior inferior iliac spine. In the former case, pin application is percutaneous, whereas in the latter it is open owing to the presence of the lateral femoral cutaneous nerve of the thigh. From the biomechanical point of view it is advisable to choose the anterior application in order to have a better grip of the pin–bone interface due to the thickness of the ilium in the area of insertion and a suitable mechanical performance of the frame in the horizontal plane. Associated posterior instability requires internal fixation after the patient stabilizes.

**Complex articular fractures (Box 12.14.9)**

The ideal treatment of articular fractures entails anatomical reconstruction of the articular surface and adequate stabilization of the meta-epiphyseal lesion so as to permit early rehabilitation. In complex articular fractures, external fixation may be used as an adjunct to obtaining these goals. These fractures present two major problems, namely articular incongruence and metaphyseal comminution. The metaphysis can be treated by means of external fixation, which enables adequate alignment and good stability to be achieved. The treatment of articular incongruence is facilitated by the presence of the fixator distracting across the joint. The articular reconstruction is then obtained with an adjunctive percutaneous (closed reduction external fixation, CREF) or open minimal internal fixation (limited open external fixation, LOREF). In this case the open approach necessary for articular reduction is limited, stripping of periosteeum is reduced, and the use of metallic elements is minimized, thus decreasing the risk of the serious complications, such as pseudarthrosis and infection, associated with wide open approach.

**Box 12.14.8 Pelvic fractures and external fixation**

- Reduced mortality if bleeding is severe
- May be used in isolation in most type B fractures
- Inadequate alone in type C fractures.

Most monolateral external fixators used for articular fractures are spanning fixators, i.e. they cross the involved joint. The external fixator is applied in distraction, utilizing ligamentotaxis with gripping elements placed at a considerable distance from the fracture site. Limited internal fixation of the articular surface is then applied secondarily. The external fixator may also serve as a tool for the definitive fixation of the articular lesion without additional internal fixation, when the reduction obtained is satisfactory, or when a ‘biological’ approach to the treatment of such lesions is adopted from the outset. Less commonly, the metaphyseal fracture may
be treated by placing the monolateral fixator on the same side of the joint. This technique is useful in less comminuted cases, and has been utilized for the distal radius and proximal tibia (Figure 12.14.9).

Fig. 12.14.9
Articular fracture of the wrist in a 37-year-old patient treated with an external fixator with ligamentotaxis. The reconstruction of the joint yields an excellent long-term clinical outcome.

These principles can be applied in various areas, such as the elbow, wrist, knee, or ankle. Experience with modern fixators spanning the elbow and fixing in the humerus and ulna, appears to be encouraging. A hinge articulated at the rotation axis of the elbow allows early mobilization of the joint, thus reducing the incidence of joint stiffness, which is a frequent and serious complication. This procedure appears to be particularly indicated for open or severely comminuted fractures. Furthermore it has been proved that a condition of fracture-dislocation is well addressed by the use of stable internal fixation to treat the bony lesions and an articulated fixator in order to achieve stability and to allow early motion while the ligaments are repairing. Ideally the fixator should be maintained for a period of 6 weeks.

Specific articular fractures

Numerically, the greatest indication for monolateral fixation in traumatology is for fractures of the distal radius using a spanning fixator with or without limited internal fixation. Occasional extra-articular distal radius fractures are amenable to fixation on the same side of the joint.

The following principles must be applied in external fixation of the wrist:

- Fixation of the second metacarpal only with half-pins

**Monolateral external fixation and complex articular fractures**

- Monolateral frame can be used as temporary stabilizer
- Can reconstruct joint with percutaneous or minimally invasive fixation
- Articulated fixation may be used at elbow or knee (controversial).

- Fixation of the radius, avoiding lesions to the superficial branch of the radial nerve (avoid percutaneous application)
- Reduction, avoiding excessive distraction and excessive ulnar deviation (a neutral position is preferable)
- Compare intraoperative trays with normal side for indication and length
- Bone graft or bone substitutes if there is comminution or shortening
- Reduction fixation is required with an intra-articular step-off
- If unstable, adjunctive fixation or reconstruction of the distal radioulnar joint
- Early mobilization of the fingers to facilitate rehabilitation.

The role of joint mobilization via articulated fixators for the wrist is still controversial. Prospective studies have demonstrated that with the Pennig dynamic external fixator there are no differences between the dynamized and the static group.

Similar principles apply to the treatment of intra-articular fractures of the knee. Complex fractures with meta-epiphyseal comminution or major involvement of soft tissues benefit most from external fixation. Knee stiffness is avoided by limiting transarticular external fixation to 40–50 days (Figure 12.14.10).
Fig. 12.14.10
High-energy episdiaphyseal fracture of the proximal tibia. Owing to the epiphyseal comminution, the external stabilization is of the femorotibial bridge type. This is done in conjunction with minimal stabilization for the articular fracture. After 40 days, to allow articulation of the knee and definitive healing of the metaphyseal lesion, the bridge is removed and monosegmental stabilization is performed. Radiological and clinical picture 6 months after removal of the fixator.

Twenty-one complex fractures of the tibial plateau were treated with closed reduction, application of a monolateral fixator, and fixation of the articular fragments. A range of movement of 115 degrees in 19 of the 21 fractures was reported, and the authors concluded that this procedure yields satisfactory outcomes. In this series most cases were treated with the external fixator on the tibia only, not spanning the knee joint.

High-energy fractures of the tibial plafond are a frequent indication for spanning external fixation. Pins can be applied across the ankle joint using an articulated clamp along the rotation axis of the tibiotalar joint. Release of this articulation at 3–4 weeks helps rehabilitation of the joint. The technique is safe and effective, and significantly decreases the treatment-related complications when compared with internal fixation with plates and screws.

Recent studies have demonstrated that the use of circular fixator for high-energy bicondylar tibial plateau fractures have marginal benefits over the use of plates and significant reduction of infections.

Lengthening (Box 12.14.10)

External fixation is a means not only of achieving stabilization and healing of fractures, but also of subjecting bony segments to gradual progressive distraction of an osteotomy area so as to obtain bone-segment lengthening.

The basic prerequisites for achieving such results are stability of the lengthening device and respect for the biological conditions which allow new bone formation, such as sparing of the peristeme, adequate waiting time prior to distraction, and customized distraction in relation to individual osteogenic capabilities.

Equally important is the preoperative patient assessment in order to minimize or prevent possible complications.

The joints adjacent to the segment to be lengthened must be stable and display normal functional capacity. Any muscular contracture must be evaluated in order to avoid aggravating it during lengthening. If necessary, tenotomies must be planned at the time of the first operation or to resolve unresponsive contractures during surgery. The amount of distraction possible must be assessed so as to plan a lengthening in one or more stages. In particular, congenital diseases are more prone to complications related to difficult muscle and tendon extension with the result that lengthenings often need to be done in several stages.

Box 12.14.10 Lengthening using monolateral external fixator

- Adjacent joints must be stable
- Evaluate muscle contractures preoperatively
- Congenital shortening more prone to muscle and tendon problems
- Assess angular deformities and correct
- Assess neurovascular function.

It is equally important to assess the coexistence of associated angular defects in order to be able to plan simultaneous angular adjustments or subsequent adjustments to the lengthening via manipulation of the callus.

Lastly, factors such as bone quality, the possible presence of endocrine–metabolic diseases, and neurovascular function must be carefully considered when establishing indications for lengthening.
The lengthening process is not merely confined to the actual surgery, but requires thorough monitoring by an integrated team of surgeons, physiotherapists, and paramedic staff throughout the distraction and consolidation period until the fixator is removed.

**Osteotomy**

Osteotomies for adjustment of axial or rotational defects can be stabilized in various ways. Often internal fixation is preferred because of the intrinsic stability of the method and the resulting possibility of early rehabilitation. However, the degree of adjustment has to be precise in order to obtain a good long-term outcome, and sometimes it is not simple to achieve the desired result intraoperatively. In this context, external fixation, especially with fixators which allow gradual adjustments, yields precise results with less surgical trauma.

In osteoarthritic genu varum, precision in realigning the load axis appears to be of fundamental importance for achieving clinically acceptable results in the medium to long term with less surgical trauma (Figure 12.14.11).

---

**Surgical reconstruction for bone loss (Box 12.14.11)**

Bone loss can be treated using the principles applied in lengthening. Bone transport may be used where a segment of bone previously osteotomized above or below the gap is gradually transported across the gap to ‘dock’ against the opposite segment (Figure 12.14.12). Alternatively, a compression–distraction can be used where the gap is immediately closed by shortening, followed, either in the same operating session or later, by an osteotomy at another site which allows a lengthening to be performed to restore limb length (Figure 12.14.13).
distal-to-proximal direction. After 18 months the transport was completed. After 23 months, the lengthening site was consolidated, but pseudoarthrosis of the docking site was found, requiring an additional osteomuscular decortication. Healing was achieved in this patient 2 years postoperatively. Follow-up 3 years after healing shows good function and an appropriate mechanical axis of the lower limbs.

The bone-transport procedure is indicated when the loss of substance is more than 4cm in the tibia or more than 6cm in the femur. It is subject to the frequent complication of delayed consolidation or non-consolidation of the docking site, so that an additional procedure is needed to stimulate union.

Compression--distraction allows immediate contact between two viable contact surfaces. If the fracture site is clean and there is no risk of infection for the other sites of the same segment, a lengthening osteotomy can be performed concomitantly in a site which may be proximal or distal to the previously bridged gap. Shortening must not exceed 5cm to avoid vascular or soft tissue problems, although this depends on the characteristics of the injury. The fibula, if intact, should be resected 2cm more than the shortening distance.

Box 12.14.11 Surgical reconstruction using monolateral external fixator

For segmental loss (>4–6cm):

- Bone transport
- Compression distraction
- Treatment is lengthy
- Complications are common.

The advantage of segment-shortening over bone transport is that it allows consolidation of the contact area without any additional intervention.

When assessing whether such surgical reconstruction is indicated, the surgeon must bear in mind the patient’s age, the condition of the soft tissues, neurovascular function, and degree of patient compliance. The treatment is lengthy (on average 40 days per centimetre of gap to be bridged) and complications are common. For this reason, appropriate patient selection is mandatory and patients must be adequately informed and monitored.

The experience of the University of Verona Orthopedic Clinic is based on 38 cases, 15 treated with bone transport and 23 with compression--distraction for substance losses ranging from 3–11cm. All segments healed. The following complications have been reported: 11 (75%) pseudarthroses of the docking site, two axial deviations of 5–10 degrees (with compression--distraction), and seven (18.4%) pin loosening (with reinsertion).

The problems and complications relating to external fixation can be avoided or minimized by using scrupulous surgical technique and codified rules for patient follow-up, and having an adequate understanding of mechanics as applied to bone biology.
Problems are defined as mishaps which stand in the way of the realization of a given objective, without jeopardizing the final outcome.

Complications are defined as obstacles to the realization of a given objective which require treatment and may undermine or impair the final outcome.

For this reason, we regard as problems only those deriving from minor pin-tract problems (grades 1 and 2 of the Checketts classification), which require improved nursing and closer cooperation between surgeon and patient.

Complications can be classified as follows:

- Complications related to monolateral external fixation
- Complications related to the conditions treated with external fixation.

The latter group are specifically related to the type of trauma or the type of orthopaedic condition treated and will therefore be addressed elsewhere in this book.

Complications due to monolateral external fixation can be further subdivided as follows:

- Complications due to bone-gripping elements
- Complications due to the fixator
- Complications due to contraindications to the use of monolateral external fixation.

### Box 12.14.12 Complications of external fixation

- **Screws:**
  - Infection
  - Neuromuscular damage
  - Osteolysis
  - Bending or breakage
  - Joint stiffness

- **Fixator:**
  - Jamming of dynamizable elements
  - Non-union
  - Malunion.

### Complications due to bone-gripping elements

Complications due to bone-gripping elements are as follows:

- Pin or wire tract infections
- Wire loosening
- Osteolysis
- Bone sequestrum
- Muscular stiffness
- Bending
- Breakage.

Vascular or neurological damage from a pin can be avoided by adequate care in placement. The monolateral system involves the use of pins whose entry point is well controlled and which penetrate only a few millimetres beyond the contralateral exit cortex.

The complications of pin-tract infection, osteolysis, and sequestrum are defined as major pin-tract complications and occur for the following reasons:

- Choice of the wrong type of pin
- Defective insertion technique
- Failure to comply with loading and dynamization indications
- Metal allergy
- Improper pin care.
Some systems require different types of pins for cortical bone and cancellous bone. Therefore it is necessary to choose the correct type of pin for the anatomic area to which it is to be applied. The total length of the pin must be based on the thickness of the soft tissues and on the size of the frame to which it is applied so as to allow adequate pin–fixator contact and at the same time care of the pin tracts. The length of the thread will depend on the diameter of the bone and must be selected so as to ensure adequate contact with both bone surfaces. The pin diameter must never exceed one-third of the diameter of the bone in order to avoid secondary fractures, and must never be undersized in order to avoid bending or breakage of the pin itself. The choice of hydroxyapatite-coated pins is recommended in order to reduce the incidence of pins loosening and the rate of pin infections.

**Insertion technique**

The release of soft tissues at the point of insertion must be sufficient to prevent friction during articular excursion. In those cases where different types of pins are required for cancellous and cortical bone, care must be taken to ensure the drill diameter matches the type of pin used. The drill must always be equipped with a sharp bit in order to minimize damage due to thermal necrosis. Both bone surfaces must be drilled so as to guarantee correct insertion, avoiding any risk of the pin taking the wrong route through the bone. In those cases where it is recommended, the use of a template is essential to maintain parallelism of the pins and thus reduce preload bending at the bone–pin interface. It is recommended to apply the pins after pre-drilling using a sharp drill at a speed of 800rpm/min and the stop and go technique in order to reduce the thermal bone interface necrosis.

**Loading and dynamization**

The load must be graduated in relation to the type of fracture or condition treated, the type of bone segment to which the fixator is applied, the mechanical characteristics of the fixator, and the patient’s weight. In dynamizable fixators, the dynamization must be implemented at the right time in order to limit pin stress and facilitate healing with a view to reducing total fixation time, which is directly proportional to the incidence of pin loosening.

**Metal allergy**

A preliminary investigation is necessary in order to establish whether the patient is allergic to any of the constituent materials of stainless steel. In such cases, the use of titanium pins or hydroxyapatite-coated steel pins is indicated.

**Improper pin care**

The methods of cleaning pin tracts must be properly explained to the patient. During the period in hospital after surgery, checks must be performed to make sure that the patient complies with the instructions given.

**Muscle stiffness**

There is a close correlation between the complications related to muscular stiffness and the bony segment and condition treated. Such complications, which are almost non-existent in tibial and humeral injuries, are significant in injuries of the femur because the pins pass through the fasciae lata and the quadriceps muscle. Soft tissue release should be carried out intraoperatively, checking for any residual tension by means of extension–flexion movements while the patient is still under the anaesthetic. Maintenance of an adequate range of movement in the postoperative period may require postoperative release of any residual tension not previously identified.

**Pin bending**

This complication is unlikely to occur when using fixators with ball-joints, since the loads needed to bend pins are higher than the yield strength of the joint. However, pin bending is possible if the pin diameter is undersized and during lengthenings following early consolidation of the callus.

**Pin breakage**

This is possible if the pin diameter is undersized, particularly in cases of acute trauma when combined with breakage of the fixator body.

**Complications due to the fixator**

Generally speaking, there may be complications related to failure of the frame depending on the geometry of the fixator and on the loads to which it is subjected. For this reason we need to have an exact knowledge of the mechanical characteristics of the device and relate them to the conditions of use so as to avoid breakage of the frame or, more frequently, yielding failure with consequent misalignment.

The fixator body composed by anodized aluminium may also be subject to breakage due to tension–corrosion phenomena relating to the effects of certain disinfectants, the use of which should be expressly banned.

One possible complication of dynamizable fixators is jamming of the dynamization system when the fixator is subjected to excessive torsional stress. For this reason new jam-free dynamization systems are currently being produced.

The fixation system may be a contributory cause of malunion. Some fixators require reduction prior to application. However, all the latest monolateral fixators allow reduction adjustment with the fixator in place. It should be noted that whenever a rotatory adjustment is made with any type of monolateral fixation system, we invariably create a displacement in another plane, with the result that it is essential that limb rotation in particular should be reduced prior to application of the pins. This enables us to avoid
positioning the pins in planes which are so different as to prevent subsequent reduction. If this should happen, the only way to overcome the problem is to reposition the pins.

Malunion may also be due to secondary loosening of the pins or frame. Therefore it is essential to monitor the patient over time with serial radiographs and give precise weight-bearing instructions, checking that the patient adheres to them scrupulously. If loss of reduction occurs, the fracture must be reduced by means of external manipulation of the segments, which can be done under anaesthetic or, depending on the degree of patient cooperation and the extent of the adjustment, may be performed without anaesthetic.

Summary points

♦ Use of absorbable fracture fixation devices eliminates hardware removal procedures
♦ Of the macromolecular biodegradable compounds, suited for the manufacturing of these implants, polylactide is the most widely used
♦ Small-fragment intra-articular fractures, especially at the elbow and at the ankle, are the most rewarding clinical applications
♦ Absorbable implants can be inserted through articular surfaces and, in children, also transphyseally
♦ Mechanical failures of the implants and redisplacements of fractures are rare, but local, transient inflammatory foreign-body reactions occur
♦ In certain intra-articular applications the absorbable fixation devices are superior to metallic ones.

Introduction

When internal fixation is required for the treatment of a fracture, the implants used become unnecessary, and may even be harmful, as soon as there is secure union between the fragments. In contrast with metallic devices, absorbable implants leave no hardware in the tissues. Absorbable implants are radiolucent and do not interfere with magnetic resonance imaging (MRI). Metallic appliances sometimes require removal. In addition, they are associated with some other well-known minor disadvantages, such as excessive rigidity and corrosion. Hence efforts have been made during the past three decades to develop absorbable implants for fracture fixation. In this context, the terms absorbable, resorbable, and biodegradable are used interchangeably. A section on the use of calcium phosphate as bone void filler is also included.

Despite the obvious potential advantages of biodegradable internal fixation devices, such implants did not exist in clinical practice until the mid-1980s, when they were used first in maxillofacial surgery and then in orthopaedic fracture surgery. Once the physicochemical and technical problems associated with the construction and production of the implants were solved, development was rapid.

Description of implants

Chemical composition

Many organic macromolecular compounds are degradable and resorbable in living tissues, but few have the chemical and physical properties necessary for an internal fracture fixation device (Box 12.16.1). Most clinical experience to date has been with implants made from polyglycolic acid (PGA), polylactic acid (PLA), and polyparadoxanone, since these were the first materials used in clinical practice. More recently, other compounds, such as glycolide-trimethylene carbonate copolymer, have been used.

Box 12.16.1 Absorbable organic macromolecules suitable as materials for internal fixation devices

♦ Polyglycolide
♦ Polylactide in various stereoisomeric forms
♦ Glycolide-lactide copolymers
♦ Polyparadoxanone
♦ Glycolide-trimethylene carbonate copolymer
♦ Polyhydroxybutyrate/valerate
♦ Polycaprolactone
♦ Polyelectroesters
♦ Pseudopolyamino acids.

High-molecular-weight PGA and PLA are produced by ring-opening polymerization of the corresponding cyclic diester, glycolide, or lactide. Therefore the polymerization products are often called polyglycolide and polylactide respectively. These homopolymers, as well as copolymers of polyglycolide and polylactide in various ratios, have been used for manufacturing internal fixation devices. Because of the asymmetry of the lactic acid molecule, it occurs in two stereoisomeric forms. Consequently, PLA may be modified in stereoisomeric terms into polyglycolic acid (PLA) and a stereocopolymer of polydextro- and polyglycolic acids (PDLLA). Both PGA and PLA are α-hydroxy polymers, but PGA is hydrophilic whereas PLA is hydrophobic because of its methyl groups. This difference influences the degradation rate of these polymers.
Physical appearance and geometry

Because of their thermal behaviour, several of the synthetic biodegradable polymers are difficult to shape into complex designs such as screws and plates. For example, PLLA is relatively brittle and rigid in room temperature. Also, the strict demands on the initial mechanical strength of the devices made by the clinical applications set limits on the geometric shaping of the implants.

Internal fixation implants which are now commercially available for orthopaedic applications include cylindrical pins, rods, screws, plugs, staples, anchors, tacks, arrows, and cords. The screw profiles are best suited for fixation of cancellous bone fragments. Staples, anchors, tacks, and cords are mainly intended to fix or reconstruct ligaments and joint capsules. Small PLLA plates are in clinical use principally in maxillofacial surgery but they are also suitable for certain small-fragment fractures of the extremities. Degradable cages have been developed for spinal surgery.

Biology and mechanics

Degradation

The degradation of absorbable polymers occurs principally by a simple hydrolytic reaction and, to a lesser extent, through non-specific enzymatic action (Figure 12.16.1), with the main route of final elimination being respiration. Despite these similarities in metabolism, the rates of degradation of different polymers vary greatly. As seen in experimental studies using light microscopy, PGA totally disappears from the tissues within 36 weeks, whereas PLLA still persists after 4.5 years. Also in clinical use, macroscopic remnants of PLLA devices have been found to be present in the ankle after 4 years and in the maxillofacial region after 5 years. The degradation rates of copolymers depend on the ratios of the constituent polymers.

Fig. 12.16.1
Simplified scheme of the metabolic degradation of polyglycolide, polydioxanone, and polylactide.

In animal experiments, the polymer is seen to become gradually invaded by connective tissue as the degradation proceeds (Figure 12.16.2). The degree of final restoration of the original tissue architecture within the implant track varies greatly for reasons that are not yet fully understood.

Fig. 12.16.2
A low-magnitude photomicrograph under polarized light illustrating the degradation of a polyglycolide screw 12 weeks after implantation in the cancellous bone of distal rabbit femur. Intense new bone formation is seen along the tissue–implant interface outlining the original screw profile. Remnants of the polymer have also migrated outside the implant cavity, which is filled with disintegrating polymer (asterisk).

Tissue response

Like any other medical implant, an absorbable fracture fixation implant must be free of infectious, toxic, immunological, teratogenic, and carcinogenic hazards. The results of biocompatibility studies in test animals cannot be directly extrapolated to humans. The only adverse reaction so far recorded for these implants in clinical use is a local transient inflammatory foreign-body reaction. Such a reaction has occurred in 2–25% of the patients depending on the type of implant used and the fracture site operated on. These reactions are discussed in detail later in this chapter.
Mechanical strength

The mechanical properties of absorbable implants must be discussed in terms of initial strength, strength retention during degradation, and elasticity. The initial strength is influenced more by the manufacturing technique of the implant than by the polymer utilized. Simple melt-moulding or extrusion of synthetic biodegradable polymers into pins results in weaker implants than when certain special manufacturing techniques are used. A reinforcing technique using high pressures and temperatures gives high-strength composite implants with fibres embedded within a matrix of the same biodegradable polymer. The initial flexural strength of a 4.5-mm diameter PLLA pin manufactured by a fibre-reinforcing technique is 245MPa. On the whole, the mechanical properties of absorbable materials are very different from those of stainless steel. Indeed, a direct comparison seems meaningless, since absorbable implants were not developed to mimic metallic ones.

The fixation properties of several types of absorbable implants have been tested under conditions simulating fractures in humans. In a study on the distal radius, satisfactory fixation was reported with PLA rods of diameter 2.7mm. A PLLA screw of diameter 6.3mm was found to be as good as a conventional metal screw for fixing a bone-patellar-tendon-bone graft for the anterior cruciate ligament in a bovine experimental model.

The strength retention of an absorbable implant is determined by its degradation rate. As already discussed earlier, the degradation rate is influenced by the micro- and macrostructural properties of the implant as well as by environmental factors. A rough estimate is that half of the initial bending and shear strengths is lost within 12 weeks when the implants are made of PLLA.

Some of the mechanical properties of biodegradable implants can be expressed in terms of Young’s modulus of elasticity. The modulus of elasticity of absorbable polymers is much less than that of stainless steel. Rather, it is close to that of cortical bone and only slightly higher than that of cancellous bone. The ultimate mode of failure of an implant can be ductile or brittle.

Clinical applications

Upper extremity

In the upper extremity, absorbable implants have been used in the internal fixation of small-fragment fractures from the lateral clavicle to the phalanges. Other applications have been reported in addition to fractures (Box 12.16.2). Absorbable tacks, staples and anchors are used in reconstructive procedures on the ligaments around the shoulder joint.

Box 12.16.2 Clinical applications of absorbable implants in the upper extremity

- Displaced fractures
  - Lateral clavicle
  - Acromion
  - Glenoid rim
  - Greater tubercle of the humerus
  - Proximal metaphysis of the humerus (in children)
  - Supracondylar humerus (in children)
  - Lateral condyle of the humerus (in children)
  - Medial epicondyle of the humerus (in children)
  - Capitellum of the humerus
  - Radial head or neck (also in children)
  - Olecranon
  - Distal part of the radius (also in children)
  - Scaphoid
  - Metacarpal bones
  - Phalanges of the fingers

- Dislocations and ligamentous injuries
  - At the acromioclavicular joint
  - At the glenohumeral joint
  - At the first metacarpophalangeal joint

- Fixation of arthrodeses in the wrist and hand joints.

The most common clinical applications for absorbable internal fixation devices in the upper extremity are displaced fractures of the humeral capitellum, the olecranon, the radial head, and the metacarpal bones. Exact reduction is necessary to secure the fixation when pins are used (Figures 12.16.3 and 12.16.4). The pins are inserted through the articular surfaces of the humeral capitellum.
In fractures of the olecranon screws may also be used. Absorbable pins are used in the fixation of displaced fractures of the distal part of the radius in countries where percutaneous pinning is a popular method of treatment of these fractures. Unlike K-wires, absorbable pins cannot be mounted on a chuck and be directly driven through bone fragments; a hole of the appropriate diameter must first be drilled for the implant. As a rule, postoperative plaster cast immobilization is used. In fractures of the metacarpal bones, small plates can be used.

**Fig. 12.16.5**
Schematic drawing of the fixation of a displaced fracture of the radial head using absorbable pins of diameter 2.0mm.
Lower extremity

The spectrum of the clinical applications of absorbable implants in the lower extremity (Box 12.16.3) is as broad as that in the upper extremity. With the exception of diaphyseal fractures of the femur and tibia, absorbable implants have been used in the internal fixation of almost all kinds of fracture occurring in the lower extremity.

Box 12.16.3 Clinical applications of absorbable implants in the lower extremity

- Displaced fractures
  - Acetabular rim
  - Femoral head and neck
  - Supracondylar femur (in children)
  - Femoral condyles
  - Patella
  - Tibial condyles
  - Distal tibia (also in children)
  - Malleoli (also in children)
  - Talar body or neck
  - Calcaneus
  - Metatarsal bones (also in children)

- Refixation in osteochondritis dissecans
  - At the knee and ankle joints

- Fixation of osteotomies
  - Acetabulum
  - Tibial tubercle (Hauser’s procedure)
  - First metatarsal for hallux valgus

- Fixation of acetabular cup in total hip replacement
- Fixation of bone–patellar-tendon–bone graft and meniscal tears
- Fixation of arthrodesis
- Ankle joint
  - Subtalar joint
  - First metatarsophalangeal joint.

The most common fracture type for which biodegradable implants have been used is displaced malleolar fracture of the ankle (Figure 12.16.7). The operative approach in ankle fractures, including disruptions of the syndesmosis, is similar to that used with metallic screws. However, a torque-limiting screwdriver is required to decrease the risk of screw breakage during insertion. After fixation, protruding screw heads can easily be cut off with an oscillating saw. Postoperative plaster cast immobilization has been used in the majority of the clinical studies reported.
Absorbable implants are used in many non-traumatic orthopaedic disorders in the lower extremity (Table 12.16.3). The two most common of these are the use of biodegradable interference screws to secure a tendon graft in reconstructive surgery of the anterior cruciate ligament, and the fixation of a torn meniscus by using a small absorbable arrow. Fixation of an osteotomy of the first metatarsal bone for hallux valgus (Figure 12.16.8) has been one of the more popular applications of absorbable implants.

Fractures in children

The psychological advantages of avoiding implant removal procedures would seem to be of particular value in children. Indeed, absorbable pins have been used in the fixation of many kinds of displaced small-fragment fractures in children (Tables 12.16.2 and 12.16.3). Experimental studies have shown that as long as absorbable implants piercing the growth plate occupy 3% or less of the cross-section of the plate, no growth disturbance will occur. If this limit is observed, transphyseal insertion of absorbable pins through growth plates should be safe. A transphyseal fixation is not necessary in all fracture types in children that require internal fixation, since in many the fixation can be done proximally or distally to the growth plate. The most convenient way of inserting small polymeric pins of diameter 1.1–2.0mm is first to fix the fracture temporarily with one or two K-wires and then to replace the wires one after another with an absorbable pin (Figure 12.16.9). Of course, multiple tentative K-wire drillings through the physeal plates should be avoided. Transphyseal fixations should preferably be done using implants with a shorter degradation time than those made of PLLA. Pins made of PGA or polyparadioxanone are more suitable. The diameter must be chosen according to the size of the fragments and the estimated area of the growth plate.

**Fig. 12.16.9**

A) A displaced fracture of the lateral condyle of the humerus in a 6-year-old child on admission. B) The fracture was reduced and temporarily fixed using two K-wires in an emergency operation. These were then replaced with transphyseally placed 1.5-mm polyglycolide pins. C) The fracture is shown 1 year later after uneventful union.

**Future applications**

The future applications of biodegradable implants will be influenced by the development of the devices, the inventiveness of orthopaedic surgeons, and the accumulating experience of the advantages and disadvantages of the implants. An expanding field is...
the use of absorbable implants in many kinds of arthroscopic procedures of the shoulder and the knee. Degradable cages for fusion procedures of the spine are under development.

Advantages and disadvantages (Boxes 12.16.4 and 12.16.5)

The most obvious advantage of absorbable implants is that no removal procedure has to be considered after fracture union, osteotomy, or arthrodesis.

The fact that these implants are radiolucent and do not interfere with MRI is of particular value in applications at the shoulder and the knee joints. With regard to operative techniques, an advantage of absorbable pins is that they can be inserted through articular cartilage and left in place with less concern than when using metallic devices. However, because of their long degradation time, PLLA implants should not be left protruding in joint cavities.

Box 12.16.4 Advantages of absorbable implants

- Removal not required
- No retained hardware
- Non-rigid
- Non-corrosive
- Can be inserted through articular cartilage and left in place
- Radiolucent and do not interfere with MRI.

Box 12.16.5 Disadvantages of absorbable implants

- Brittle
- Local foreign body reaction
- Loss of implant strength with time
- More expensive.

A disadvantage of biodegradable implants is their loss of mechanical strength with time which makes the use of postoperative plaster immobilization advisable in many fracture types in order to minimize the risk of redisplacement. Disadvantages that will probably resolve with time include the current limited assortment and the price of absorbable fracture fixation devices. At the time of writing, the cost of an absorbable screw is approximately five to eight times that of a metallic screw.

Results

Upper extremity

In labral and capsular stabilization procedures of the glenohumeral joint, the results of the use of absorbable tacks seem promising. Among the fractures in the upper extremity, a clear contraindication appears to be displaced fracture of the suprascapular humerus in adults, which is a fracture type with mechanical demands that are too high for the absorbable devices.

In contrast, displaced small-fragment fractures at the elbow joint seem to be a rewarding field for absorbable implants. Good results have been presented in fractures of the humeral capitellum and of the distal radius, the mechanical reliability of PGA rods was found to be good in a randomized study. Displaced fractures of the metacarpal bones can be successfully managed by small PLLA plates.

Lower extremity

Acetabular osteotomies performed for dysplasia have been successfully fixed using PLA screws in a series of 28 patients. The fixation of osteochondral flake fractures as well as fragments loosened by osteochondritis dissecans in the knee joint are established and generally accepted indications for absorbable implants. Absorbable interference screws are also widely used to fix the graft in reconstruction of the anterior cruciate ligament. However, the synovial tissues are at risk of developing aseptic inflammatory reactions to absorbable polymers.

The literature on displaced malleolar fractures of the ankle includes more patients than any other application. A fracture redisplacement requiring reoperation has occurred in approximately 1%. In two randomized studies comparing absorbable pins and screws with metallic implants no differences were found in the results of treatment.

Results have been satisfactory in fixation of osteotomies of the first metatarsal bone for hallux valgus as well as in fusion of the first metatarsophalangeal joint in rheumatoid arthritis.
Fractures in children (Box 12.16.6)

Among a variety of displaced fractures in 71 children with a mean age of 9.8 years treated using PGA pins, mechanical failure and severe redisplacement occurred in three out of 14 supracondylar fractures of the humerus. In another study of 50 different fractures, two cases with an osteolytic non-union of the radial head were observed. In a randomized study of 24 children with displaced fractures at the elbow joint, small-diameter PGA pins were found to be as effective as K-wires for fixation. This study did not include patients with supracondylar fractures of the humerus. Growth disturbances have not been reported.

Complications

Mechanical failures

Owing to the ductile mode of failure of fibre-reinforced absorbable implants, they lose their shear strength more slowly than their bending strength. Therefore angulation rather than lateral displacement between fixed fracture fragments is likely to occur when moderate overloading occurs.

Inflammatory reactions (Box 12.16.7)

An aseptic inflammatory reaction to biodegradable polymers occurs. The reaction presents clinically as a local painful fluctuant erythematous swelling approximately 0.5cm in diameter. Unless promptly aspirated or drained, it results in a discharging sinus. The bacterial cultures are negative but a secondary infection may ensue. The reactions occur in the final liquefaction phase of the degradation process of the polymer in question. Accordingly, they are seen on average 12 weeks postoperatively with implants made of PGA, but after 2–5 years with PLLA implants. The reactions usually subside within 4 weeks but occasionally show a protracted course. In biopsy specimens the lesions have the histopathological characteristics of a non-specific foreign-body reaction. Polymeric debris is seen lying intracellularly within abundant phagocytically active macrophages. Osteolytic changes may be seen on plain radiographs.

Box 12.16.6 Use of absorbable implants in children

♦ Particular value of avoiding implant removal procedures
♦ Growth is not disturbed if the implant occupies <3% of the cross-section of the growth plate
♦ Transphyseal implants should have short degeneration time.

Box 12.16.7 Inflammatory reaction to absorbable implants

♦ Reported in 2–40% of cases
♦ Local swelling, fluctuant, erythematous
♦ Requires drainage to avoid sinus forming
♦ May have associated osteolytic reactions
♦ Does not interfere with fracture healing
♦ No difference in infection rate compared with metal.

The incidence for PLA (<2%) seems to be lower than for PGA, at least as far as screws and ankle fractures are concerned. In contrast, use of PLA plates to fix mandibular fractures has resulted in a considerably higher rate of local inflammatory reactions (up to 40%).

Use of calcium phosphate as bone void filler

It is often difficult to achieve stable fixation and retention of a comminuted cancellous bone fracture associated with a significant metaphyseal defect. Augmentation by using calcium phosphate synthetic substitutes may then be helpful. Since these materials are resorbable, they are included in this chapter, although implants made of calcium phosphate actually are not fracture fixation devices. Calcium phosphate is available in a variety of different forms, including ceramic blocks, granules, powders and cements. Such devices provide an osteoconductive matrix for host osteogenic cells, but they are not osteoinductive unless specific osteoinductive substances are added. Calcium phosphate bone void filler appliances are relatively brittle and have little tensile strength. Their rate of integration depends on their crystalline size and stoichiometry.

One of the available resorbable ceramics is tricalcium phosphate. Another calcium phosphate-based bone substitute, synthetic coraline or cancellous hydroxyapatite is manufactured as a ceramic through a sintering process. Hydroxyapatite is not commonly used alone as an osteoconductive bone substitute because of its slow resorption and high brittleness. Tricalcium phosphate is less brittle and has a faster resorption. It has not yet been possible to exactly determine the resorption rate of calcium phosphate in humans. The resorption process occurs by dissolution and osteoclast activity.
Calcium phosphate can be manufactured as a cement by adding an aqueous solution to dissolve the calcium. An advantage of cements over blocks or granules is the ability to custom-fill the metaphyseal bone defects. Injectable cement can, however, be extruded beyond the boundaries of the defect, thus potentially disturbing or even damaging the surrounding tissues. If calcium phosphate migrates into a joint, it will not dissolve and become resorbed.

The ability of calcium phosphate bone substitutes to act as bone void filler in cancellous bone has been documented experimentally and clinically.

### Conclusions

When judiciously used, absorbable implants provide a valuable extension of current internal fixation devices. In certain intra-articular fracture types they are already superior to metallic fixation devices. Avoiding hardware removals may provide economic benefits. So far, a methodical clinical use of absorbable implants has a history of only two decades. Although absorbable implants never will become universal for fracture fixation, these devices will undoubtedly be used in those specific clinical applications, in which they possess clear advantages over metallic devices.

### Further reading

Stress fractures are fractures occurring as the result of repetitive, submaximal loads, in the absence of a specific precipitating traumatic event. These fractures can be subdivided into two groups on the basis of aetiology. Whereas ‘fatigue fractures’ result from the excessive repetitive (i.e. abnormal) loading of normal bone, ‘insufficiency fractures’ are fractures resulting from normal forces acting on abnormal bone. Early diagnosis allows the initiation of effective treatment that can prevent prolonged pain and disability, as well as avoiding the progression to displacement or a non-union. While management decisions are generally focused on activity modification, protection of weight bearing, and immobilization, there is a subset of fractures at high risk for progression to complete fracture, non-union, or delayed union. These high-risk stress fractures, including tension-side femoral neck fractures and anterior tibial cortex fractures, require aggressive treatment to prevent the sequelae of poor healing.

Introduction (Box 12.17.1)

Stress fractures represent excessive loading of bone, resulting in repetitive microtrauma that exceeds the bone’s ability to repair itself through osteoblastic remodelling. As the microtrauma continues, the rate of osteoclastic resorption of bone surpasses the reparative process, leading to failure of the bone. This process begins as a stress reaction, according to Wolff’s law, then progresses to a stress fracture. The fractures are generally symptomatic well before any displacement occurs. A strong index of suspicion, thorough history, and appropriate use of imaging can lead to early diagnosis before progression to a complete, displaced fracture.

Box 12.17.1 Essentials

- Fatigue fractures—excessive use
- Insufficiency fractures—abnormal bone
- High risk fractures need active management.

Stress fractures have been reported in almost every bone. The relative frequency depends on the population studied, according to the age and the predominant activity in that population. The most commonly affected bones are the metatarsals, tarsals, tibia, femur, pelvis, and vertebrae. Although in the past there has been much emphasis on fatigue fractures in healthy individuals such as high-level competitive athletes or military recruits, insufficiency fractures are becoming more important as the population ages. Involvement in competitive youth sports is also increasing, resulting in the increased frequency of recognition of overuse injuries in the paediatric and adolescent populations. The female athlete has also been shown to be at increased risk of stress fractures compared to her male counterparts, which may be related to alterations in oestrogen levels and a resultant decreased bone mineral density.

Fatigue fractures

While early literature focused on fatigue fractures in military recruits, there has recently been increased recognition of stress fractures in all age groups and activity levels. Many reports show that these fractures are related to an abrupt increase in the duration, intensity, or frequency of activity. It is felt that the microtrauma sustained with repetitive loading, without adequate rest, leads to an increase in osteoclastic activity that exceeds the bone’s inherent adaptability and ability to remodel. Experimental work also shows that normal bone can sustain stress fractures under the repeated application of submaximal loads.

Insufficiency fractures

With an active, aging population there has been an increased recognition of stress fractures. While in many cases there is no description of a history of change in activity level, many of the patients sustaining stress fractures have been shown to have decreased bone density. Older patients with no apparent musculoskeletal disease have thus developed stress fractures. Similarly, there are reports of insufficiency fractures in patients with decreased bone density as a result of rheumatoid arthritis, lupus erythematosus, osteoarthritis, chronic renal disease, osteomalacia, and osteoporosis. Insufficiency fractures can also occur adjacent to joint replacements and arthrodeses.
Incidence: 1%
• Commoner in females (oestrogen)
• Some runners incidence: 20%
• Common in tibia, metatarsals, and tarsals
• Spondylolysis in 6% of normal population.

Epidemiology (Box 12.17.2)

The reported incidence of stress fractures in the general athletic population is less than 1%. However, certain subgroups have much higher risk of developing stress fractures, such as runners with an incidence that may be as high as 20% (Table 12.17.1). One review of 370 athletes with stress fractures showed that the tibia was the most commonly affected bone (49.1% of fractures). Stress fractures of the tarsals (25.3%) and metatarsals (8.8%) were also commonly seen. This has been supported by subsequent studies, however one prospective study of 914 college athletes reported that the femoral shaft was involved in over 20% of stress fractures over a 2-year period. In this report, metatarsal fractures were shown to be more common in endurance runners, while tibial stress fractures were more common in sports with rapid decelerations such as tennis and basketball. Spondylolysis, a stress fracture of the pars interarticularis most frequently of L5, occurs in 3–6% of the general population, and is associated with activities such as weightlifting and gymnastics.

Many risk factors have been identified in the development of stress fractures. In competitive female track and field athletes, a history of menstrual disturbance, nutritional disturbance, and decreased bone mineral density have been identified as risk factors. In addition, anatomical variations such as leg length discrepancies, leg alignment, and bone geometry have also been shown to be related to stress fracture development. Insufficiency fractures in the elderly are clearly related to decreased bone mineral density.

Clinical features

Fatigue and insufficiency fractures can present with the clinical signs and symptoms of both benign and malignant skeletal disorders. There is commonly an insidious onset of pain over a variable period of time, from days to weeks. The pain is exacerbated by activity and relieved by rest, although some patients may continue to experience night pain. Although a careful history should elicit any recent trauma or changes in activity, the absence of such cannot rule out a stress fracture. The history should include general health, diet, occupation and activities, and a menstrual history in women, as well as more ominous features such as weight loss or constitutional symptoms.

Bone tenderness is the most obvious physical finding in superficial regions, while pain with a gentle range of motion or compression of the bone is also often useful. Stress fractures may cause local signs of inflammation such as local swelling or redness of overlying skin.

Differential diagnosis (Box 12.17.3)

The differential diagnosis of stress fractures is varied, and depends largely on the location, signs, and symptoms. A stress reaction, where the bone is weakened in an area of bone remodelling, has no physical disruption. Other pathological entities in the differential include avulsion injuries, infection, muscle strain, medial tibial stress syndrome (shin splints), exertional compartment syndrome, nerve entrapment, periostitis, and neoplasm.
Clinical investigation (Box 12.17.4)

A careful history and physical examination can usually be suggestive of a stress fracture; however, imaging studies are imperative to confirm the diagnosis. Plain radiographs are the first studies to order for suspected stress fractures. Although they are more likely to be normal within the first 2–3 weeks following the onset of symptoms, later films often show periosteal reaction, cortical lucency, or a fracture line.

Box 12.17.3 Differential diagnosis of stress of insufficiency fractures

- Trauma (avulsion, muscle strain)
- Vascular (exertional compartment syndrome)
- Neurologic (nerve entrapment)
- Inflammatory (enthesisitis, periostitis, tendonitis)
- Infection (chronic or acute osteomyelitis)
- Primary benign neoplasm (osteoid osteoma, eosinophilic granuloma)
- Primary malignant neoplasm (osteosarcoma)
- Metastatic neoplasm (carcinomas of breast, kidney, prostate).

Box 12.17.4 Investigation

- Pain commonest symptom
- X-rays abnormal at 2–3 weeks
- MRI scan most sensitive for diagnosis
- CT useful to assess healing.

Radionuclide imaging, using technetium-99 diphosphonate bone scans, is highly sensitive for stress fractures; however, it is not specific as increased uptake will be seen with any insult causing increased osteoblastic activity. Acute stress fractures will exhibit increased uptake in all three phases of the bone scan, whereas soft tissue injuries will only show increased uptake in phases 1 and 2.

Computed tomography (CT) can show fractures that are not demonstrated on plain radiographs, and can be used to evaluate and document fracture healing. The axial image acquisition of CT, however, can fail to delineate many stress fractures, as they are usually transversely oriented in the appendicular skeleton. Compared with magnetic resonance imaging (MRI), CT is better at delineating the osseous changes with stress fractures.

MRI is well documented to be superior for imaging and diagnosis of stress fractures. It is sensitive for detecting bone marrow oedema that occurs with stress reactions and stress fractures, and has the potential to demonstrate the presence of a fracture before changes are visible on plain radiographs or CT. However, oedema is somewhat non-specific and is also seen with both infection and neoplasm. The characteristic pattern of a stress fracture is a linear abnormal signal involving both the cortex and the medullary canal. Grading systems have been developed based on MRI or bone scan findings, with significant differences in time from diagnosis to return to sport according to the fracture grade (Table 12.17.2).

STIR, short T1 inversion recovery.

The majority of stress fractures are singular and oriented in the transverse plane, though multiple fractures in the same orientation may occur. Uncommonly, a stress fracture may run in a longitudinal direction in long bones, typically in the anterior cortex of the distal tibia. These fractures have a confusing appearance on MRI, but have a characteristic pattern on several consecutive CT scans.
Stress fractures of the lumbar spine

Fractures of the pars interarticularis are the most frequent. Repetitive hyperextension places stress on the lumbar spine, predisposing certain athletes (ballet dancers, gymnasts, and football linemen) to developing stress fractures of the lumbar spine, usually at the L5. Spondylolysis, a stress fracture of the pars, is a result of mechanical failure. It is seen in 4–6% of the general population, but has been reported to be much higher (11%) in the previously-mentioned groups.

Though there is a lack of images, with a small cortical break and both endosteal and periosteal reaction.

**Treatment (Box 12.17.5)**

The key to the treatment of stress fractures is timely identification and diagnosis. Any intrinsic (hormonal, nutritional, etc.) or extrinsic (training regimen, activity level) factors must be assessed and corrected. Most fractures can usually be treated by analgesics, activity modification, and occasionally orthoses or casts. Stress fractures can broadly be divided into either low-risk or high-risk injuries. Low-risk stress fractures are often diagnosed on the basis of a thorough history, physical examination, and plain radiographs, without the need for advanced imaging modalities. A period of rest and restricted activities is usually adequate, with possible supplementation with bracing or cast immobilization. This period of relative inactivity is followed by a rehabilitation program with low-impact activities such as cycling or swimming, until the patient can perform without discomfort. The athlete can then gradually progress to higher impact activities and increase the intensity before returning to sport-specific exercises. In general, operative intervention for low-risk stress fractures is limited to those fractures that have failed non-operative management, non-unions, and malunions. Electromagnetic field therapy has been tried, but a recent prospective study failed to show a difference in time to healing between placebo and treatment groups.

**Box 12.17.5 Treatment**

- Timely diagnosis important
- Rest and immobilization for low risk fractures
- Surgery for failed treatment, non-union, and malunion
- Fix high-risk fractures.

High-risk fractures are those that have a tendency to progress to displaced complete fractures, and those with a propensity to go on to delayed union or non-union. Also of consideration is the morbidity of the development of a complete fracture. For this reason, stress fractures of the tension side of the femoral neck and fractures of the anterior cortex of the tibia are considered to be high risk. Other bones occasionally considered high risk include the patella, medial malleolus, talus, and fifth metatarsal. Because of the high complication rate, these fractures should be treated as acute fractures. Algorithms for the evaluation and treatment of suspected high-risk fractures have been developed.

**Femoral neck stress fractures**

Although uncommon, stress fractures of the proximal femur have a high rate of complications if the patient is not appropriately managed. Osteopenia and coxa vara may predispose the femoral neck to fracture. These fractures can occur on either the tension side, or more commonly, on the compression side of the neck. Compression side fractures of the inferior neck are stable injuries, and hence non-operative management is appropriate. In contrast, tension side fractures of the superior neck have a much higher risk of propagation across the neck, and are more likely to become complete and displaced. Complications of delayed or inadequate treatment include avascular necrosis, non-union, and delayed union. Given the significant morbidity of these outcomes, aggressive treatment including surgical intervention is indicated. Once a fracture has become displaced, many patients are unable to return to pre-injury activities, despite appropriate surgical intervention. Percutaneous cannulated screw fixation will prevent completion of a tension side stress fracture and thus avoid the significant sequelae of a displaced fracture. As stress fractures take longer to heal than acute traumatic injuries, the patient with a displaced fracture needs to be kept non-weight bearing for 6 weeks, followed by 6 weeks of partial weight bearing.

**Anterior tibial cortex fractures**

The most common location of stress fractures in athletes is the tibial shaft. The incidence has been reported as 20–75% depending on the study group. Most frequently these fractures occur along the compression side of the tibia, the posterior-medial cortex. These are seen more commonly in distance runners, and generally heal with activity modification alone. Less commonly, a stress fracture occurs on the tension side of the tibia at the anterior cortex of the mid-third. These fractures are more frequently seen in athletes with repetitive jumping activities Stress fractures in this area have the potential to progress to complete fracture. Initially rest and immobilization can be tried. The recalcitrant stress fracture of the anterior tibial cortex is best treated with reamed unlocked intramedullary nailing of the tibia.

**Other high-risk stress fractures**

Other fractures that the clinician must be aware of include those of the patellar, medial malleolus, talus, navicular, fifth metatarsal, and great toe sesamoids. Fractures at each of these sites have the tendency to progress delayed union or non-union, and must be treated appropriately to permit a return to sport and to avoid poor long-term outcomes. Frequently a high-risk stress fracture in one of these bones necessitates aggressive management and surgical intervention.

**Stress fractures of the lumbar spine**

Fractures of the pars interarticularis are the most frequent. Repetitive hyperextension places stress on the lumbar spine, predisposing certain athletes (ballet dancers, gymnasts, and football linemen) to developing stress fractures of the lumbar spine, usually at the L5. Spondylolysis, a stress fracture of the pars, is a result of mechanical failure. It is seen in 4–6% of the population, but has been reported to be much higher (11%) in the previously-mentioned groups.
general population, but has been reported to be much higher (11%) in the previously-mentioned groups. Though there is a lack of consensus regarding the best management for spondylolysis, the most appropriate treatment plan starts with a removal from sports. Physical therapy to promote pelvic flexibility and core strengthening to counter lordosis should then be undertaken. Stationary cycling and swimming are the only activities that should be allowed. Bracing may be indicated to decrease lumbar lordosis. After a 6-week period to allow healing, if the athlete is asymptomatic they may begin a return to sport programme. If symptomatic, ongoing physical therapy and bracing are indicated. For the athlete that fails non-operative management, surgical intervention such as a posterolateral transverse body fusion is indicated. Postoperative bracing is then continued for several months before sports are allowed.

Pathological fractures

Summary points

- Pathological fractures should be recognized before treatment, but often are not.
- If solitary and potentially malignant, pathological fractures should be investigated prior to treatment.
- Inappropriate management may compromise outcome.
- Maximize patient fitness for surgery.
- Preoperative assessment to look for other tumours e.g. CT scan of chest and abdomen.
- Biopsy if possible before definitive management.
- Aim to relieve pain and restore function.

Introduction

In describing the mechanical effect of the environment on materials, cause and effect are related through stress and strain. A fracture occurs when the force applied to bone is greater than the ability of bone to dissipate the stress through its elastic properties as described by strain.

The skeleton which is constituted of bone of normal structure and physiology will require significant force to break at all ages. The patient’s clinical history will register an impact of high energy and the radiographic appearance of the adjacent bone will appear normal. In contrast, bone may be weakened by a pathological process so that a fracture may occur with trivial force. Hence a pathological fracture is defined both by the application of trivial force, and, if sought, evidence of pre-existing weakened bone. It is important to elicit that minimal energy caused the fracture since bony fragments may obscure other evidence of localized bone loss. Consequently, inadvertent reaming of a primary malignant bone tumour or a hypervascular renal-cell cancer metastasis occurs with disappointing regularity and may compromise patient survival. Further evidence of localized bone disease is a subtle history of vague mechanical pain predating the fracture by days or weeks.

Types

Generalized

Bone may be weakened by:

- Generalized pathological processes:
  - Senile osteoporosis—the commonest
  - Osteogenesis imperfecta
  - Transient juvenile osteoporosis
  - Transient osteoporosis of pregnancy
  - Disuse osteoporosis, e.g. cerebral palsy
  - Long-term steroids, chemotherapy and bisphosphonates
  - Osteopetrosis.

- Metabolic diseases (see Chapter 10.1):
  - Osteomalacia will cause incomplete stress fractures (Looser’s lines) on the compression side of lower limb long bones
  - 10% of children with rickets are diagnosed as a result of an associated true fracture
  - Paget’s disease causes both complete fractures and single cortex stress fractures on the distraction (anterolateral) side of the femur. Think of fracture through osteosarcoma although this disease is rare with bisphosphonate treatment.

Localized

Non-tumorous

- Osteonecrosis may result in dense mineral which is not immediately weak. Microfractures and crescentic collapse may occur during the revascularization phase. A specific type of osteonecrosis occurs following radiotherapy. Historically administered to the chest wall and shoulder-area in high dose in breast cancer, fractures of affected bone may occur up to 30 years following treatment. In such circumstances it is important to discriminate pure postradiation osteonecrosis from radiation-induced sarcoma by means of comparison with earlier radiographs and magnetic resonance imaging.
Bone infection rarely results in fracture.

The inherited defect of neurofibromatosis-associated pseudarthrosis is a special case which will not heal with conservative measures. Radical excision and reconstruction may be required with a risk of amputation in intractable non-union.

**Tumorous**

Although pain often drives a patient to seek the medical attention which results in the diagnosis of a tumorous lesion of bone, pathological fracture is perhaps the first presentation especially in benign lesions. Benign neoplastic lesions are most common in childhood and young adulthood. With increasing age, however, metastatic bone disease eventually becomes the most frequent cause of a localized pathological fracture.

**Benign**

All the benign intramedullary neoplasms of childhood can be associated with pathological fractures. Unicameral (simple) bone cysts are the most frequent but others include aneurysmal bone cyst, enchondroma, fibrous dysplasia, osteofibrous dysplasia, and eosinophilic granuloma.

In young adulthood, simple bone cysts seem to resolve and giant cell tumour can be added to the earlier list. Cortically based lesions such as fibrous cortical defect can result in a unicortical stress fracture. Even a pedunculated osteochondroma may fracture through its stalk and require excision.

Since the histology of new fracture callus includes plump active osteoblasts in a cellular osteoid matrix, it is important to inform the histopathologist of a fracture when sending material, otherwise a spurious diagnosis of osteosarcoma may be entertained.

**Malignant**

Primary malignant bone tumours infrequently present as a pathological fracture in childhood, although in osteosarcoma this complication may occur during biopsy or while undergoing neoadjuvant chemotherapy and awaiting surgery. Although univariate analyses suggest that pathological fracture is associated with poor survival, more recent multivariate studies point to other features of tumour aggression as more responsible for this. A chondroid tumour which fractures in one of the proximal long bones may hint of a chondrosarcoma, although in the hand or foot fractures tend to represent a benign enchondroma.

In the patient over 50 years old, a pathological fracture is usually due to metastatic disease. The usual suspect primary tumours are well recognized: breast, prostate, lung, thyroid, and kidney are all carcinomas. Added to this will be the myeloproliferative disorders of myeloma and lymphoma. Except for the special case of a late isolated renal cell carcinoma deposit, it may be impossible to cure the patient. However, an accurate diagnosis will provide the oncologist with the best chance of providing effective palliative treatment.

**Investigation and diagnosis**

The importance of identifying that a fracture is pathological cannot be emphasized too strongly. Among some doctors there may be a belief that cancers do not occur in children; others may believe that there can be no harm in promptly fixing all femoral long-bone fractures in the elderly.

Taking a comprehensive history and procuring good quality radiographs will go a long way to ensuring a minimum of mistaken diagnoses.

It is recognized that appropriate investigations may take several days to organize. In the interim it is important to reassure the patient and ensure that adequate analgesia is administered and fracture immobilization achieved. During this period, efforts can be made to maximize patient fitness for surgery—in particular hypercalcaemia of malignancy can be identified and corrected with fluid management and bisphosphonates. Clinical examination of lung fields, abdomen, prostate, and breast may be required. Further imaging may include magnetic resonance imaging of the local area, bone scintigraphy to assess for further skeletal lesions and computed tomography of the chest, abdomen, and pelvis where a primary adenocarcinoma is sought. Where the lesion proves to be solitary, a biopsy should be undertaken with the aim of discriminating a primary malignant bone tumour from a metastasis. This should be discussed with the local or regional bone tumour specialist service to ensure the biopsy method does not compromise further potential optimum management.

In the child and young adult, radiographs alone may be diagnostic, for example, in simple bone cysts of the proximal humerus and digital enchondromas. Age and site and tumour matrix may also be useful pointers in identifying fibrous dysplasia, giant cell tumour and chondroblastoma.

Where a skeletal metastasis is already identified, the risk of future fracture arises. If this risk is high, prophylactic fixation may be indicated. Where 50% of a single cortex is destroyed, pathological fracture may be regarded as inevitable. Furthermore, avulsion of the lesser trochanter points to an imminent hip fracture. It is recommended that each trauma unit has a named surgeon who has responsibility for liaison with colleagues and other specialists such as oncologists to allow early assessment and treatment of such impending fractures. Mirels has developed a scoring system which ranks radiographic and clinical features as shown in Table 12.18.1.

* As seen on plain x-ray, maximum destruction in any view.

A score of 8 or above indicates a high likelihood of impending fracture and prophylactic fixation is recommended prior to radiotherapy.

**Management**

**Generalized conditions**

In most generalized conditions, bone will heal as rapidly or almost as rapidly as in normal bone. Choice of treatment depends upon the fracture configuration, comorbid factors, age, and mobility.

**Localized conditions**

In benign lesions, upper limb pathological fractures are perhaps more common than those in the lower limb. However, fractures in the lower limb are more difficult to manage with a higher malunion risk and so surgeons will be more likely to undertake prophylactic treatment of an impending femoral fracture. It is important to advise use of crutches while awaiting surgery, or at least explain the risk of fracture to avoid accusations of neglect.

In many types of benign bone lesions, a fracture may stimulate osteogenesis within the lesion so that both fracture healing and lesional obliteration occur together. This is seen in simple and aneurysmal bone cysts, enchondromas, fibrous cortical defects, and fibrous dysplasia. It is recommended that the patient is followed-up until lesional obliteration. In the lower limb long bones, however, internal fixation may be necessary to achieve an accurate anatomical reduction. A giant cell tumour may represent a difficult reconstructive problem when an intra-articular fracture occurs around the knee. If there is sufficient bone to secure both medial and lateral cortices, then curettage, grafting, and plate fixation may be appropriate. Otherwise an extended tumour prosthesis might be required.

The British Orthopaedic Association has stated that the aim of surgery in a pathological fracture due to metastatic disease is to relieve pain and restore function. An over-riding principle is to provide immediate postoperative stability, allowing weight bearing, and to stabilize all lesions in the affected bone, where possible.

In long-bone biopsy-proven solitary metastases and in multiple bony metastases without biopsy a pathological fracture of the diaphysis or metaphysis is most reliably managed with a load-bearing implant—typically an intramedullary nail. The reason for this is that the fracture cannot be assumed to be capable of healing—at some point the tumour will grow again locally. The aim of surgery is therefore to stabilize the bone for the duration of the patient’s life—typically this is 1–2 years in non-breast cancer, perhaps 2–5 years in breast cancer. Modern intramedullary fixation will not undergo fatigue-failure in cyclical loading within 2 years. It is probably worth stabilizing a long-bone fracture if life expectancy exceeds at least 6 weeks although each case is judged on its own merits with full involvement of patient and family in decision-making. Where surgery is too great a risk, then a portable epidural catheter may allow comfort and even some transfer-mobility. In renal cell metastasis, there is a risk of severe haemorrhage, so that preoperative angiography plus coil-embolization is warranted. In solitary renal cell metastases which have developed some years after nephrectomy, then treatment as for a primary malignant bone cancer might be undertaken with a high chance of cure.

Where a fracture is juxta-articular, then plate fixation together with bone–cement reconstruction is advisable. The exception to this, however, is a peritrochanteric fracture of the femur or proximal humerus fracture which may be treated by an intramedullary nail of reconstruction type, or a cemented joint prosthesis. The latter has a low failure rate. Occasionally, a tumour prosthesis may be required but the loss of some hip or shoulder abductor function will have to be accepted. A fracture through the ilium adjacent or proximal to the hip joint will require hip replacement with acetabular reconstruction. Harrington has described useful principles of surgical treatment depending on the anatomical site of the pathological pelvic fracture. Cement and metal pins will produce a ‘reinforced concrete’ effect proximal to the acetabulum into which a polyethylene cup can be cemented.

All reamings and curetted material should be submitted to histopathological examination to confirm the tumour diagnosis. Oncological postoperative treatment will be guided by the diagnosis and radiotherapy will frequently be directed to the tumour bed.

Certain cancers will not prevent fracture healing when treated with appropriate chemo-, endocrine, or radiation therapy. These include lymphoma, myeloma, thyroid, and breast and prostate cancer. New oncogene inhibitors in renal cell metastases now seem to provide a similar gratifying effect.

Management of segmental bone defects

Summary points

- Segmental defects are a significant, but surmountable, problem for the Trauma surgeon.
- The best results will only be achieved if all potential solutions are considered and used correctly in either: isolation; sequentially; or concurrently.
- Failure to create a bone defect, during debridement of some open fractures, may be catastrophic. An appreciation of the techniques available to treat segmental defects is necessary to allow the surgeon to debride with confidence.

Introduction

A segmental defect may be defined in a number of ways. The simplest definition is wherever a segment of bone is missing and usually refers to the diaphysis of a long bone in colloquial orthopaedic parlance. Examples may include extrusion wedges debrided during surgery due to lack of soft tissue attachment or lost at the roadside. Such situations refer to high-energy fractures of type B or type C pattern and the defect may be complete or incomplete, and so there may be bone-to-bone contact or a gap when the bone is restored to its original length.

A defect may also be defined by its size (Box 12.19.1). It thus may be referred to as a critical-sized defect or subcritical-sized defect. A critical-sized defect may be defined as one that cannot be successfully treated using standard techniques with cancellous autografts. Segmental defects are generally regarded as critical when in the region of 5cm or above.

Box 12.19.1 Definition

- Subcritical
- Critical

Methods

Although cancellous bone grafting remains to this day the gold standard material for bridging and uniting complete or incomplete sized bone defects, there is a limit to the size of defect that may be treated using cancellous autografting. Other techniques and materials need to be considered:

- Bone graft:
  - Autograft
  - Allograft
- Demineralized bone matrix
- Ceramics:
  - Calcium hydroxapatite
  - Calcium phosphate
- Free vascularized tissue transfers
- Distraction histiogenesis
- Bone morphogenetic proteins
- LIPUS (pulsed ultrasound)
- Tissue engineering

Subcritical-sized defects

Autograft

Nature of autograft

Autograft may be cancellous bone from metaphyseal regions of a bone within the same patient or segments of cortical, usually corticocancellous bone, the latter providing structural support to the grafted area and often inserted as a pedicled or free...
microvascular tissue transfer although rib is used as a avascular graft in some circumstances such as the spine. Examples of pedicled flaps include the pronator quadratus to the scaphoid or a DCIA (deep circumflex iliac artery) to the neck of the femur. One of the most versatile of free flaps is a free fibular microvascular transfer. It has found applications in the treatment of segmental defects of the tibia, forearm bones, and the mandible. The needs of reconstruction surgeons have lead to applying free fibulas to other more inventive sites.

Box 12.19.2 Cancellous autograft

- Osteoconductive, osteoinductive, and osteogenic
- Large quantities available in iliac crest and femur
- Associated donor site morbidity:
  - Bleeding
  - Infection
  - Nerve damage (lateral cutaneous nerve of thigh)
  - Iatrogenic fractures
  - Arterial injury
- Avoid in the presence of sepsis.

Properties of autograft

Cancellous bone graft consists of portions of spongy bone spicules with living bone cells.

Sources of autograft

The commonest source of autograft is cancellous bone and the commonest source harvested is between the two tables of the iliac crest, be it anterior or posterior. Methods consists of: trephine biopsies; lifting the superior cortex like a lid of a seaman’s chest; peeling down ribbons of cortex from the outer table; scooping out the cancellous bone with either a gouge or using the acetabular (strawberry) reamer under power from a hip arthroplasty set.

Other sources include the femoral condyles or greater trochanteric regions at the hip. The distal radius is a ready source of cancellous graft when operating around the wrist and carpus where small volumes are required.

The main problem with cancellous autograft is the limited volume available to the surgeon which is much diminished in the elderly. Harvesting from all four iliac crests may be necessary to obtain a sufficient volume but even in fit young adult males all four crests are unlikely to yield more than 40–60mL with the average volume in a 75-kg man being 17g for the anterior crest and 40g from the posterior crest. The use of the reamer aspiration irrigator system passed through the intramedullary canal of the femur has yielded significantly greater volumes (20–90mL) of graft and there is evidence to show that even the irrigation fluid has osteogenic properties.

Morbidity of bone grafting

A variety of complications are associated with cancellous bone grafting. Not only is it common experience that the donor site is very painful and may indeed delay ambulation, but the technique has been associated with bleeding, infection, nerve damage (the commonest being lateral cutaneous nerve of thigh), and iatrogenic fractures and even arterial injury.

Indications for autografting

Autografting is the treatment of choice for non-critical bone defects and to encourage union in cases of delayed or non-union. Cancellous grafting comes sterile, is immunocompatible, and has no storage issues. Its availability is limited but may be increased by harvesting the femur with a Reamer Irrigator Aspirator (RIA) system.

The mechanical environment

Stability is essential (Figure 12.19.1). Too much micromovement may inhibit neovascularization of the graft. There may be a natural tendency to compare the defect to a segmental (type C) fracture and to apply relative stability, especially if the osteosynthesis uses a spanning plate.
The biological environment

Logically, as autograft is osteoconductive as well as osteoinductive, for successful neovascularization it is best if the graft is covered by a well-vascularized bed of healthy muscle and this may dictate the chosen surgical approach. Surgery is aided in instances where there is delayed management of segmental defects whilst the soft tissue bed matures following, for example, a free vascularized tissue transfer, by insertion of a spacer. A useful tool is a moulded piece of antibiotic-laden acrylic cement which leaves a cavity, following removal, that can accommodate an appropriate volume of graft as often the soft tissue envelope may be non-pliable and difficult to expand to accommodate sufficient graft to be of mechanical use.

There is a growing role for the mixture of autograft with human recombinant bone morphogenic proteins (BMPs) to enhance and extend autograft, especially in subcritical-sized defects. Its role in combination for critical-sized defects has yet to be established although the author has had anecdotal success using this technique.

Timing of grafting

Based on the premise that all osteosynthesis is a race between the bone uniting and load absorbing and implant failure, the surgeon is under pressure to graft as early as possible any segmental defects to prevent disastrous mechanical failure.

The options open to the surgeon are at initial closure in the open fracture scenario or delayed grafting. The majority of surgeons in the open fracture situation will opt for a delayed approach due to fear of sepsis complicating the graft which is regarded as a potential iatrogenic sequestrum. Sepsis will also cause graft lysis. Autograft, however, has the same propensity to become colonized as metal implants and the trend in recent years has been to internally fix open fractures at initium and thus grafting at the time of closure should not add significantly to the burden of implant related sepsis. Thus, if at the time of soft tissue closure, be it at the first sitting in a fx and flap setting (Figure 12.19.2), or delayed free flap, if the soft tissue bed is macroscopically healthy, then grafting may be performed with sepsis rates comparable to delayed grafting. This approach however is only appropriate in combined orthoplastic units when the zone of injury has undergone a sarcoma type excision from outside of the zone of injury, with immediate reconstruction.

In most situations, it may be considered appropriate to defer grafting to when any occult sepsis may have declared itself and any soft tissue reconstruction will have picked up a blood supply of its own and oedema has resolved, but before the soft tissues become scarred and woody. Appropriate timing is at 6–8 weeks after initial surgery when serum markers are normal (erythrocyte sedimentation rate (ESR), plasma viscosity (PV) levels, and C-reactive protein (CRP) levels) and the patient is no longer on antibiotics.

Small areas of unhealed skin graft at the edges should not delay surgery as long as the mentioned criteria are met. These areas may be excised as part of the incision and primarily closed. In all cases the surgeon should send five deep samples of tissue for microbiological evaluation and a sample for histology (to look for fungal hyphae). If three out of the five samples are positive for the same organism then infection, dormant or otherwise, can be assumed and a 6-week course of appropriate intravenous antibiotics given under the guidance of the microbiologist. Clinical control of sepsis is guided by regular charted ESR, PV, and CRP.
estimations.

Long-term effects

Autograft will incorporate and remodel but it is always of inferior mechanical strength compared to the original bone and morphologically it forms a solid but heterogeneous block. The cortex and medullary cavity are not reformed.

Ceramics and allograft-based materials

Ceramic implants such as calcium phosphate or calcium hydroxyapatite pastes have no place in the management of segmental defects. Their role is well established as metaphyseal void fillers and in this locus their use may be equal or indeed superior to autograft.

Allograft has realistically only osteoconductive properties and little osteoinductive ones and cannot provide the rapid progress towards union to win the race against failure of osteosynthesis.

Box 12.19.3 Critical defects

- DH
- Acute shortening
- BMPs
- Free vascularized tissue transfer
- Tissue engineering.

Demineralized bone matrix (DBX) has yet to establish a clear role but its protagonists refer to the BMP content. The use of BMPs is well established but evidence is that they are only effective in supraphysiological doses and the BMP content in DBX is of no proven clinical value.

Critical-sized bone defects

The use of free osseous vascularized grafts such as DCMIA and free fibulas has been the mainstay of management of critical-sized defects and their role is well established. Their role in the management of diaphyseal long-bone defects has been superseded by distraction histiogenesis (DH) colloquially referred to as Ilizarov techniques, using circular frames and tensioned wires. The technique is now so mainstream that it will be described in some detail.

Distraction histiogenesis

DH has revolutionized the management of diaphyseal segmental defects of all sizes providing mechanical stability, the ability to modulate the new bone, and to simultaneously correct deformity, whilst at the same time creating new bone that has morphological features comparable to the original bone with similar mechanical properties once remodelling is complete. This technique, whilst powerful and at times spectacular, is not without its problems.

The theory behind the technique

An ‘atraumatic’ osteotomy is performed by lifting up the periosteum around the elected site for distraction. The bone is tensioned using the frame and the cortices are ‘postage stamped’ using a 2.5-mm drill. The postage stamping is connected with a sharp osteotomy (Figure 12.19.3), and slid along the axis of the cortex (without penetrating the medullary cavity). Particular care is paid to the posterior cortex and this may be broken by loosening the frame and rotating the bone ends around their longitudinal axis. The direction of rotation is chosen so as to slacken off major nerves. The frame is tightened down to compress the osteotomy which by this method is referred to as a corticotomy. The aim is to leave the periosteal and endosteal blood supply intact. Having said that, osteotomies performed with a Gigli saw appear as effective.
A latent period is required for callus to form and the frame is then used to distract the callus at a rate that osteogenesis occurs in a manner akin to endomembranous ossification. Rates of distraction are up to a millimetre a day, usually in four quarter millimetre increments during the day. For successful DH to occur the 'regenerate' bone requires mechanical stability avoiding shear and rotation. Axial compression is beneficial to regenerate bone and the beam loading biomechanics of circular frames lends itself to this as does a frame construct that is strong enough to allow weight bearing. Progress is monitored using radiographs that show a speculated area of regenerate bone of at least equal volume to the radiologically translucent fibrous interzone.

Ultrasound (Figure 12.19.4), is useful to look for cysts in the regenerate that are indicators that distraction is progressing faster than neovascularization and that distraction should be slowed down. Thus it is clear that the frame should hold onto each end of the bone as well as to the segment being transported. The technique of detaching a segment of bone to force it into the gap of missing bone is called bone transport and because there is a focus of distraction and a focus of compression at the other end, it is referred to as bifocal bone transport. The focus of compression is referred to as the docking site. When docking is complete, the docking site is compressed until union occurs by maintaining tension by compression for 1 day once a week or once a fortnight. It is not unusual to elect to autograft the docking site.

Once docking is completed, the frame needs to stay on until the regenerate is strong enough. The rule of thumb is that the frame on time is 1 month for every centimetre of transport required. Frame removal time is determined by waiting until there is good cortical bone on all cortices radiologically and the patient can fully weight bear without pain. The frame may be progressively loosened over the next few weeks until it is effectively completely loose. The frame can be removed and the limb placed in a weight bearing cast for 6 weeks and early x-rays taken to ensure there is no catastrophic collapse of the regenerate bone. If this occurs a frame may need to be reapplied. This is a disastrous complication and must not be allowed to occur. The author would rather take the frame off a month too late than a day too early. Correction of a collapsed regenerate may be very difficult to achieve.

Frame-on times may be reduced by use of the monorail technique (Figure 12.19.5), and it is perfectly possible to transport a segment of bone over an interlocked intramedullary nail. Early fears about implant related sepsis have not proven to be a major problem. The advantage is that transport is very accurate, frame-on times are much reduced, and collapse of regenerate bone is avoided. Regenerate quality does not appear to be compromised.
Failure of regenerate bone may be dealt with a number of ways. One can go into reverse for a time and then go forwards more slowly. One can simply stop for another latent period and go forwards when radiology supports mineralization or autograft and anecdotally the author has used BMP7 with good results.

The two major issues with circular frames are pin/wire site sepsis and frame-on times. Other issues are failure of the technique to make new bone, neurovascular damage, and joint contractures and subluxations. Autografting may also be required to complete the treatment.

**Wire site sepsis**

In Ilizarov's unit in Kurgan in Russia, wire site sepsis (WSS) is not found to be a major problem. They have an aggressive outlook on wire site care regarding the wire site as a surgical wound with cleaning with alcohol, application of sterile dressings which are applied with the attendant being scrubbed, gowned, masked, and gloved. The dressings are left undisturbed until the next appointment is due unless there is a problem. In the United Kingdom, a laissez faire attitude has developed with wire sites with no dressings and patients being allowed to shower and go about their daily activities as if there was no issue. This has resulted in WSS rates of greater than 60%. A pragmatic approach more closely following the Russian method can reduce WSS rates to below 20%. One major factor in WSS is the technique of wire insertion.

**The Oxford regimen for wire sites**

At surgery each wire is dressed with an alcohol sponge that is half split and ‘rides’ on the wire site and is held close to the skin as a pressure dressing with the clips that slide up and down the wires. This forms a sterile sealed environment and prevents the formation of haematomas as well as movement of the skin edges against the skin which would otherwise break down the wire to skin symbiosis. The sponges are changed under sterile conditions at 48h with the skin pushed down from around the wire and ‘descabbed’ and cleaned with alcohol and redressed under sterile conditions with sterile dressings and the proprietary clips pushed down onto the dressings so as to supply enough pressure to prevent movement at the wire skin interface. Dressings are left undisturbed and changed once a fortnight unless a problem arises.

**Surgical technique**

Only sharp wires must be used. If a wire has failed during the process of insertion it must be discarded and a new one used. The wire is inserted under power. The wire insertion site, once chosen, is cleaned again with alcohol. The wire is pushed through the skin and the assistant stretches the muscle compartment that is to be traversed until the wire abuts the bone. The dominant hand of the surgeon holds the drill while the non-dominant hand holds the wire with an alcohol-soaked swab. Drilling occurs in short bursts so as to reduce the chances of thermal necrosis and the formation of a ring sequestrum. Once the wire enters the exiting muscle compartment, the assistant passively stretches this too until the skin on the far side is breached. Power is not used when traversing muscle compartments and the wire is tapped with a mallet during this journey so as to reduce the risks of snagging neurovascular bundles.

**Box 12.19.4 Distraction histiogenesis**

- 1mm/day (4 × ¼ mm increments)
- Consolidation phase (1 month/cm gained)
- Can be used in conjunction with intramedullary nail
- Complications:
  - Infection
  - Neurological damage
  - Vascular damage
  - Joint contracture
  - Non-union docking site
  - Failure of regenerate
  - Fracture.
Acute shortening

This procedure is a useful adjunct in fresh injuries in selected cases (Figure 12.19.6). It is only effective in acute cases when the soft tissue envelope is pliable. Once oedematous it is difficult to achieve. The bone ends may be squared off with a saw until healthy bone is reached and the fracture may be stabilized and even plated and compressed at the time of soft tissue cover, if needed. A deferred DH procedure may then restore the limb to its original length and the docking site has effectively already docked and has started to unite, aided by the limb hyperaemia which results from DH.

In transverse open wounds, shortening may allow primary closure and avoid the need for a free tissue transfer but it will cause longitudinal wounds to gape. It should always be done with the tourniquet released as arterial kinking of empty vessels can occur resulting in an ischaemic foot. If done without an inflated tourniquet, the bone ends can be gently apposed and the vascularity of the foot assessed.

The multidisciplinary team

No one should embark on Ilizarov surgery without adequate experience and ancillary support. The surgeon requires more than an industry produced course (although a useful introduction) and should ideally go on a Fellowship to learn and apply the technique under guidance and supervision. Also they should not perform Ilizarov techniques on patients unless they have a similarly trained colleague or senior Fellow as part of the unit unless they are prepared never to go on holiday. The ultimate success of the procedure depends on a low complication rate with appropriate rehabilitation. The surgeon must work out of a unit with ilizarov trained nurses and ilizarov trained physiotherapists and clinical psychologists. A good x-ray in a septic leg with contractures is a failure.

Lastly, patient-related factors play a major role in the success or otherwise of this technique. Patients need to be fully cognitive of the principles that underlie this technique and be able to follow complex instructions, as well as understand the realistic objectives and how they are to be achieved.

Bone morphogenic proteins

BMPs are multifunctional cytokines of the transforming growth factor beta (TGF-β) superfamily. BMP2 and BMP7 are in commercial use. They work by inducing chemotaxis and mitogenesis and cause cellular differentiation and modulate vascularization and calcification. In the skeleton they orchestrate the pathway from mesenchymal stem cell to osteoblast and osteocyte. They work in supraphysiological doses and as such are effective as autograft and are frequently used in combination for large defects. They are difficult to handle for the surgeon as come as granules like sand and so have poor handling characteristics and thus the use of drains is contraindicated. It is said that one ampoule has the same amount of BMP as contained in 10,000 human skeletons. Consequently expense has proved a barrier to their regular usage. They have a proven role in improving union rates in open fracture when used at the time of wound closure/coverage. The author has used BMP7 in combination with autograft when filling critical-sized defects with success (Figure 12.19.7). The response has been unpredictable but their role is well established in the treatment of critical and subcritical segmental defects and as usage is increased it is hoped that costs will decrease.
Free tissue transfers

These techniques require the involvement of an experienced plastic surgical team. They are a good ‘one-stop shop’ for massive defects and have certain attractions. Results have been very good long term but these techniques also have their problems.

There are difficulties with correcting and holding the mechanical axis of the bone. Non-union of one side or other in free fibulas is not uncommon. The graft takes a very long time (up to 4 years) to hypertrophy and may never completely do so. The quality and strength of successful cases is inferior to successful cases of DH. Donor site morbidity may be significant. Plastic surgical and orthopaedic objectives for the patient are not always entirely the same.

Tissue engineering

This is the exciting future with bespoke implants and mesenchymal stem cells harvested from the patient that are grown in culture onto a suitable anatomically formed implantable matrix with recombinant signalling molecules. Research is ongoing with regards to a suitable matrix on ceramics, starch-based materials, and nanomaterials. The aim is to provide normal living tissue at the site but stability is an issue as the tissue develops. This is presently experimental or used in specialist research units.

The unforeseeable future

Great hope is held for genetic manipulation following the mapping of the human genome but reality and hope have a temporal mismatch. Nevertheless it is clear that some individuals have an idiosyncratic response to injury and nature can work in tandem with the surgeon as exemplified in the case demonstrated in Figure 12.19.8. This patient sustained a segmental defect following trauma in which the bone was stabilized and the soft tissue defect made good with a free muscle flap. The patient was awaiting maturation of the soft tissues prior to embarking on a monorail bifocal bone transport but rapidly started weight bearing without pain.

Spontaneous filling in of a 10-cm defect after stabilization and free flap coverage.

Summary

Autograft is the gold standard for the treatment of subcritical segmental defects. Its volume is limited but may be enhanced by harvesting from the femoral canal using reaming aspiration irrigation systems.

Autograft mixed with BMPs have a role in the management of critical-sized segmental defects but DH and Ilizarov techniques are now the gold standard for managing critical-sized defects producing bone of near morphological normality.

The future lies with tissue engineering with signalling molecules and genetic manipulation with bespoke implants.

Further reading

Injuries to muscle–tendon units

Summary points

- Most injuries at junction of muscle and tendon
- Early gentle movement best for recovery
- Tendon heals more slowly than muscle
- Surgery may include direct repair or more complex procedures e.g. lengthening/augmentation
- Minimally invasive procedures often best e.g. Achilles tendon.

Introduction

Skeletal muscle is the human body’s largest single tissue by weight, comprising 40–45% of total body weight. Muscle’s main function is to generate power for movement and maintain posture. Other functions include storage of energy and blood volume and thermoregulation. Muscles have tendons at each end which insert into bone or fascia.

Muscle, the musculotendinous (or myotendinous) junctions, tendon, and bony insertion together form a muscle–tendon unit.

Acute injuries to muscle–tendon units are common and cause considerable morbidity due to the site of injury and the age of those affected. They can occasionally be life- or limb-threatening. Much clinical and research experience on these injuries is the result of work by sports medicine clinicians. Chronic injuries to muscle–tendon units are discussed in Chapters 4.6 and 8.9.

There are controversies and deficiencies regarding natural history, classification, and treatment of these injuries, particularly when one compares the literature on bony and articular surface injuries. An understanding of structure, pathology, and healing helps in understanding the basis of operative and surgical treatments.

Epidemiology (Box 12.20.1)

Epidemiologic data regarding the incidence and prevalence of muscle–tendon unit injuries in the general population are poor. Some estimate a point prevalence of muscle injury of 1–2% of the population in industrialized countries.

These injuries are uncommon in young children, but the incidence increases in the second decade to peak and plateau in the third and fourth decades. There is then a decline in acute injuries, and chronic or acute-on-chronic problems increase in frequency. They are more common in males.

The most common type is the indirect minimal or partial muscle rupture. These are the most commonly occurring sports injuries, but are also frequent in the workplace and therefore have a significant economic impact. The economic cost in the of acute non-articular soft-tissue problems in the United Kingdom has been estimated at over £1 billion per year.

The incidence of muscle–tendon unit injuries seems to be increasing, due to increasing awareness and demand for treatment and increased adult participation in regular sport and exercise.

Current classifications are mainly based on the site, cause, and severity of injury. Unfortunately there is continuing confusion over nomenclature and terminology, and controversy over indications and optimal modes of treatment.

Anatomy

Skeletal muscle consists of multinucleate myocytes or fibres containing myofibrils which provide its contractile properties. Groups of muscle fibres form fasciculi. Groups of fasciculi form the whole muscle. There are other cells within muscle, such as satellite cells, which have important functions in healing and regeneration. Layers of connective tissue around muscle are the endomysium, which provides the extracellular space, the perimysium, which surrounds the fasciculi, and the epimysium, which surrounds the whole muscle (Figure 12.20.1A). A rich nerve and blood supply runs within these layers. The circulation within muscle is nutritive or non-nutritive; the latter are impedance and storage channels. The connective tissue sheaths fuse at the musculotendinous junction with tendon connective tissue.

Fig. 12.20.1
Structure of the muscle–tendon unit: A) muscle and investing layers; B) tendon and investing layers; C) ultrastructure of the musculotendinous junction (magnified).

Tendons are mainly composed of type I collagen (70% by dry weight) and are relatively acellular. Bands of collagen fibrils form fasciculi, and groups of fasciculi form bundles. Fasciculi are surrounded by the endotenon, containing nerves and small blood vessels. The outer connective tissue layer is the epitenon, which lies in loose areolar tissue (paratenon) or within a tendon sheath (Figure 12.20.1B). Tendon sheaths and bursae occur where moving structures are in tight apposition. The nerve supply is mainly efferent and the blood supply is poor, running in plexi between fasciculi. Watershed areas where the tendon blood supply is poorest have been identified and are linked to tendon pathology and rupture.

The musculotendinous junction is the interface between muscle and tendon. There is an intimate relationship between muscle fibres and collagen fibrils but no direct continuity (Figure 12.20.1C). The sarcolemma has multiple finger-like invaginations, known as terminal interdigitations, providing a large contact area to which collagen fibrils adhere. Adhesion is aided by glycoproteins and type III collagen. The junction is densely packed with sarcoplasmic organelles, mitochondria, and satellite cells, indicating potential for growth, repair, and regeneration. There is a portal blood supply and a rich efferent nerve supply.

The osseotendinous junction is also known as the enthesis. Tendons attach to bone at the periosteum and cortical bone, where they intermingle with perforating fibres of Sharpey, thus firmly anchoring them. If the attachment to bone is smooth, it implies the presence of a fibrocartilaginous plate which has anchoring properties.

**Biomechanics (Box 12.20.2)**

Muscle contraction, controlled by voluntary or reflex neural activity, produces a force depending on the number of muscle fibres available, muscle adaptation, muscle fibre type, muscle length, velocity of shortening, state of activation, and temperature.

Tendon properties vary depending on functional requirement, balancing tensile strength with elasticity. Tendons have high tensile strength, similar to bone, with 1cm² supporting 600–1000kg. Tendons display viscoelastic properties of stress relaxation, hysteresis, and creep. Overloading causes permanent lengthening damage—plastic deformation. Ultimate tensile strength is reached when all fibrils have failed—complete rupture.

The musculotendinous junction is important in force transmission, particularly during eccentric muscle contractions which occur in lengthening muscle; for example, landing from a jump causes eccentric contraction of the quadriceps, putting severe demands on the musculotendinous junction.

*In vitro* studies have shown that muscles tested to failure do so in the region of the musculotendinous junction on the muscle side of the junctional membrane. Muscle fatigue, prior injury, poorly conditioned muscle, and denervation all predispose strongly to. In human lower limbs, proximal rupture occurs in the proximal lower limb and distal rupture occurs in the distal lower limb. In the first and second decades the enthesis is the weakest part of the unit, and is thus more prone to injury.

**Box 12.20.2 Biomechanics of tendons**

- High tensile strength
- Overloading causes plastic deformation, then rupture
- Musculo-tendinous junction commonest site of injury.
Pathology and healing (Box 12.20.3)

General principles

The pathology of injury and healing are intimately connected. Injury incites an acute inflammatory response, of lag phase, lasting for 2–10 days, in proportion to and dependent on the degree of cellular injury and cell death. The inflammatory process will usually resolve and a cellular phase will commence. If there has been no tissue destruction, there is rapid resolution of the inflammatory exudate and return to normal, i.e. a grade I muscle injury. In the relatively avascular tendons, phases are prolonged. Sepsis or continuing injury will cause continuing inflammation. At 3–4 weeks postinjury the cellular regenerative phase will give way to a remodelling phase, which may go on for months.

Factors affecting healing

Local and systemic factors influencing muscle–tendon unit healing are shown in Box 12.20.5.

Box 12.20.5 Factors influencing the type of muscle–tendon injuries

- Mechanism of injury (e.g. crush, cut, etc.)
- Severity (force applied etc.)
- Muscle involved
- Location of injury in the muscle tendon unit
- Pre-existing pathology (e.g. steroid therapy, degeneration)
- Other injuries (e.g. vascular, neurological)
- Acute/acute on chronic/chronic.

Pathological events following injury and healing in muscle

Traditionally it was thought that muscle mainly healed by scarring. However, the capacity for muscle to compensate and return to full function by regeneration and hypertrophy has been demonstrated. Soon after muscle fibre injury, the fibres at each end of the injury zone break into short cylinders back to the next intact Z-disc and hypercontract, restricting the injury, although there is fibre necrosis. Rupture of epimysial vessels cause intermuscular haematomas with extensive ecchymosis and mild pain. Central ruptures cause intermuscular haematomas with more localized swelling, intense pain, muscle inhibition, and stiffness.

Box 12.20.3 Healing

- Muscle:
  - Always some scarring
  - Mobilization is probably good
- Musculotendinous junction—healing is slower
- Tendon:
  - By week 4, 40% of strength has returned
  - Cyclical loading is probably good
- Osteotendinous healing—is rapid.

Musculotendinous junction healing

Events at the musculotendinous junction are similar to but slower than those in muscle, with a central core of necrosis and a zone of hypercontracted fibres. Myotube formation occurs at 7–14 days, new sarcoplasmic contents appear at 21–28 days, and the cellular phase continues for 5–7 weeks postinjury.
Tendon healing

In tendon the inflammatory response takes over 14 days to settle. The tendon ends fill with fibrinous clot and granulation.

Repair occurs by proliferation of fibroblasts, either tenocytes from the tendon or from surrounding connective tissue layers, which synthesize collagen commencing on day 7 and continuing for several weeks. Fibroblast numbers and metabolism peak at day 14 and then slowly decline. Tendon strength increases as collagen fibrils are formed and reorientate. By week 4 the tendon has regained 70% of its pre-rupture stiffness and 40% of its strength.

Remodelling commences at week 4. Eight weeks postinjury, peritendinous adhesions break down and the tendon strength continues to increase. The collagen fibres are realigned fully at 9 months and remodelling continues for a year postinjury. In sutured tendons the lowest breaking strength is at day 7. It is doubled at 2–3 weeks and again at 4–12 weeks postinjury.

Experimentally, cyclical loading and early mobilization improve collagen fibril realignment, capillary ingrowth, time to normal strength, and viscoelasticity, and reduce stiffness. Immobilization of muscle–tendon units reduces tensile strength at the musculotendinous junction, increases risk of strain injury, and causes a 30% reduction in vascular density following 3 weeks of immobilization.

Osseotendinous junction healing

Unlike other injuries, immobilization is a prerequisite for healing to occur. Given the age of the patients with disruptions at this level, healing is rapid and occurs by fracture-type healing of the bony avulsion.

Compartment and crush syndromes

In these two conditions, muscle injuries can cause limb- or life-threatening problems.

Compartment syndrome is caused by swelling confined by osseofascial compartments, causing interruption of the normal capillary arteriolar circulation which can result in a vicious cycle of cell death and further swelling, eventually causing infarction of muscle, nerves, and other structures within the compartment. Management of compartment syndromes is discussed in Chapter 12.2.

Crush syndrome may occur after any blunt trauma, classically entrapment or prolonged ischaemic revascularization injury where there has been extensive rhabdomyolysis causing release of muscle proteins and waste products. This leads to intravascular activation, circulatory collapse, and acute renal failure, which is also caused by intrinsic nephron damage by the free muscle products, frequently exacerbated by inadequate resuscitation.

Complications of muscle–tendon unit injuries

Complications can be classified by time of onset from injury or by cause—the injury itself or iatrogenic (see Box 12.20.4).

Box 12.20.4 Complications

- Early:
  - Crush
  - Compartment syndrome
  - Haematoma
- Intermediate:
  - Muscle pain and spasm
  - Sepsis
- Late:
  - Scarring
  - Wasting
  - Stiffness
  - Myositis ossificans.

Classification

The type and severity of injury to muscle–tendon units is determined by a number of factors summarized in Box 12.20.5. There is no equivalent to the comprehensive classification system for fractures.

Muscle injury can be divided broadly into indirect and direct injury, in terms of the force transmission causing injury.

Indirect muscle injury
Indirect muscle injuries are most common and are also known as muscle strain injury, intrinsic muscle injury, pulled muscle, muscle sprain, or muscle tear. They occur when an abnormal force is applied to a muscle usually when it is activated and contracting, often eccentrically. Other factors associated with indirect injuries are muscle conditioning, fatigue, warm-up or muscle stretch, muscle temperature, anabolic steroid use, and previous injury.

Indirect muscle injury occurs most commonly at the musculotendinous junction in adults, the tendon in older patients, and the enthesis in young adults. In older patients there is often underlying degeneration within the tendon.

Muscles prone to indirect injury are those which cross two joints, contract eccentrically, and have a high proportion of type II fast-twitch fibres. Common sites of indirect injury are the medial head gastrocnemius (tennis leg), triceps surae, rectus femoris, adductor longus, semimembranosus, triceps brachii, and pectoralis major.

Indirect injuries form a spectrum from minor sprains to complete muscle ruptures, which have been graded as follows.

- **First-degree injury (grade 1)** is a strain with no significant muscle tissue disruption, but only with some disruptions of the connective tissue layers. There is minimal inflammation and no loss of strength or motion.
- **Second-degree injury (grade 2)** implies damage to muscle fibres and connective tissue that compromises muscle function, i.e. a partial rupture. The partial rupture is associated with haemorrhage from ruptured blood vessels of the perimysium and, depending on its location, may cause a central haematoma.
- **Third-degree (grade 3) rupture** implies complete disruption of some portion of the muscle–tendon unit, with concomitant loss of function and significant haemorrhage in the zone of injury.

**Direct muscle injuries**

Direct muscle injuries are divided into open and closed injuries. Closed injuries generally occur as a direct blow or crush as the result of sports injury (also known as extrinsic injury), blunt assault, industrial accidents, or road traffic collisions. Open injuries are associated with a sharp laceration or tissue loss such as those caused by glass, open fracture, gunshot injury, or burn. Direct injuries also form a spectrum from minimal to severe, and the O'Donoghue grading can be applied.

**Other traumatic causes of muscle cell injury**

Other causes of muscle cell injury are injuries to structures such as major blood vessels or nerves which result in muscle fibre death or dysfunction. Compartment syndromes can also cause muscle fibre death.

### Management

**Principles**

Definitive management of patients with muscle–tendon unit injuries involves diagnosis, treatment, and rehabilitation of the patient. (This is summarized later in Box 12.20.9.) The terms emergency, initial treatment, and definitive treatment are not mutually exclusive; initial treatment of an indirect muscle injury is often definitive as well.

**Box 12.20.9 Investigations**

- MRI
- Ultrasound
- CT
- Radiography
- Arthrography
- Bone scan
- Blood tests
- Urine tests
- Compartment pressure measurement
- EMG.

The first aim is to ensure the patient does not have a life- or limb-threatening condition; if this is the case the patient should be resuscitated and treated appropriately.

**Clinical assessment**

Clinical assessment involves history and examination, which is sufficient to diagnose most isolated injuries to muscle–tendon units. Compartment and crush syndromes, other injuries, and comorbidity should be identified, and this guides the need for further investigation and treatment. Initial clinical assessment is also a baseline for monitoring progress. Thorough note taking is advisable, particularly if treatment is going to be prolonged and multidisciplinary.
Differential diagnosis

A number of conditions can be mistaken for acute muscle–tendon unit injuries; some affect the muscle–tendon unit from within and some originate outside the unit, as summarized in Box 12.20.6.

Box 12.20.6 Differential diagnosis

♦ Extrinsic:
  • Stress fractures
  • Ligamentous/capsular injury
  • Bursitis
  • Referred pain
  • Radicular pain
  • Peripheral nerve pain
  • Skeletal infection
  • Skeletal tumour

♦ Intrinsic:
  • Tendonitis
  • Myositis
  • Infection
  • Muscle hernia
  • Muscle tumour.

History

The history should provide information regarding the injury and the patient to aid diagnosis and plan the extent of examination and investigation. Principle symptoms of muscle–tendon unit injuries are localized pain, swelling, and loss of function. Key points in the history are shown in Box 12.20.7.

Box 12.20.7 History taking

♦ Evaluation of injury:
  • Circumstances
  • Timing
  • Ability to continue activity

♦ Evaluation of patient:
  • Age
  • Occupation
  • Location of symptoms
  • Onset of symptoms
  • Treatment to date
  • Past treatment
  • Social history
  • Level of sports performance.

Examination

The clinical examination should be sufficiently thorough to confirm or suggest one diagnosis and exclude others. The basic principles are to inspect, palpate, and move the affected limb passively and actively. The neurovascular status of the limb is examined and, where applicable, specific tests of muscle or tendon integrity should be performed. These are summarized in Box 12.20.8.

Box 12.20.8 Examination
Joint movement is important in differentiating between intra- and extra-articular problems; for example, pain and reduced power on testing active external rotation of the shoulder implies an injury to the teres minor or infrapinatus components of the rotator cuff.

Thompson's calf squeeze test for the ruptured Achilles tendon is an example of a specific test of muscle tendon integrity.

Investigations

Investigations, summarized in Box 12.20.9, are not essential for all muscle–tendon unit injuries. There should be clear indications, which are to confirm a diagnosis prior to definitive treatment, to define which treatment option is optimal, to aid operative planning, to diagnose or exclude other pathologies, and/or to give prognostic information.

The investigation of choice for muscle–tendon unit injuries is magnetic resonance imaging (MRI), which gives excellent resolution of normal and pathological musculoskeletal and neurovascular structures shown in Figure 12.20.2. Ultrasound and computed tomography (CT) are also useful, particularly the former. Plain radiographs have a role, particularly in osseotendinous junction injuries and suspected fractures in conjunction with MRI are also useful.

![Click to view larger](Fig. 12.20.2 Imaging of muscle–tendon unit injury: MRI scan showing rupture of the Achilles tendon.)

Treatment

Principles of treatment

Most muscle–tendon unit injuries are treated non-operatively. The aims of treatment are to restore the muscle–tendon unit to normal function as quickly as possible and to prevent complications (see Box 12.20.4). Return to normal function can be improved by prompt adequate treatment and rehabilitation. A small proportion of patients will require specialized non-operative or surgical treatment, and in the latter a delayed operation or not operating may result in significant long-term morbidity.

Non-operative treatment

Emergency

Immobilization of the injured extremity, using a splint if necessary, is analgesic and avoids worsening the injury. Fluid resuscitation diuretics, dopamine, and dialysis are used for crush syndrome. Diagnosis, monitoring, and treatment are detailed elsewhere (Chapter 12.10).

Initial treatment

Painkillers, rest, ice, compression, and elevation (PRICE) form the initial treatment for a significant proportion of patients with
muscle–tendon unit injuries. It is commonly used as a postoperative regimen as well. The regime minimizes the inflammatory process symptoms and therefore the formation of fibrous adhesions. It is adequate for most grade 1 and grade 2 acute muscle–tendon unit injuries. This type of treatment is usually indicated for the first 3 to 7 days post-injury.

**Definitive treatment (Box 12.20.10)**

PRICE is frequently the definitive treatment. A smaller proportion of patients, particularly those seen in a hospital or clinic may require additional non-operative treatments.

**Pharmacological treatments**

Non-steroidal anti-inflammatory drugs (NSAIDs) are widely used for musculoskeletal problems and act by inhibiting arachidonic acid metabolism, reducing inflammation and platelet activation. They also have secondary analgesic properties. The exact mode of action of NSAIDs is unknown and qualitative proof of efficacy is poor. Inhibiting the cellular phase has theoretical risks of inhibition of healing.

Simple analgesics, such as paracetamol and opiate derivatives, have no direct effect on the injury, but are useful for symptom control. They can be used in conjunction with, or as an alternative to, NSAIDs.

**Box 12.20.10 Treatment**

- **Pharmacological:**
  - NSAIDs
  - Analgaesia
  - Sedation/muscle relaxants
  - Local anaesthetics

- **Physical:**
  - Initial ‘PRICE’
  - Splinting
  - Movement/exercise
  - Therapeutic ultrasound
  - Short wave diathermy
  - Aspirate haematoma.

Sedatives or muscle relaxants may be used to counter severe or painful muscle spasms, particularly in an anxious or agitated patient. They should be avoided in patients with head injury, if there is a specific contraindication, if there is a history of allergy or drug dependency, or if there is inadequate monitoring.

Local anaesthetics can be given proximal to a lesion as a regional block or epidural in lower-limb problems, for pain control, or for operative anaesthesia. In the acute situation there is a theoretical risk of masking a compartment syndrome, as blocks may cause sensory and motor deficits. Hyperbaric oxygen has been used in a few patients with muscle–tendon unit injuries.

There is no role for the use of corticosteroids in the acute phase of muscle–tendon unit injury.

**Physical treatments**

Rest, ice, compression, and elevation are most important in the first 72h postinjury.

Splinting, casting, or other forms of immobilization can be important in early management to help reduce pain and muscle spasm. They are also indicated for the definitive management of non-operatively treated tendon ruptures, most commonly of the Achilles tendon, as well as following surgical repairs. Various materials are available, including fibreglass and thermoplastics plaster of Paris. Splints can be removable, allowing for wound and skin care, and hinged to allow controlled joint motion.

Movement and exercise: understanding the normal healing process will guide the balance between immobilization to prevent rerupture or commencing mobilization to encourage faster return of normal blood supply and better remodelling. Ideally, exercise should be supervised, preferably by a physiotherapist.

Massage and counter-irritation have analgesic and potentially beneficial effects after the early inflammatory phase, similarly to other physical therapy treatment modalities (see later).

Ultrasound and short-wave diathermy are the most frequently used electrotherapy modalities in the treatment of muscle injuries. Others include electrical field stimulation and cryotherapy. Therapeutic ultrasound produces local thermal and non-thermal effects which reduces the duration of the inflammatory response by increasing macrophage and fibroblast activity, accelerates oedema and haematoma resorption, and improves the strength of scar tissue.
**Needle aspiration** of a persistent or worsening haematoma causing pain and muscle inhibition can be performed in the clinic or the radiology department. It must be carried out under aseptic conditions and a firm pressure dressing should be applied to the affected area to prevent recurrence.

**Operative treatment**

**Rationale and timing**

The decision to undertake operative treatment is based on a number of factors (Box 12.20.11). The potential benefits of surgery should outweigh the risks. The aims of surgery are as for treatment in general.

**Box 12.20.11 Factors affecting treatment**

- **Injury factors:**
  - Compartment syndrome
  - Fracture
  - Complete rupture
  - Retraction of rupture
  - Open wound
  - Wound contamination

- **Patient factors:**
  - Age
  - Fitness for surgery
  - Comorbidity
  - Pre-injury level of function
  - Expectations of recovery

- **Institution factors:** e.g. personnel, expertise, etc.

The timing of surgery is largely dependent on the pathology, although patient factors such as injury in top-class athletes are important. Acute compartment syndromes should be decompressed urgently as the warm ischaemic time to irreversible muscle damage is about 6h. After this period, and particularly after 10 days, there is marked adhesion formation and fibrosis, so that dissection and surgical trauma are more extensive, increasing the risks of complications and delayed healing.

**Operative principles and technique**

The principles of the surgery of soft tissues are summarized in Box 12.20.12.

**Box 12.20.12 Surgical principles**

- Asepsis
- Antibiotics if implants used
- Tourniquet is safe and indicated
- Adequate exposure
- Excise dead tissue
- Tension free apposition.

**Types of procedure**

The main types of procedure are shown in Box 12.20.13. A combination of procedures may be needed.

**Box 12.20.13 Types of procedure**

- **Closed injuries:**
  - Direct suture
  - V–Y lengthening
• Reinsertion into bone and fixation
• Augmentation, e.g. tendon, wire, graft.
• Fasciotomy
• Evacuation of haematoma

♦ Open injuries:
• Wound excision
• Delayed repair
• Soft tissue cover procedures.

Compartment decompression

The diagnosis of compartment syndrome and the surgical techniques used in its management are discussed elsewhere (Chapter 12.2).

Haematoma evacuation

Haematoma evacuation is only indicated as the sole procedure when a large intramuscular haematoma fails to resolve, increases in size, causes incipient skin and subcutaneous tissue necrosis, inhibits muscle activity or causes spasms, or is likely to progress to an ancient haematoma (commonly in thigh muscle groups). These types of haematomas are more common in patients with bleeding diatheses, and prompt correction of the clotting abnormality is the priority in such cases. Ultrasound guided biopsy is preferable in this group. Early haematoma evacuation may have a role in top-class athletes.

Direct suture

Direct suture or apposition is most readily used in fresh ruptures of the muscle–tendon unit at the mid-tendon, musculotendinous junction, or muscle belly. It can be a formally open technique or minimally invasive or percutaneous. Given the longitudinal alignment of the muscle fibres and tendon fibrils, simple suture techniques are not applicable and more complex sutures such as mattress, Kessler, or Strickland sutures are more applicable.

Lengthening with repair

Lengthening with repair is sometimes necessary to gain length to allow tension-free apposition of ruptured ends. Separation is caused by tissue loss at the time of trauma, fraying of tendon ends, retraction and shortening of the ruptured muscle, underlying muscle pathology, or a combination of these factors. An example of this type of repair is the V–Y lengthening of muscle, as used in quadriceps and Achilles tendon repairs (Figure 12.20.3B). Another method is to turn down flaps of the affected tendon as in rotator cuff or Achilles tendon repairs (Figure 12.20.3C).
Operative techniques of muscle–tendon unit repair: A) direct suture; B) V–Y tissue-advancement procedure; C) local flap advancement procedure; D) augmentation procedure with neighboring tendon; E) augmentation of repair with a tension band wire; F) fixation to bone with sutures through drill holes; G) fixation to bone with screw or plate, using a spiked washer or soft-tissue plate; H) fixation to bone with anchor suture.

Fixation to bone

Avulsed bone at the enthesis or avulsion of the tendon nearby may require direct fixation to bone. The former can be repaired using a small plate or toothed washer (Figure 12.20.3G), and the latter by using sutures with drill holes through bone or specially designed anchor sutures (Figure 12.20.3F, H).

Augmentation

A muscle–tendon unit repair can be augmented by using neighbouring muscle–tendon units as direct supports or brought into apposition as a flap, free fascia lata strips, implants such as Dacron or Marlex wrapped around the repair, or wires to protect the repair (Figure 12.20.3D, E).

Toilet and debridement

In the presence of an open contaminated wound, the priority is toilet and debridement to render the wound tidy, prior to definitive repair of the muscle–tendon unit and soft tissue cover.

Postoperative treatment

The initial priority is for early wound healing without infection. Early immobilization facilitates wound healing in the early phase. The immobilization time depends on the strength of the repair, the vascularity, the preoperative condition of the muscle–tendon unit and integument, and the treating physician’s preference.

For the lower limb, a consensus period of immobilization would be 6 weeks, followed by increasing protected and supervised mobilization over the next 6–12 weeks, and a return to normal activity profile at 6–12 months depending on the injury, the strength of the repair, and the pre-injury level of function.

Rehabilitation

Principles

Rehabilitation is the third and final part of the management of a patient with a muscle–tendon unit injury, forming a continuum with diagnosis and treatment. It is frequently neglected by physicians.

Rehabilitation aims to restore to normal function, or as normal as pathology allows, the injured muscle–tendon unit, adjacent joints, the affected limb, and the whole patient. Additional aims are to reduce complications and prevent further injury both during the remodelling phase (reinjury) and in the longer term.

The rehabilitation phase should take into account the diagnoses, treatment, pre-injury level of activity, and expectations of recovery. Physical, social, ergonomic, and psychological factors should be considered in rehabilitation. Most rehabilitation is performed by the patient, guided by physiotherapists. Physicians commonly prescribe rehabilitation without supervising it. Less commonly, pain clinics, psychologists, and psychiatrists are involved.

Treatments in rehabilitation

The treatment options are similar to those used in the early treatment, although the emphasis is different. Mobilization and exercise, following splintage and immobilization, are the cornerstones of rehabilitation. Other treatment modalities include counselling and drugs.
Common muscle tendon injuries requiring repair

The most common closed muscle–tendon unit injuries requiring repair, excluding open direct injuries, are listed in Box 12.20.14. They are generally complete ruptures due to indirect trauma. Ruptures and subsequent repair of almost every muscle–tendon unit have been described. Further details are given in this section and in the relevant chapters.

Box 12.20.14 Injuries often requiring repair

- Achilles tendon
- Rotator cuff
- Groin strain
- Quadriceps
- Patellar tendon
- Hamstring
- Biceps tendon
- Tibialis posterior
- Pectoralis major.

Achilles tendon and distal musculotendinous injuries

Complete ruptures of the Achilles tendon are the most commonly operated tendon ruptures. They occur most frequently in the fourth and fifth decades, and are twice as common in males. This is the most commonly occurring tendon rupture in sport.

The location of ruptures (2–4cm from the calcaneal insertion) is the watershed area of hypovascularity most prone to microtrauma and degenerative change, strongly associated with tendon ruptures.

The usual cause is sudden dorsiflexion of a plantarflexed foot, although it can be caused by direct sharp or blunt trauma. The classic symptom is of a feeling of being kicked above the heel. There is loss of active plantarflexion and no passive foot movement on squeezing the calf.

Partial ruptures do occur, but confirmation should be sought with ultrasound or MRI scanning, as the plantaris may continue to plantarflex the foot when the tendo-Achilles is ruptured. Musculotendinous junction injuries of the soleus or gastrocnemius are common, but rarely require surgery except in the case of high-class athletes.

Most authors agree that ruptures over a week old and reruptures should be treated operatively. More recently, non-operative treatment has been recommended if the gap that closes to less than 6mm in equines, as seen on ultrasound.

Developments in surgical technique include percutaneous repair (see Figure 12.20.3A) and the increasing use of a paramedian incision, which have reduced wound complication rates compared with earlier series. The immobilization time for both operatively and non-operatively treated patients is now 6–8 weeks.

In acute presentations the choice lies between the higher risk of rerupture if treated non-operatively (8–20%) and wound infection, breakdown, or rerupture (5–8%) if treated operatively.

Thus the optimal treatment for a fit athletic patient with an acute rupture is an early repair, which can be minimally invasive, followed by 4 weeks of cast immobilization or ‘minimal immobilization’ in a hinged cast, 2–4 weeks in a removable orthosis with passive ankle motion, 3 months with a heel raise and no running sports, and finally a graded return to full activity. Early weight bearing in an orthosis has not been found to be detrimental. Non-operative treatment would follow a similar course of immobilization, with a higher rerupture risk, and is a reasonable alternative.

Rotator cuff injury

Injuries to the rotator cuff cover the entire spectrum from minor strains to complete massive ruptures. There is a strong association with degenerative change within the cuff prior to injury in older adults. Acute-on-chronic ruptures in the middle-aged population make up the largest group of patients. Ruptures in young adults most commonly occur following a fall on the outstretched hand, injuring the supraspinatus. Full-thickness cuff tears are unusual in the younger age group (under 40), but the majority are acute and may be associated with fractures or dislocations. Definitive diagnosis may be difficult and is confirmed by arthrography, ultrasound, or MRI. Younger patients with ruptures make up a disproportionate group of those undergoing surgical repair. The epidemiology and specific management of rotator cuff injuries are discussed elsewhere (Chapter 4.3).

The majority of patients with full-thickness tears have fixation of the tendon to bone, possibly with intertendinous sutures, a transposition of subscapularis tendon, or a V–Y type repair. Other alternatives are Marlex, fascial autograft, or another tendon flap augmentation, with or without acromioplasty. Seventy to ninety per cent of patients undergoing surgery have reported good or excellent outcomes. Those who had surgery within 3 weeks of injury and no chronic radiological changes seemed to do best following acute injuries.
In a longer-term follow-up series younger women had slightly poorer outcomes than younger men, but at 4 years postsurgery there was an overall 94% satisfaction rate. There has been a move towards arthroscopic repair of some smaller acute tears over the past decade.

Aftercare of surgically repaired cuffs follows a regime of passive movements building slowly to active resisted movements over 12 weeks.

**Groin strain**

Groin strain injury encompasses a number of muscle–tendon unit injuries around the inguinal and anterior hip area. The most common injury sites are the proximal adductor origin at the enthesis or tendon, the distal iliacosas enthesis, the proximal insertion of the rectus femoris at the anterior superior iliac spine, or disruption of muscles inserting into or near the inguinal ligament. The last of these injuries, in the absence of a hernia, is sometimes termed ‘the groin disruption syndrome’ or ‘sportsman’s hernia’. These injuries commonly occur acutely in athletes who sprint, and are commonly reported in the sports literature. MRI scanning, ultrasound, and herniography are valuable in confirming the diagnosis and the need for treatment.

Treatment for the majority of the injuries is non-operative. A large avulsion from the ischium or iliac spine can be fixed using a screw or small plate and screws. The groin disruption syndrome (‘Gilmore groin’) can be treated operatively with direct or augmented repair of disrupted parts with a reported 90% success rate, i.e. a return to sport.

**Quadriceps tendon and muscle**

Acute indirect injury commonly occurs in the rectus femoris muscle. The quadriceps muscles are also commonly affected by direct injury in sport, with the risk of a painful intramuscular haematoma, and in association with femur fractures. The most common cause of indirect injury is a fall or stumble against resistance, causing eccentric contraction.

The mean age of injury is about 45 years, more commonly in males. In patients over 40 the site of rupture is in the distal mid-tendon, while in patients under 40, rupture is more likely to occur near the distal enthesis. In middle-aged and elderly patients there is a strong association with chronic systemic diseases, such as gout, diabetes, or renal failure, or long-term steroid therapy.

Case reports and small series demonstrate good or excellent functional outcomes in over 90% of patients who receive early repair, followed by 6 weeks of immobilization in extension and rehabilitation for 3 months.

Injury to the muscle belly is more difficult to repair surgically and in most cases the treatment is non-operative, with splinting for 6 weeks followed by rehabilitation. A delayed presentation mid-belly rupture may mimic a soft-tissue tumour, which should be excluded by investigations.

**Patellar tendon rupture**

Ruptures occur distally in the adolescent or proximally in the athlete aged over 20 years. There may be a history of a recent previous injury or chronic pain around the patellar tendon (jumper’s knee). Compared with other muscle–tendon units, particularly the quadriceps, there is a lower association with chronic systemic diseases states or tendinopathy in older adults.

Repair often involves opposing the tendon to bone using drill holes and multiple sutures, or a tension band wire around the patellar tendon mechanism, or both. Bony avulsions can be fixed back using screws.

**Hamstring ruptures**

Partial injuries to the hamstrings are very common, particularly in activities involving sprinting. Complete ruptures are rarer, but occur most commonly in sprinting athletes. The most common site is the proximal enthesis and the rupture is often an avulsion injury, seen on radiography. The distal musculotendinous junction is the next most common site.

Isolated hamstring ruptures are being diagnosed with increased frequency using ultrasound and MRI.

Surgical repairs of bony avulsions and musculotendinous junctions with good results have been reported in a small series.

**Biceps brachii**

Most ruptures are due to sudden forced flexion of the arm against resistance. The most common site of rupture is the long head tendon proximally in the bicipital groove, followed by the proximal musculotendinous junction, the short head tendon, the muscle belly, and most rarely the distal enthesis. Rupture is generally well tolerated in terms of function and cosmesis.

Surgery may be indicated in athletes and heavy manual workers, if the symptoms persist, or if there is a cosmetic defect. Reattachment procedures using anchor sutures, drill holes, and sutures have been described, with good functional outcomes in up to 80%.

**Tibialis posterior rupture**

This rarely occurs as an acute event, and is usually an acute-on-chronic rupture in a middle-aged or elderly patient who notes pain posterior to the medial malleolus, followed by an acute correctable flat foot. In younger patients it occurs following a sharp laceration, usually due to glass.

Surgery involves exploration at the level of or proximal to the medial malleolus. Direct repair is not usually possible. A tenodesis to the flexor digitorum longus is used, followed by distal transfer of the latter into the navicular. Use of the flexor hallucis longus is a
more complex procedure.

**Pectoralis muscle rupture**

This rupture occurs rarely in young adults lifting heavy weights. Considerable pain, bruising, and blood loss is associated with the injury. Scanning will differentiate partial from complete ruptures, and direct repairs have been reported with good or excellent functional outcomes.

**Further reading**

Summary points

- Dislocation – X-ray first if possible, then early reduction
- Many injuries can be treated with splintage
- Many unstable injuries can be treated with percutaneous wire fixation
- Chronic instability most commonly affects the thumb
- CMC joint injuries often need wiring if unstable.

Function of joints

Joints have two functions: movement and transmission of load. The failure of these functions—leading respectively to stiffness and instability—may seriously reduce hand function. But the relative importance of movement and stability varies between joints; the metacarpophalangeal (MCP) joint of the thumb needs stability more than motion, whereas motion at the proximal interphalangeal (PIP) and MCP joints of the fingers is crucial for gripping.

The effect of stiffness depends on the distance between the stiff joint and the tip of the digit. The MCP and PIP joints contribute much more to the total arc of finger motion than the distal joint. Stiffness of the DIP joint is well tolerated if the other joints are supple, and, therefore, any treatment directed at the distal joint should not risk inducing stiffness at other joints. The index finger, which performs most of its functions in a semi-extended posture for pinch against the thumb, tolerates stiffness better than the ring and little fingers, which must flex fully to the palm during power grip.

The exposed position of the hand at work, at home and at sport places its joints at risk of excessive forces that may disrupt their capsules and ligaments. These injuries are very common and may cause prolonged disability, especially at the PIP joint.

Clinical assessment

Any joint that is bruised or swollen after injury may contain a fracture or ligamentous injury. It needs both clinical and radiological examination. Palpation of an injured joint can be guided by a mental picture of the underlying anatomy; tenderness is then localized to bone, ligament attachments and tendon insertions by gentle palpation with a fine blunt object such as a pen top. Radiographs of the injured joint should include anteroposterior and true lateral views, supplemented by oblique views if necessary. Computed tomography (CT) may be useful where superimposition of adjacent rays obscures the lateral view.

Dislocations should be reduced promptly (Box 12.21.1), in order to restore circulation and reduce pressure on the skin, but the state of the nerves and vessels must be determined and recorded before any manipulation is performed or local anaesthetic block is administered. If x-ray facilities are available without delay, a radiograph should be taken before reduction; it may provide valuable evidence of injury to articular surfaces, ligament attachments, and tendon insertions. The direction of the dislocation often influences subsequent management but may not be known if the reduction was performed prior to radiographs. Open dislocations should be reduced promptly in the operating room after the wound has been irrigated; otherwise contamination may be carried into the joint as a protruding bone is reduced.

Box 12.21.1 Dislocations

- Reduce promptly
- X-ray before reduction if possible
- Open injuries should be reduced after wound debridement in the operating room.

Joint laxity may be demonstrated by stress examination and documented with a stress radiograph. Laxity may be masked by muscle spasm due to pain and it may be necessary to give a local anaesthetic block before a proper examination is possible.

Distal interphalangeal joint

Anatomy

The DIP joint is a hinge joint. The convex bicondylar head of the middle phalanx articulates with the base of the distal phalanx, which has matching biconcave surfaces separated by a vertical median ridge. The head of the middle phalanx is attached to the base of the distal phalanx by stout collateral ligaments and by the fibrocartilaginous palmar plate, which resists hyperextension.
The terminal tendon of the dorsal aponeurosis attaches to the epiphysis of the terminal phalanx, while the profundus tendon inserts into the metaphysis. Dislocations are less frequent at the DIP joint than at the PIP joint, probably because of the short lever arm of the distal phalanx and the strength of the ligamentous supports.

Dorsal dislocation

Dorsal dislocation is the result of rupture of the palmar plate by a hyperextension force. Reduction is occasionally blocked by interposition of the palmar plate or the flexor tendon, in which case open reduction via a dorsolateral approach is needed. Lateral stability is seldom impaired. Active flexion may begin immediately and late instability is rare.

Dorsal fracture–dislocation

Dorsal dislocation may be accompanied by fracture of the palmar lip of the distal phalanx; stability after reduction depends on the size of the fragment and the joint may require pinning in the reduced position. If the insertion of the profundus tendon is detached, it should be reattached via a palmar approach.

Palmar fracture–dislocation

Avulsion fractures of the extensor tendon insertion (‘mallet fracture’) that involve more than 40% of the articular surface may be associated with palmar subluxation or dislocation of the DIP joint. The injury is usually the result of a blow that imparts flexion and axial compression force to the end of the finger. The subluxation is maintained by the unopposed action of the profundus tendon. The indications for operative correction of the subluxation are controversial. Operative fixation is difficult unless there is a single large fragment. Surgical complications are common, and the results of non-operative treatment are generally good. Transarticular pinning of the reduced joint is the safest operative method.

Proximal interphalangeal joint

Anatomy

The PIP joint is a hinge joint and is stable to lateral stress at all angles of flexion. The head of the proximal phalanx has two convex condyles that articulate with matching surfaces of the middle phalanx.

The collateral and accessory collateral ligaments form, together with the palmar plate, a three-sided box that encloses the head of the proximal phalanx. The PIP joint cannot be displaced unless the box-like ligament array is disrupted in at least two planes. The collateral ligament arises from a depression just dorsal to the mid-axial line of the head of the proximal phalanx and inserts into the palmar lateral tubercle at the base of the middle phalanx. The accessory collateral ligament runs obliquely from the head of the proximal phalanx into the palmar plate. The palmar plate provides a static restraint to hyperextension; it is a tough fibrocartilaginous structure that has strong attachments to the palmar-lateral corners of the middle phalanx. The central portion of the palmar plate is rather loosely attached to the periosteum of the base of the middle phalanx. Proximally, the palmar plate has a long fibrous attachment (‘check-rein ligament’) to each side of the proximal phalanx at the distal margin of the A2 pulley.

PIP joint injuries

Ligament injuries to the PIP joint may be dorsal, lateral, palmar, or combined. The severity of injury varies from simple PIP joint sprains, which are common in athletes, to fracture–dislocation. Local tenderness may indicate the structures that are injured. Integrity of the extensor mechanism, collateral ligaments and palmar plate should be assessed and the joint should be observed for instability or deviation during active motion, under digital nerve block if necessary.

Dorsal PIP joint dislocation (Box 12.21.2)

Mechanism

Hyperextension force tears the distal insertion of the palmar plate or avulses a small bone fragment from its attachment at the base of the middle phalanx. The tear propagates longitudinally within the collateral ligament, or between the collateral and accessory collateral ligaments, allowing the base of the middle phalanx to dislocate dorsally (Figure 12.21.2).
collateral ligament remains intact and the joint is stable to lateral stress after reduction.

![Figure 12.21.2](image)

**Fig. 12.21.2**
Dorsal dislocation of the PIP joint. The line of injury passes through the distal insertion of the palmar plate and runs proximally along the fibres of the collateral ligament. The dorsal part of the collateral ligament remains intact (A, B).

**Treatment**

Dorsal dislocations are generally stable after reduction and require minimal treatment. The aim of treatment is early restoration of movement, but splintage in 10 degrees of flexion for 5–7 days may be useful for relief of pain. Swelling, discomfort, and stiffness may persist for several months. The presence of a small avulsion fracture at the palmar lip of the base of the middle phalanx does not jeopardize stability or affect the management of this injury.

**Open dorsal dislocation**

Open dislocation of the PIP joint is usually associated with a transverse palmar wound at the level of the PIP joint; the skin splits as the joint is hyperextended. The serious risk of infection and stiffness may be underestimated if it is not appreciated that the wound communicates with the joint and with the flexor tendon sheath. Patients managed in the emergency room by closed reduction and suture are at risk of disastrous joint and tendon sheath infection. The wound should be debrided and the joint irrigated in the operating room.

**Box 12.21.2 Dorsal PIP joint dislocations**

- Generally stable after reduction
- Early movement as tolerated
- Beware open dislocations.

**Complications**

Flexion contracture is an unpredictable but common complication of PIP joint sprain or dislocation. The key to successful management is early recognition and treatment by static or dynamic splintage.

**Dorsal PIP joint fracture–dislocation (Box 12.21.3)**

**Mechanism**

The combination of hyperextension and axial loading produces a fracture of the palmar edge of the base of the middle phalanx and dorsal dislocation (Figure 12.21.3). Instability is directly related to the size of the fracture fragment. Since the collateral ligaments insert into the palmar aspect of the base of the middle phalanx, involvement of more than 40% of the articular surface effectively separates the ligaments from the middle phalanx and stability is lost. Stability is also impaired by loss of conformity of the articular surfaces, especially of the palmar lip of the middle phalanx.
A) Dorsal fracture–dislocation of the PIP joint. When the fragment comprises 40% or more of the base of the middle phalanx, it contains most or all of the insertion of the collateral ligament. B) Late result of untreated dorsal fracture–dislocation.

Assessment

Swelling masks the deformity and the fracture–dislocation can be overlooked if a true lateral radiograph is not taken. Congruity of the joint surfaces is the aim of treatment; the relationship of the proximal phalanx to the middle phalanx is more important than the position of the palmar fragments. However, dorsal fracture–dislocation is a serious injury that may impair function of the PIP joint in the long term. Management is determined in part by the size and number of the fragments; however, the treatment of severe injuries remains controversial.

Box 12.21.3 Dorsal PIP joint fracture–dislocation

- True lateral x-ray necessary to assess joint reduction
- Treatment options:
  - Extension block splintage
  - Transarticular pin
  - Open reduction and internal fixation
  - External fixation-traction system
  - Palmar plate arthroplasty
  - Hemihamate arthroplasty.

Extension block splintage

Fractures which comprise 10–30% of the joint surface may be stable in flexion, in which case the joint can be moved within a limited range in a splint which blocks extension. A dorsal padded aluminium splint is incorporated into a forearm cast and the splint is bent to block extension at the angle of flexion that is just sufficient to maintain a congruent reduction, usually about 50 degrees (Figure 12.21.4A). Active flexion is encouraged. The extension block is decreased by 10–15 degrees each week, provided that congruity is maintained on the lateral radiograph. The splint is worn for 4–6 weeks. Static or dynamic extension splintage may be needed to overcome a residual flexion contracture.
Operative treatment

Operative treatment is required when congruent reduction cannot be maintained in flexion, which is usually because the fracture comprises more than 30% of the articular surface, or because treatment was delayed. There is no consensus about the best means of operative stabilization.

Percutaneous pin fixation.

The reduced joint is transfixed in about 25 degrees of flexion for 3–4 weeks by a pin inserted though the bare area of the middle phalanx, just distal to the central slip insertion (Figure 12.21.4B). The simplicity of this method, which concentrates on restoring the correct relationship between the proximal and middle phalanges rather than precise reduction of the fracture fragments, has much to commend it.

Open reduction and internal fixation.

Open reduction may be performed through a palmar approach, opening the flexor sheath between A2 and A4 pulleys and retracting the tendons. A single large fragment that can be reduced and held with one or more small screws, but multifragmentary fractures are challenging and may require buttressing with a cage plate and bone grafting.

External fixation.

Several ingenious techniques have been devised to exert traction on the middle phalanx whilst allowing movement of the PIP joint. The principle is sound but the technical aspects are demanding. The axis of motion of the device must coincide with the axis of the joint, and the device should permit joint motion without rotation of pins in the bone.

Palmar plate arthroplasty.

The palmar plate is used to reconstruct the articular surface of the palmar half of the middle phalanx. After excision of the bone fragments, the palmar plate is advanced into a transverse groove created in the defect in the base of the middle phalanx. The plate is held in place by a suture passed through drill holes in the middle phalanx and tied over a button on the dorsum of the finger or to a suture anchor. In late cases, it is usually necessary to excise the collateral ligaments in order to reduce the joint. The joint is immobilized for two weeks by a transarticular K–wire and then mobilized in an extension-block splint for a further two weeks. At 5 weeks, dynamic splintage may be needed to correct a flexion contracture.

Hemihamate arthroplasty.

The damaged palmar lip of the middle phalanx is replaced with a size-matched portion of the hamate obtained from its distal dorsal articular surface between the ring and little metacarpals, thereby restoring joint stability and allowing early movement (Figure 12.21.5). This method is the best means of reconstruction of severe and late-presenting injuries.
Palmar PIP joint dislocation (Box 12.21.4)

Palmar dislocation of the PIP joint is more serious but much less common than dorsal dislocation. A rotational force tears one collateral ligament, the palmar plate and sometimes the central slip of the dorsal aponeurosis. The joint is unstable and liable to palmar subluxation, rotation and boutonnière deformity. If the central slip remains intact, reduction may be prevented by entrapment of the head of the proximal phalanx between the central slip and the lateral band. Early recognition and treatment of this serious injury is crucial in maintaining function of the finger, in contrast to dorsal dislocation which generally does well with minimal treatment.

Entrapment of the head of the proximal phalanx may be reduced by flexion of the MCP joint, which slackens the dorsal aponeurosis. If the central slip is intact, the joint can be immobilized in extension for two weeks and then mobilized with active flexion and dynamic and/or static splintage to prevent development of a flexion contracture. The joint should be reduced and held in full extension while the injured structures heal; this is most easily and reliably achieved with a transarticular pin. Open reduction and repair may be needed for displaced intra-articular fractures, irreducibility or fixed contracture.

Lateral PIP joint dislocation

Laterally directed force may rupture the collateral ligament and the ipsilateral half of the palmar plate, thus disrupting the box-like ligament array and allowing lateral dislocation. If the joint surfaces are congruous on x-ray after reduction and the joint is stable during flexion and extension, early protected motion is permitted. The finger can be supported during mobilization by taping to the adjacent digit on the side of the collateral ligament injury. Late instability is rare.

Box 12.21.4 Palmar PIP joint dislocation

- Open reduction occasionally required
- Splint in extension
- May need transarticular wire.

PIP strains

Lateral and hyperextension strains of the PIP joint are frequent in athletes. The primary restraint to lateral angulation stress at the PIP joint is the collateral ligament. Under load, the ligament fails at the proximal end and the tear then extends between the collateral and accessory collateral ligaments before running across the palmar plate. Protected active movement with buddy taping for 2–3 weeks is sufficient in most cases. Pain, swelling and stiffness often persist for several months after lateral ligament strains. Late instability is rare, but some joints develop troublesome flexion contractures that require static and/or dynamic splintage.

Hyperextension strains may be associated with avulsion of a small flake of bone at the distal insertion of the palmar plate. Flexion contracture is a common but unpredictable consequence of hyperextension injury and may require intensive splintage and exercise.

Hyperextension laxity is uncommon but may be aggravated by pre-existing ligament laxity or previous injuries. The finger adopts a ‘swan-neck’ posture with hyperextension at the PIP joint and flexion at the DIP joint, but mechanical difficulty in initiating PIP joint flexion is usually the presenting symptom. As the finger is flexed, the PIP joint “hangs up” in hyperextension, snapping down into flexion as the voluntary effort is increased. Repair of the attenuated palmar plate, if possible, or construction of a new static
restraint to hyperextension is required. Tenodesis using one slip of the superficialis tendon is a simple and reliable technique.

Metacarpophalangeal joints of the fingers

Anatomy

The strong collateral ligaments and palmar plate protect the MCP joints from dislocation. The palmar plate has stout attachments to the proximal phalanx but its proximal attachment is thinner and it lacks the fibrous ‘check-reins’ of its counterpart at the PIP joint. The MCP joint resembles the PIP joint in having a box-like arrangement of collateral and accessory collateral ligaments, which insert into the edges of the palmar plate. The MCP joint is linked to adjacent rays by the deep transverse metacarpal ligaments, which are continuous with the lateral edges of the palmar plate. The primary stabilising structures are the collateral ligaments. The palmar plate resists hyperextension and only contributes to lateral stability when it is taut in extension.

Dorsal dislocation (Box 12.21.5)

Dorsal dislocation of the MCP joint of the finger is uncommon (though it is the most common dislocation in children) and may affect the index and little fingers. The middle and ring fingers are protected by adjacent digits and are seldom dislocated unless the border digit is also injured. The thin proximal attachment of the palmar plate is torn by hyperextension force but the collateral ligaments remain intact.

Dorsal dislocation of the MCP joints may be simple or complex. Simple dislocation is characterized by marked hyperextension (60 –80 degrees). The palmar plate is ruptured proximally and remains attached to the proximal phalanx; it is draped over the head of the metacarpal but does not block reduction (Figure 12.21.6A). The articular surface of the base of the proximal phalanx lies in contact with the dorsum of the metacarpal head. The dislocation may be converted to the complex type by traction, which may flip the palmar plate onto the dorsum of the metacarpal head. Reduction can be accomplished by direct pressure over the dorsum of the base of the proximal phalanx in a distal and palmar direction, pushing it back over the metacarpal head. Late instability does not occur and no splintage is needed.

Complex dorsal dislocation

Pathology

Complex dislocation of the MCP joint occurs when the palmar plate becomes interposed between the base of the proximal phalanx and the metacarpal head. The joint rests in modest hyperextension (20–40 degrees) (Figure 12.21.6B). Anterior displacement of the metacarpal head creates a prominence in the palm, with blanching of the palmar skin (Figure 12.21.6C), and a hollow just proximal to the base of the proximal phalanx dorsally. There may be an osteochondral fracture of the metacarpal head.

The primary block to reduction of a complex dislocation is the palmar plate, which remains attached distally to the base of the proximal phalanx and lies on the dorsal surface of the metacarpal head. Although closed manipulation is sometimes successful, open reduction is usually required.

Operative treatment

A dorsal approach to complex MCP joint dislocation avoids the risk of digital nerve injury in the palmar approach, allows access to osteochondral fractures and is both simpler and quicker than a palmar approach. The extensor tendon is split in the midline, exposing the base of the proximal phalanx and the palmar plate as it lies on the head of the metacarpal. Longitudinal incision of the palmar plate allows the two halves to slip back over the head of the metacarpal. The MCP joint is stable after reduction. Immobilization is unnecessary and may lead to stiffness. Recurrent dislocation and late instability do not seem to occur in the fingers, though injury to the palmar plate of the thumb MCP joint may contribute to hyperextension laxity.

Complex palmar dislocation of the MCP joint is rare but may require open reduction of the entrapped palmar plate or dorsal capsule.

Locked MCP Joint (Box 12.21.6)
Locking of the MCP joint is characterized by the sudden onset of a flexion deformity that cannot be corrected passively. Locking may be acute, chronic or intermittent. Entrapment of the palmar plate on an osteophyte arising from the palmar/lateral corner of the metacarpal head is the usual cause of locking in older patients. Oblique views or CT may be needed to demonstrate the osteophyte; its removal will correct the deformity. Distension of the joint with local anaesthetic may lift the palmar plate off the osteophyte, but locking may recur. Other causes of locking include loose bodies, malunited articular fractures and entrapment of an interosseous tendon or collateral ligament on bony prominences of the metacarpal head.

Box 12.21.5 MCP joint dislocation

- Simple:
  - Presents with 60–80 degrees hyperextension
  - Reducible closed
- Complex:
  - Presents with 20–30 degrees hyperextension
  - Palmar plate entrapment
  - Open reduction required
  - Dorsal approach.

Box 12.21.6 Locked MCP joint

- Usually older patient
- Palmar plate caught on osteophyte palmar/lateral aspect metacarpal head
- Oblique x-rays or CT may be needed
- Closed and open reduction techniques.

Metacarpophalangeal joint of the thumb

Anatomy

The collateral ligaments and palmar plate are the primary stabilizers of the MCP joint of the thumb, but additional dynamic stability is provided by the insertion of the adductor pollicis muscle at the base of the proximal phalanx. The adductor aponeurosis lies directly over the ulnar collateral ligament and is formed from fibres that pass from the adductor muscle into the ulnar side of the dorsal aponeurosis. Stability is the most important attribute of the MCP joint of the thumb; movement is much less important provided that the basal joint is mobile. Indeed, some normal individuals have very little MCP joint flexion, but the average range is 75 degrees flexion, 20 degrees hyperextension, and 10 degrees abduction/adduction.

Dorsal dislocation

Dislocation of the thumb MCP joint is similar in many respects to dislocation of the index and little finger MCP joints. It results from forcible hyperextension and may be simple or complex, the latter resulting from interposition of the palmar plate. The management is the same as in the index finger. After reduction the stability of the collateral ligaments should be checked and any instability managed as described below.

Hyperextension injury of the thumb MCP joint may strain or rupture the palmar plate; comparing the range of hyperextension with the opposite thumb, using a local anaesthetic block if necessary, may identify these injuries. Strains require symptomatic treatment only. Complete ruptures should be immobilized with the MCP joint in 10–20 degrees flexion for 3–4 weeks to encourage healing of the palmar plate at its correct length. Hyperextension injuries occasionally lead to laxity and dynamic collapse of the thumb skeleton with hyperextension of the MCP joint and flexion at the IP and CMC joints. The collapse deformity can be corrected by capsulodesis or tenodesis of the MCP joint, if the joint surfaces are healthy, or by arthrodesis if the surfaces are degenerate.

Ulnar collateral ligament injury

Mechanism

Rupture of the ulnar collateral ligament is caused by forced abduction stress, with or without hyperextension. The degree of injury varies from a stable ligamentous strain to disruption of the collateral ligament, palmar plate and dorsal capsule. Motorcycle accidents, falls onto the outstretched thumb and ski-pole injuries are common causes of MCP joint ligament rupture. The ulnar collateral ligament resists laterally directed forces during pinch against the index finger; laxity of the ligament is associated with a weak painful pinch and predisposes to degenerative arthritis of the MCP joint.
Pathology

The ulnar collateral ligament is usually injured at its attachment to the proximal phalanx, where it may avulse a fragment of bone, but mid-substance ruptures are occasionally seen. An anatomical peculiarity of the ulnar side of the MCP joint may account for the poor results of non-operative management of complete collateral ligament ruptures. The ligament may slip around the proximal free edge of the adductor aponeurosis as the aponeurosis slides distally at the moment of injury—the Stener lesion. The aponeurosis then separates the torn end of the ligament and its site of attachment to the proximal phalanx (Figure 12.21.7A). The Stener lesion is present in the majority of complete ulnar collateral ligament ruptures. The ulnar collateral ligament may avulse a small fragment of bone at its insertion and the presence of a Stener lesion may be inferred from the position of the fragment on x-ray.

Assessment

Radiographs should be taken before stress testing is performed, lest an undisplaced fracture is displaced. If there is no fracture, the integrity of the ligament can be assessed by applying radial deviation stress and comparing the range of abduction with the opposite side (Figure 12.21.7B, C). It may be necessary to relieve pain and muscle spasm by infiltration of local anaesthetic before an adequate examination is possible. The examination should be performed in 15-degree flexion, which is sufficient to relax the palmar plate but not enough to allow rotation of the proximal phalanx during testing. The amount of laxity and the ‘end-point feel’ are compared with the uninjured side. A 30-degree excess of laxity compared to the opposite side indicates rupture of the ulnar collateral ligament and the need for operative repair.

Treatment (Box 12.21.7)

Ligament injuries which are not associated with excess laxity, and those with undisplaced avulsion fractures, may be treated with strapping but are often more comfortable in a thumb spica cast for 3–4 weeks. Those with excess laxity should be explored and repaired via a dorsoulnar incision, protecting the branch of the superficial radial nerve that lies here. Avulsion fractures which are displaced by more than 2mm should be reduced operatively and fixed with a K-wire, interosseous wire or small lag screw, depending on the size of the fragment. If a Stener lesion is present, the distal end of the collateral ligament is usually found turned back upon itself immediately proximal to the edge of the adductor aponeurosis. The ligament is usually torn at its attachment to the palmar and ulnar corner of the base of the proximal phalanx, and may be reattached by suture to local tissues or by a suture anchor. Protection of the repair with a transarticular pin is optional. The joint is mobilized after 4 weeks but protected from stress until the 8th week. Some limitation of MCP joint flexion is common but is not disabling in a joint where stability is more important than movement.

Chronic MCP joint instability

After 2 weeks from injury, the ruptured ligament shortens and it may be difficult to achieve a secure repair. The ligament may be reconstructed with a strip of palmaris longus tendon passed in a figure-of-eight fashion though vertical drill holes in the bone on each side of the joint. In the presence of degenerative arthritis, arthrodesis is an excellent procedure that provides stable pain-free pinch. Very little disability results from loss of MCP joint movement provided that there is good motion at the basal joint.

Radial collateral ligament injury

Tears of the radial collateral ligament account for about a quarter of MCP joint collateral ligament injuries. The ligament may tear at either end and there is no counterpart of the Stener lesion on the radial side of the joint. Pain occurs when pressure is placed on the radial side of the thumb, particularly when pushing against a surface with the hand flat. Excessive ulnar deviation occurs on adduction stress. Unstable radial collateral ligament injuries should be repaired.
**Carpometacarpal joints of the fingers**

**Anatomy**

The CMC joints of the index and middle rays have interlocking articular surfaces and strong ligaments that allow very little movement. The base of the fourth metacarpal articulates with the radial facet of the hamate and has 10–15 degrees flexion-extension. The fifth CMC joint allows 15–20 degrees flexion as well as some rotation, aiding opposition of the thumb to the little finger and cupping of the palm. The deep branch of the ulnar nerve runs close to the palmar aspect of the fourth and fifth CMC joints, where it may suffer injury or operative damage.

**Mechanism of injury**

Dislocation of the CMC joints of the fingers may involve one or more joints, with or without fracture of the articular surfaces, and may be associated with fracture of adjacent metacarpal bones. The displacement is usually dorsal and the fifth ray is most frequently injured, though several types of multiple dislocation have been reported (Box 12.21.8).

**Box 12.21.7 Thumb MCP joint ulnar collateral ligament injuries**

- Radiograph before testing stability
- Relieve pain before testing stability
- Test in 15 degrees flexion
- Splint stable injuries
- Operative repair for most complete ruptures

**Box 12.21.8 CMC dislocations of the fingers**

- Easily missed
- Associated with polytrauma and severe swelling
- Assess with oblique radiographs/CT scan
- May require open reduction

**Assessment**

Examination shortly after injury will often detect the dorsal displacement that may have been noticed by the patient. However, CMC joint dislocations are easily overlooked. Contributory factors are obliteration of deformity by swelling, inadequate radiographs or their incorrect interpretation and the presence of multiple injuries. The frequent combination of a displaced metacarpal fracture with CMC joint dislocation in an adjacent ray is a pitfall; the fracture catches the eye and the dislocation is missed.

Severe swelling of the wrist after a violent injury frequently conceals a serious carpometacarpal or carpal injury. The minimum radiographic examination comprises PA, true lateral view and oblique views in 30 degrees pronation and supination from the lateral position. CT examination may be very helpful in defining the injury and particularly in determining if comminution precludes operative reconstruction of the articular surfaces.

**Dorsal CMC joint dislocation**

Single CMC joint dislocations may result from blows to the hand or from falls, causing flexion and axial loading of the metacarpal. The fifth ray is most often affected. Disruption of several joints, especially the strong second and third, requires high energy trauma and these patients frequently have multiple injuries. The dislocations can usually be reduced without difficulty; stability can be assessed at the time of reduction and a K-wire inserted if necessary.

**Dorsal CMC joint fracture dislocation**

Undisplaced articular fractures of the CMC joints may be treated satisfactorily with external splintage of the wrist and protected motion of the fingers. Fracture-subluxation of the fifth CMC joint is sometimes called ‘reverse Bennett’s fracture’ because of its similarity to fracture-subluxation of the first CMC joint. The fracture line runs obliquely across the metacarpal base, leaving the radial fragment attached to the base of the fourth metacarpal and hamate by the strong intermetacarpal ligaments and allowing the shaft of the metacarpal to displace in an ulnar and dorsal direction. The sloping surface of the hamate, the obliquity of the fracture line and the pull of the extensor carpi ulnaris tendon all contribute towards redisplacement after reduction. Closed reduction can usually be achieved without difficulty using a combination of traction and direct pressure but the injury is unstable and requires percutaneous pin fixation. The aim is restoration of the relationship between the metacarpal shaft and the hamate; slight displacement of the intra-articular fracture may be accepted. Open reduction is indicated for failed closed reduction, soft-tissue interposition or late presentation, and for open injuries.

Multiple CMC joint fracture dislocations are accompanied by severe swelling which precludes effective control by external
Multiple CMC joint fracture dislocations are accompanied by severe swelling which precludes effective control by external splintage. Percutaneous pin fixation may be possible but it can be difficult to achieve in the presence of swelling and reduction is sometimes blocked by interposition of soft-tissues such as the extensor carpi radialis brevis tendon. Multiple pins are required and they tend to interfere with movement of the extensor tendons if the ends are left long. The potential for stiffness of the fingers in these severe injuries demands mobilization as soon as possible. Open reduction with fixation by buried K-wires, together with screw fixation of associated metacarpal fractures and large intra-articular fragments, permits early movement and also ensures an accurate reduction.

Box 12.21.9 Trapeziometacarpal dislocation

- Dislocation without fracture uncommon
- Reduction often unstable—transarticular pin
- Late instability may require ligament reconstruction or arthrodesis.

Trapeziometacarpal joint

Anatomy

The basal joint of the thumb is saddle-shaped. The primary stabilizing ligaments are the anterior oblique and dorsoradial ligaments, but the first intermetacarpal, ulnar collateral and posterior oblique ligaments act as secondary stabilizers.

Dislocation of CMC joint of thumb (Box 12.21.9)

Dislocation of the basal joint of the thumb without fracture is uncommon and results from longitudinal force applied along the metacarpal shaft to the flexed basal joint (Figure 12.21.8). The dorsoradial ligament tears and the anterior oblique ligament is stripped subperiosteally from the base and proximal shaft of the metacarpal. Immediate closed reduction and maintenance of a stable reduction in a cast is associated with a good long-term outcome, but many joints are unstable and require percutaneous pin fixation. Painful instability is common in patients presenting late and may occur despite primary pin fixation.

Late instability of the basal joint predisposes to early degenerative arthritis. An anteroposterior stress radiograph with the radial surfaces of the thumbs pressed together may demonstrate instability. The treatment of painful instability or subluxation is determined by the state of the articular surfaces. Ligament reconstruction using a distally-based strip of the flexor carpi radialis tendon is appropriate if the articular surfaces are healthy. The tendon strip is passed through a drill-hole in the base of the metacarpal so as to replicate the function of the anterior oblique ligament. If painful instability is accompanied by degenerative change, the options are trapezial excision arthroplasty with ligament reconstruction and arthrodesis. The choice of procedure will be influenced by age, the state of other thumb joints and the requirements of the patient.

Chapter: Flexor tendon injuries

Author(s): Robert Savage

Summary points

♦ Restoring continuity to the supple yet high tensile flexor tendon system presents a challenge unique in surgery. Although there is continuing debate about many details of technique, the central tenet of modern flexor tendon surgery is to repair and move the flexor tendons within a few days of injury.

♦ Knowledge and experience count for everything at all points of patient care beginning with accurate and timely diagnosis. Emergency services should be arranged to relocate these injuries to appropriately trained surgeons and team-work with specialist hand therapists is an essential part of today’s treatment.

♦ While all flexor tendon surgery is complicated, it is simplest in the newly injured and unscarred digit, and the results of the correctly rehabilitated primary repair appear to be the best attainable.

♦ However, occasions will arise when secondary surgery will be necessary and the appropriate skills must be learned.

History

In the early 1900s there were several reports of primary repair of divided flexor tendons using principles that were not so different to those we use today; however, Sterling Bunnell declared zone 2 of the finger ‘no man’s land’ for primary surgery, on account of finger and tendon stiffness or repair failure. He advocated a delayed tendon graft, effectively removing the repair from the site of maximum adhesion in the flexor sheath and performing the two graft repairs at the finger end and in the palm. In Britain, Guy Pulvertaft became famous for his teaching on this technique in the 1950s and 1960s. Predominant suture materials were silk and wire.

The reversal of this policy back to early direct repair, pioneered by Kleinert and Verdan in the 1960s, and enhanced by improved postsurgery rehabilitation, showed that results can be better than after tendon grafting.

The last 30 years have seen progressive improvements following research into tendon healing, tendon suture mechanics, and protected mobilization after surgical repair, and the current trend is for multistranded repairs with early protected ‘active’ finger movement. We have returned full cycle, but mainly with good evidence of satisfactory outcomes.

Anatomy (Figure 12.22.1)

Tendons

The four flexor digitorum profundus (FDP) tendons pass from the forearm to the distal phalanges providing power grip. The ulnar three tendons are relatively conjoined, such that one cannot be flexed without the others flexing also.

Flexor digitorum superficialis (FDS) tendons insert to the middle phalanges and act individually. They contribute to power grip, and...
with the interossei, to dexterity, but are not necessary for full finger roll-up. In the finger, under the A2 pulley (see later) and at the
decussation there is extra potential for tendon adhesion following repair.

**Paratenon and vincula**

Tendons are supported by paratenon via a thin mesentery within the palm, carpal tunnel, and distal forearm. In the finger there is no
mesentery except where blood flow enters the tendon dorsally through two vascular pedicles, the long and short vincula; which give
rise to a dorsal tendon artery and veins, that supply the tendon, branching into the tendon substance, becoming rarefied and
absent towards the margins and volar aspect.

**Fibrous flexor sheath—‘the pulley system’**

Within the finger the paratenon is supported by fibrous arches (pulleys) attached to the palmar lateral margins of the phalanges and
volar plates.

The annular (A) pulleys prevent bowstringing of flexor tendons promoting mechanical efficiency during flexion. The toughest pulleys
are:

- A1 at the metacarpophalangeal (MCP) volar plate,
- A2 at the proximal phalanx
- A4 at the middle phalanx.

Soft parts of sheath with cruciate fibres (C) allow the finger to bend:

- C1 and C2 at the proximal interphalangeal (PIP) joint
- C3 at the distal interphalangeal (DIP) joint.

The hard edges of the A2 and A4 pulleys may cause blockage of tendon movement against an irregular tendon repair or a partial
division.

**Zones of injury**

- Zone 1 is distal to the insertion of FDS, where only FDP can be divided
- Zone 2 is where FDS and FDP coexist within the fibrous flexor sheath—the site for maximum adhesion potential
- Zone 3 is within the palm proximal to the flexor sheath but distal to the carpal tunnel. FDS is superficial to FDP and traumatic
division may not be obvious
- Zone 4 is within the carpal tunnel
- Zone 5 is proximal to the carpal tunnel—from superficial to deep the structures are: palmaris longus, median nerve, FDS,
  FDP, with wrist flexors to each side.

**Pathology of healing and repair**

Following much controversy in which it was thought that tendons had little vitality and healing potential, dye injection studies in the
rabbit flexor tendon model showed the vascular supply (see ‘Paratenon and vincula’ section).

**Synovial nutrition**

The fact that tendon is nourished by synovial fluid diffusion (in addition to blood flow) was shown when a segment of tendon was
divided, devascularized, and allowed to retract within the fibrous flexor sheath. Sequential histological studies demonstrated cellular
proliferation over the cut tendon ends and immature collagen fibrils.

**Tendon healing without surgical repair**

The rabbit flexor tendon was drawn proximal to the fibrous sheath, partly divided, and then allowed to retract within the sheath: the
tendon was still in continuity, but nevertheless injured with a partial gap to observe. Sequential histology demonstrated gradual
healing and maturation of the tendon gap, but notably without any adhesion to the tendon sheath.

**Adhesion factors after surgical flexor tendon repair**

The rabbit flexor tendon was partly divided (as earlier) and then subjected to three factors which occur during repair surgery: suture,
sheath injury, and immobilization. Each single factor caused modest adhesion, paired factors caused moderate adhesion, and all
three factors together caused dense restrictive adhesion.

**Tendon and repair mechanics**

**Tendon strength**

Laboratory testing showed breakage of human flexor tendons at 1200 Newtons (N) and tendon avulsion from bone at 600N. After
injury significant weakening occurs for about 3 weeks.
Forces during activity
In patients having carpal tunnel surgery under local anaesthetic, light active unresisted finger and wrist movement induced tendon forces of 35N, and tip pinch, 120N.

Friction
Tendon repair bunching, swelling, irregularities, knots, and gaps; and tissue adhesion, cause increased friction during movement.

Repair strength
The advantages of a multistrand repair are now established. Tendon repair strength is increased by:

- Suture strand number in a proportional relation. The approximate expected core strength, when combined with a simple peripheral suture is:
  - Two-stranded core repair, 20N
  - Four-stranded core repair, 40N (double Pennington/Kessler or modified four stranded Savage)
  - Six-stranded Savage core repair, 60 N

60N approximately can also be obtained by a two-stranded core repair combined with either the very effective Halsted peripheral repair or the Silfverskiöld peripheral repair.

- Suture calibre—3/0 core suture is stronger than the usual 4/0 but can only be used if the finished repair is not too bulky
- Suture material—typically braided polyester and ‘fibrewire’ (Arthrex) is tougher (for the core suture) than polypropylene (for the peripheral suture)
- Effective ‘anchor points’ where the suture grips onto tendon fibres.

Core sutures 1cm from the cut tendon end and peripheral sutures up to 5mm from the cut tendon end share load to create a firm gap-resistant construct.

A summary diagram (Figure 12.22.2) shows that in theory a four-strand repair has a margin of safety during light active movement.

![Click to view larger](Fig. 12.22.2)

Strength of Two-, four-, and six-strand repairs plotted against passive movement, light active, and strong grip. Adjusted for friction, oedema, and stress. Reproduced with permission.

Clinical presentation

Complete division
Diagnosis is clear on finding a classic triad.

- A history of laceration by a sharp object, such as glass or a knife, over the palmar aspect of a finger, the palm, or wrist
- Finger resting posture is relatively extended compared to adjacent fingers
- Failure of the finger to flex on request.

Careful examination of all flexor tendons to the fingers, thumb, and wrist; and to all neurological and vascular structures relevant to the level of injury is essential. Special imaging is not required.

Partial tendon division
This injury can easily be overlooked because:

♦ The only sign is the skin laceration
♦ There is no loss of resting posture
♦ Nor inability to flex on request.

Suspicion of partial injury should be high, but particularly when considering a palmar laceration with the finger in a gripping action, when profuse bleeding suggests (neuro)vascular damage, and rarely when triggering, suggests the tendon is catching on a sheath edge.

**Complex injuries**

Association with crush or machine trauma and widespread tissue contusion, nerve injury, and/or fracture, will cause a poor outcome from resultant general scarring.

**Closed rupture**

In closed injury, rupture of the FDP insertion may result typically from a rugby tackle. The clinical signs are:

♦ No skin laceration
♦ Loss of resting posture
♦ Loss of active movement.

Non-traumatic causes of rupture include rheumatoid tendon disease and rarely, no particular cause at all.

**Differential diagnosis**

Rarely, anterior interosseous nerve palsy may cause loss of index FDP and flexor pollicis longus (FPL). Tendon blockage can result from trigger digit or rheumatoid nodules without tendon rupture.

**Imaging**

Magnetic resonance imaging (MRI) or ultrasound may be helpful in cases of repair rerupture and delayed partial tendon division.

**Management (Box 12.22.1)**

**Partial tendon division**

Diagnosis by local wound exploration is essential. The wound limit is sought to identify damage to tendon sheath, and the finger is moved to and fro to inspect the underlying tendon. It may not be possible to do this effectively under local anaesthetic, so doubtfully visualized and partial injuries must be explored fully under regional or general anaesthetic.

**Complete tendon division**

Complete injuries or unresolved suspected partial injuries must be treated by knowledgeable and practiced personnel, with referral and transfer to a centre of special expertise if the required skill is not available locally.

**Non-operative treatment**

Occasionally other factors will outweigh the importance of tendon injury, such as serious general ill health, age-related infirmity, or inability to comply with postsurgery rehabilitation through reasons of mental state, work, or domestic commitments.

**Box 12.22.1 Primary repair of flexor tendons**

♦ Immediate or up to 3 days is preferable
♦ Experienced surgeon and therapist
♦ Tourniquet and regional or general anaesthesia
♦ Zig-zag skin incisions
♦ Open windows in soft parts of flexor sheath
♦ A2 and A4 pulleys should not be disturbed unless essential
♦ Core and peripheral multi-strand repairs
♦ Sheath laid over tendon and not repaired.

**Timing of surgery**
Surgery within a few days of injury is ideal but delay up to about 5 days is acceptable. Beyond this time tendon adhesion and muscle retraction significantly reduce the possibility of a neat primary repair.

Consent for treatment should indicate reasonable chances of satisfactory outcome, dependant on compliance with rehabilitation: and moderate risk of infection, adhesion, repair rupture, and stiffness.

**Surgery**

An arm tourniquet is essential to obtain a bloodless field, so full regional or general anaesthetic is necessary. Surgery may take up to 1h and longer, particularly in cases of multiple tendon division, and microneural repair may be required.

Skin wound extensions (zig-zag) followed by carefully planned ‘window’ opening in the soft parts of tendon sheath (and sometimes partial opening of A2 and A4) relevant to the position of tendon division, will give access for the tendon repair. Proximal tendon retraction is likely unless prevented by an intact vinculum, where the cut end may be pushed distally by ‘milking’ the soft tissues, or flexing the finger joints. A separate proximal opening, such as in the palm for a finger injury, may be required to pass the tendon distally.

Careful handling of the divided tendon should minimize further surface and substance damage. Such damage is certainly increased with multi-stranded techniques and causes significant concern, but clinical outcomes suggest the advantages of increased strength outweigh the disadvantages of tissue damage.

**Repair technique**

There is mounting evidence that a minimum four-stranded core suture is required to obtain satisfactory results, e.g.:

- Double Pennington/Kessler: Adelaide (Figure 12.22.3A): Strickland and/or a complex peripheral repair, e.g.
- Silfverskiöld (Figure 12.22.3C): Halsted.

Six-strand repairs (Tang, Sandow, Savage) are equally or more effective. The techniques can be learnt in the laboratory, prior to attempting clinical work, aiming to achieve a robust smooth repair with no gaps.

**Fibrous flexor sheath**

The hard edge of annular pulleys may cause difficulty completing the repair or snagging of the completed repair, so minimal partial lateral release of a pulley is essential to obtain free movement of the repair. At completion of tendon repair the fibrous sheath is laid over the repair without suture closure.

**Rehabilitation**

Until healing is sufficiently advanced the finger cannot be used actively. During this time, and up to 6 weeks, a dorsal splint is applied to the wrist and fingers, preventing full finger extension and using a controlled movement programme. All resistance on the palm side, such as dressings, must be loosened from day 1 and removed later.

The repaired tendon must move within the flexor sheath to prevent one of the adhesion factors described by Matthews: immobilization. Force on moving the finger must be minimal so it does not exceed the repair strength.

A skilled hand therapist should direct the movement programme.
Controlled active motion

The currently named ‘controlled active motion’ regimen (CAM) is probably the most widely used rehabilitation programme in the United Kingdom and is the best suited for repairs of reasonable strength (Box 12.22.2). Originating in Belfast and also called by that name it described ‘early active movement’ but that was only a small part of the treatment.

Box 12.22.2 CAM regimen

- Skilled hand therapist
- Early mobilization to prevent adhesions
- Dorsal blocking splint
- Passive and ‘place and hold’ exercises
- No active grasping for 6 weeks
- Gradual increase in activity over next 6 weeks
- No gripping for 12 weeks.

- First, the fingers are mobilized passively to reduce joint and tissue stiffness
- Next, the fingers are exercised in a 'place and hold' manner; passive movement into flexion, and then the finger is held flexed actively, thus causing the tendon to move within its sheath
- All four fingers move together, remembering the conjoined action of FDP, and FDS is exercised individually
- Exercises are performed hourly
- As full a range of movement as can be achieved easily is satisfactory during the first few weeks, but preferable about three-quarters range, for the final one-quarter range requires most force. Provided the repair does not stick completely a full range can be regained later, as tissue swelling and adhesion subsides
- After 6 weeks the splint is discarded and light activity is permitted, but not gripping, pulling of can rings, and driving for a further 6 weeks during scar maturation
- An illustrated exercise and instruction chart helps with compliance to the tedious and restrictive regimen.

Splint position

In the CAM regimen the splint position should be

- Wrist 0-30 degrees extended
- MCP joints flexed 30-70 degrees
- IP joints 0 degrees.

There is least force on the flexor tendons during gentle active movement with the wrist in an extended position. The MCP flexed and IP extended position is the safe resting position to prevent joint contracture.

In the passive and elastic band regimen (below) the splint position is

- Wrist flexed 20 degrees
- MCP flexed 20 degrees
- IP joints 0 degrees.

Passive regimen

From the resting position (above) fingers are only moved by passive guidance from a therapist or the patient’s other hand.

Kleinert elastic band traction

From the resting position (above) fingers are moved into a flexed position by elastic bands (attached to the finger nails and to the distal forearm), reducing force within the repaired flexor tendon. Finger extension is performed actively.

Complications

General swelling and stiffness are common and contribute to adhesion (see later) and poor function.

Infection

Pus formation and tissue necrosis is rare following adequate primary treatment, but leads to irrecoverable scarring and stiffness. Obvious infective cellulitis is also uncommon but minor degrees probably contribute to unwelcome tissue swelling.
Repair rupture

In partial repair rupture a scar bridges the tendon gap which sticks to the surrounding tissue, with resultant loss of movement and grip strength.

In typical complete tendon repair rupture the patient ‘feels something go’, and there is recurrence of the loss of resting posture and lack of active movement signs.

Adhesion

The repaired tendon sticks to neighbouring soft tissue, fibrous sheath, and bone, partly or completely, causing loss of finger movement and reduced hand function.

Results

Outcome is assessed by measurement of:

♦ Range of active movement
♦ Flexion and extension deficit
♦ Grip strength
♦ Quality of movement
♦ Rupture rate.

Good and excellent results

This implies near full movement and function. A combination of technical factors is required to achieve reliably good outcomes:

♦ High repair strength to give a margin of safety from repair dehiscence during mobilization
♦ Adequate sheath release to prevent repair impingement
♦ Highly skilled rehabilitation.

Mediocre to poor results

Stiffness, induced by varying degrees of adhesion or partial rupture, causes reduced flexor power with or without the quadriga effect (explanation under ‘amputation’), flexion deformity with catching on tools and pockets, and reduced dexterity.

Rupture

Total failure of the treatment method is characterized by a floppy finger that fails to flex next to its neighbours. Published rupture rates of 2 strand core sutures, using the CAM regimen of 5–40 % in different hand centres in the United Kingdom using similar methods, have suggested that two-strand repairs are not adequate for all patients, and later studies strongly suggest that multistranded core and peripheral suture techniques, and improved therapy skill reduce the incidence of repair rupture to less than 5%.

Treatment of complications (Box 12.22.3)

General

For general swelling and stiffness prevention is the best treatment, by ensuring hand elevation and by maintaining movement. Modest infection is controlled by antibiotics but major infection may require tissue debridement.

Rerepair for repair rupture

Diagnosis and rerepair within several days may yield good results but the surgery is more complicated than the initial surgery. Excessive scarring in the tendon sheath and loss of tendon/muscle flexibility requires a two-stage tendon graft or salvage procedures.

Box 12.22.3 Options for repair rupture

♦ Presentation within several days—rerepair as for primary repair
♦ Later presentation:
  • 1- or 2-stage tendon graft
  • Leave alone
  • Tenodesis
  • Arthrodesis
• Amputation.

**Box 12.22.4 Flexor tendon grafting**

- Imperfect results and frequent complications
- Donor tendon palmaris longus or fourth toe extensor
- Graft between FDS or FDP tendon proximally to distal phalanx
- Immobilize or CAM regimen
- Two-stage grafting using Hunter rod may reduce adhesions.

**Tenolysis for adhesion**

Where there is no separation of the initial tendon repair, adherent tendon is carefully dissected from surrounding paratenon in zones 3–5 and from the fibrous sheath in zones 1 and 2, retaining essential A2 and A4 pulleys. A continuous infusion local anaesthetic nerve block at wrist level is useful to ensure full active movement for a few days after surgery, and physiotherapy continues until all risk of recurrent stiffness has passed.

If the released tendon is ragged and weak, and where there is also gapping of the initial repair with a scar between the tendon ends, a two-stage tendon graft or salvage procedures may be necessary.

**Tendon grafting (Box 12.22.4)**

In one-stage tendon grafting the palmaris longus (or fourth toe extensor) donor is used, in an unscarred tendon sheath, for a severely damaged tendon or a segmental tendon loss.

**Two-stage tendon graft**

In the first stage, the damaged FDS and FDP tendons are excised and essential A2 and A4 pulleys are reconstructed if necessary. A flexible silicone (Hunter) rod (3- or 4-mm. diameter) is sutured to the FDP stump and passed within the flexor sheath to reach zone 5 where it is not connected to a tendon. A smooth synovial lining forms around the silicone rod, into which a tendon graft can be inserted 3–6 months later. Full passive mobilization is achieved following the first stage operation.

In the second stage tendon graft operation a palmaris longus tendon is drawn through the new synovial tube by the existing silicone rod, sutureing the tendon graft to the distal FDP stump and to an appropriately flexible FDS or FDP tendon donor in zone 5. Postsurgical rehabilitation is either by immobilization or by controlled active movement.

The potential for complications following tendon grafting is greater than following primary repair, with two repairs and the graft to fail or stick, and two periods of 3 months of physiotherapy; so great care is required in selecting a tolerant compliant patient.

**Salvage procedures**

Considering the difficulty in achieving success with a two-stage tendon graft these are common practical alternatives for treating failed tendon surgery. The principle is to focus on hand function overall, rather than to strive for one finger alone.

- Leave it alone: functional deficit may not be sufficient to merit intervention
- Tenodasis: FDP can be tenodesed across the DIP joint, thus transmitting FDS and intrinsic power to the finger tip
- Arthrodesis: arthrodesis can be done in either IP joint, though not usually both in one finger, and not for MCP joints which are flexed by intrinsic muscles
- Amputation: adhesion and reduced range of movement in one finger may reduce power in neighbouring fingers due to the conjoined nature of the FDP muscle and tendons (quadriga effect). Amputating the affected digit can free up the flexor system, restoring hand flexibility, power, and function.

**Future directions**

Future advances may come from simplified suture techniques, enhanced repair strength, and gadgets that achieve a strong repair reliably. Biological research may find methods that improve healing or reduce adhesion but currently none is available for clinical use.

**Conclusion**

Attention to all the important aspects of presentation, repair, and rehabilitation, in a team of knowledgeable experienced staff, should give near full movement and function following clean incised division of flexor tendons. However, many pitfalls and traps...
await the unwary occasional practitioner and the untrain-able patient, so that poor results and complications are all too common.

Extensor tendon injuries in the hand and wrist

Summary points

- Injuries common as tendons vulnerable
- 5 zones described
- Mallet finger usually treated in splint, but some fractures may require fixation
- Capener splint for boutonniere deformity, but sometimes surgery necessary
- Most open tendon injuries need direct repair
- Rehabilitation needs attention to detail.

Introduction

Extension of the wrist and fingers is vital to hand function. Although it is more obvious that flexion is required for pinch and grip, these functions can only be successfully accomplished if the extensor mechanism is intact. Extension allows the tactile surfaces of the hand and fingers to be exposed and brought into contact with objects being manipulated, and extension of the wrist both positions the fingers correctly for grasping and potentiates the long flexors of the fingers by passively increasing their tension, the tenodesis effect. Extension at the metacarpophalangeal (MCP) joints can only be produced by the long extensors of the fingers and thumb (the extrinsic system), but the interphalangeal (IP) joints are extended by both extrinsic and intrinsic systems, so that extensor tendon division proximal to the MCP joint does not eliminate all interphalangeal extension.

The extensor tendons transmit power from the muscle groups situated in the dorsal forearm compartments to the wrist, MCP, and IP joints, producing extension at four sequential joint levels across five rays. Contributions are received from the intrinsic muscles of the hand, entering the system distal to the MCP joints. This network of tendons can be injured at any point, by closed injury usually involving a traction force, or open penetrating, lacerating, or crushing injury. The consequences of such injury mainly affect joints directly controlled by the particular tendon(s) damaged, but effects may be seen at other joints, since the tendons in the system have to act across sequential joints which are inherently unstable without balanced control; they have complex interconnections, and the effects of unopposed antagonist muscles also have to be taken into account. The anatomy of the extensor tendons is shown in Figure 12.23.1.

Fig. 12.23.1
The extensor tendons and their connections, and the zones by which injuries are classified. These are shown on the left for the fingers, and on the right for the thumb, with the prefix T.

Because of the exposed and vulnerable position of the extensor mechanism, injury to its tendons is common, occurring in all settings where the hand is at risk from injury, including the workplace, the home, especially the kitchen, and sports situations.

All tendons are vulnerable to sharp injury, and tendons weakened by age (as in mallet finger), trauma (as in extensor pollicis longus (EPL) rupture after distal radial fracture), and disease (as in rheumatoid arthritis) are more prone to closed rupture.

Figure 12.23.1 shows the zones into which the extensor tendons are divided for the purposes of classifying injuries and describing their treatment. In this chapter the zones of injury will be considered in sequence in all their aspects, starting with the most distal.
Injuries to the extensor mechanism

Zones 1 and T1

Mallet finger

Injuries resulting in loss of extension power at the distal interphalangeal (DIP) joint are most commonly closed injuries, but open laceration dividing the tendon close to its distal insertion has a similar effect.

Closed mallet finger

This common injury usually occurs in surprisingly innocuous circumstances, such as when the finger is stubbed or forced into sudden flexion while bed-making. Usually the patient is immediately aware of a flexion deformity but may not seek help straight away since the injury seems trivial. The injury either involves a stretching and softening disturbance of the tendon resulting in lengthening, or avulsion of a bone fragment at the tendon’s insertion. The clinical effect is the same. Patients with normal joint ranges simply show a DIP flexion deformity allowing passive extension. If the proximal interphalangeal (PIP) joint allows some natural hyperextension, a swan-neck deformity may be observed within a few days. This results from the modification in force distribution of the extensor mechanism as it tries to migrate proximally following distal detachment. This proximal movement is restrained by the central slip attachment at the PIP joint (Figure 12.23.2), and the increased tension there can cause hyperextension, or restriction of full flexion where hyperextension is not possible. An understanding of this dynamic change is important.

Box 12.23.1 Mallet finger

- Splint 80% successful
- May have associated fracture
- Fix large bone fragments
- Can result in swan-neck deformity
- Fowler’s release at 6 months for failed splintage
- DIP joint fusion if all else fails.

Investigation includes radiography, with a lateral view to demonstrate an avulsion fracture (Figure 12.23.3).

Fig. 12.23.2
A) The extensor mechanism of the finger. B) The change that results from division or rupture of the distal insertion. If volar plate laxity allows it, PIP hyperextension may occur, causing a swan-neck deformity.

Fig. 12.23.3
A) and B) Mallet finger due to an avulsion fracture of the dorsal lip of the base of the proximal phalanx, showing the method of...
It is helpful if the patient can learn the habit of allowing the finger to sit in flexion at the PIP joint as this reduces the tension at the sit of distal tendon rupture.

Occasionally a red and slightly oedematous appearance develops over the middle phalanx, usually after splintage has been completed. This is not usually infection, though antibiotic treatment is wise, but it seems to represent inflammation or possibly avascular changes in the disrupted tendon. It settles slowly.

Correctly applied splintage for mallet finger is effective in approximately 80% of cases, although 10–20 degrees of extension lag may persist without functional disturbance. More than 30 degrees of lag can be corrected after a delay of 6 months by Fowler’s release of the central slip at the PIP joint. This adjusts the imbalance between the tendon insertions at PIP and DIP levels, restoring tension distally, and can therefore only be done after complete healing of the disrupted tendon has occurred at its new length. Release can be performed under metacarpal block through a longitudinal incision on the side of the finger. The extensor mechanism is lifted intact by dissecting beneath the palmar edge of the lateral band, then the central slip is divided at its insertion without causing separation between lateral and central tendon components, or lateral migration of the lateral bands could cause a boutonnière deformity. This complication has to be protected against by splintage (see later) for 2–3 weeks after the operation. DIP extension is usually restored within days, the occasional failure being due to continued complete disruption of the distal extensor tendon. If the continued flexion deformity is severe enough, DIP fusion might be indicated.

A similar injury can affect the thumb, giving a flexion deformity of the IP joint, in contrast to loss of extension mainly at the MCP joint due to EPL rupture. Mallet thumb, like mallet finger, can be treated conservatively.

Avulsion fracture

A very small chip fracture can be treated by splintage, but large fragments include a significant proportion of the joint surface, which should be restored. The fragment is wired or sutured back in place through drill-holes in the distal phalanx (Figure 12.23.3), supporting the joint in extension with a percutaneous K-wire crossing the joint and kept in place for 3–4 weeks. A brief period of dorsal splintage may be needed after wire removal.

Zones 2 and 4, and T2

The extensor hood over the shafts of the proximal and middle phalanges is broad and flat, and because of its superficial position it is often divided by sharp lacerations. Because it is broad, division may be incomplete and therefore not obvious on clinical examination. The divided tendon can be approximated by simple interrupted sutures. Untidy injuries may involve loss of tendon, but it is usually possible to restore continuity unless tendon is actually missing, in which case a small graft may be needed. Skin cover needs to be secure. Adhesions form easily, and tenolysis may be needed later. This is particularly likely when tendon injury in this area is associated with an underlying fracture. Rigid internal fixation helps by allowing earlier mobilization, and separation of the tendon from bare bone should be attempted by peristeal repair (Box 12.23.2).

Box 12.23.2 Extensor tendon repair over phalanges

- Requires soft tissue cover
- Adhesion may require tenolysis.

Zone 3

Boutonnière deformity (Box 12.23.3)

This is caused by disruption of the central slip of the extensor mechanism at the PIP joint. It may be a closed injury due to forced flexion, or an open laceration at or proximal to the joint. Open laceration is not infrequently missed at the time of repair of a small laceration, because PIP extension can initially be produced by the lateral bands. However, propagation of the tear in the tendon between central and lateral components allows them to migrate palmar-wards round the joint, and they lose their extension force, becoming flexors. As they do so the pull at the DIP joint increases, causing hyperextension (Figure 12.23.4). The dysfunction is now obvious, and the patient seeks treatment, but delayed repair after this disturbance in the mechanism is often unsatisfactory.

Treatment of closed mallet finger without fracture is by splintage. Repair of the tendon gives poor results because it is stretched and denatured. Various splints have been described, although the simplest is a padded malleable metal splint placed across the DIP joint, strapped to the middle and distal sections of the finger to maintain DIP extension. The splint should not be bent dorsally with the intention of forcing the joint into hyperextension because the pressure exerted directly over the joint dorsally can result in skin damage or loss. Splintage should be continuous, and if the patient wishes to remove it to wash the finger, DIP extension should be maintained throughout, since any drop into flexion recreates the injury. This form of splintage needs to be maintained for at least 6 weeks, during which time the patient should be seen regularly and the condition of the dorsal skin checked for pressure. If after 6 weeks there is any tendency for persistent deformity, splintage should be continued, and often this is necessary for up to 10 or 12 weeks.

Correctly applied splintage for mallet finger is effective in approximately 80% of cases, although 10–20 degrees of extension lag may persist without functional disturbance. More than 30 degrees of lag can be corrected after a delay of 6 months by Fowler’s release of the central slip at the PIP joint. This adjusts the imbalance between the tendon insertions at PIP and DIP levels, restoring tension distally, and can therefore only be done after complete healing of the disrupted tendon has occurred at its new length. Release can be performed under metacarpal block through a longitudinal incision on the side of the finger. The extensor mechanism is lifted intact by dissecting beneath the palmar edge of the lateral band, then the central slip is divided at its insertion without causing separation between lateral and central tendon components, or lateral migration of the lateral bands could cause a boutonnière deformity. This complication has to be protected against by splintage (see later) for 2–3 weeks after the operation. DIP extension is usually restored within days, the occasional failure being due to continued complete disruption of the distal extensor tendon. If the continued flexion deformity is severe enough, DIP fusion might be indicated.

A similar injury can affect the thumb, giving a flexion deformity of the IP joint, in contrast to loss of extension mainly at the MCP joint due to EPL rupture. Mallet thumb, like mallet finger, can be treated conservatively.
When open tendon injury is identified primarily it should be repaired by direct suture with interrupted non-absorbable sutures (about 4/0), and the PIP joint supported in extension with a percutaneous K-wire for about 10 days. During this time, DIP flexion is encouraged, and after which active PIP movement is regained under the supervision of a physiotherapist. Some patients have difficulty in regaining movement.

Closed boutonnière deformity can also develop insidiously by the same mechanism, and patients frequently present 2–3 weeks later. Smith and Ross (1994) have described a test to detect the central slip rupture before it is clinically obvious. The wrist and MCP joint of the affected finger are passively flexed fully, and an intact central slip should produce full PIP extension. If it does not, there is laxity of the central slip, and early treatment is indicated.

The ability of dorsally placed lateral bands to extend the PIP joint is used in the method of closed treatment for this condition with a spring splint (the Capener splint) giving dynamic PIP extension while allowing active DIP flexion. This in turn helps to maintain the dorsal line of the lateral bands by tightening them. It is important that the splint selected is not tight, and the distal stems are short enough to allow DIP flexion (Figure 12.23.5). Splintage needs to be maintained for several weeks under the supervision of a therapist. Initially the joint is rested in extension in the splint, if necessary using a static volar splint until swelling has subsided to allow fitting of the dynamic splint. Then the patient is encouraged to start active flexion in the splint. Provided the treatment has been instituted early enough, migration of the lateral bands will be prevented and the torn tendon can heal without significant lengthening. If treatment is started too late, delayed reconstruction may become necessary. This is extremely difficult, and seldom gives entirely satisfactory results.

Various methods have been described, and involve either dorsal advancement and approximation of the lateral bands, use of a tendon graft, or a turnover procedure from the central extensor more proximally to secure reinsertion at the base of the middle phalanx. All methods should involve lengthening of the extensor mechanism distal to the PIP joint. Support with a K-wire for 10 days is needed, and patients often experience stiffness, or recurrent deformity to some extent, or both. Physiotherapy and splintage may need to be continued for some time.

Skin loss associated with extensor tendon division presents a special problem, and soft-tissue repair, usually by local skin flaps, may be required as well as tendon repair.
Zones 5 and T3

Injuries over the MCP joint

Closed injury—sagittal band rupture

There have been sporadic reports of closed sagittal band rupture causing extensor tendon subluxation at the MCP joint. This can happen at any age, but requires more force in the young, and can occur with very little force when tendons are weakened, as, for example, in rheumatoid arthritis. The mechanism is usually a blow on the dorsum of the hand, particularly the base of the finger, with a clenched fist. The sagittal band, usually on the radial side, gives way, allowing the extensor tendon to move in an ulnar direction (Figure 12.23.6). From the beginning there is loss of full power of extension at the MCP joint, and this tends to increase as the tendon slides further across. It may reach a point of equilibrium, or deterioration may continue until there is full loss of extension.

If the injury is recognized immediately, splintage may be enough to allow healing without extensor tendon subluxation. Later referral usually leads to the need for direct repair of the tear of the sagittal band.

Extensor tendon division over the MCP joint (Box 12.23.4)

Open laceration at this level can occur as the result of a sharp injury such as a knife, or contact with a tooth during a fight. A limited sharp injury may not initially cause much loss of extension because intact sagittal bands on either side can splint the ends together. However, they easily split, allowing the tendon ends to separate with extensor lag at the MCP joint. Lacerations in this area should be carefully explored for unexpected tendon injury. The tendon is repaired using a core stitch and running marginal stitch.

Human bite injuries

It is common for a tooth to penetrate the stretched skin over an MCP joint, usually of the middle finger, during a fight. Because all the tissues are stretched tight the tooth enters the joint, often causing delayed infection if appropriate action is not taken primarily. If the extensor tendon is in the path of the tooth it can also be divided. Because of the circumstances of the injury, the patient may not attend for treatment immediately. If he/she does, the wound should be explored, the joint irrigated and drained, and the central part of the tendon repaired if divided, under broad-spectrum antibiotic cover appropriate for oral flora. If treatment has been delayed and infection is developing, joint irrigation should be added to the regimen; tendon repair may be delayed if the infection is significant, and completed as a secondary procedure when infection has been eliminated.

Box 12.23.4 Extensor tendon injury over MCP joint

- Early repair best
- Explore open injuries
- Bite injuries often present late
- Delay repair if active infection.
Zones 6 and 7, and T4 and T5

Extensor tendon injury over the dorsum of the hand and wrist (Box 12.23.5)

The tendons are vulnerable to sharp injury throughout this area, but slightly less so at wrist joint level, being more deeply placed here, covered by the extensor retinaculum, and in the concavity of the joint in its neutral posture of slight extension. At the wrist, the tendons are more closely bunched together; therefore multiple tendon divisions are more likely than on the dorsum of the hand where they diverge.

The diagnosis is usually obvious from the posture of the fingers and the position of the laceration. Exploration usually requires extension of the original cut, and if that is oblique or transverse a zigzag design is best, taking into account the likely position of the divided tendon ends. When the injury is in the zone beneath the extensor retinaculum, it is necessary to reflect a section of the retinaculum to expose the appropriate compartment containing the injured tendons (see Figure 12.23.1). This is best done by lifting a flap based on one side or the other, rather than incising it longitudinally, which would allow bow-stringing. Extension is the usual posture of the wrist during contraction of the digital extensors, and so a pulley mechanism is needed.

When exploring multiple extensor tendon injuries it is important to identify and match individual tendons correctly, since slight differences of level of injury can create significant discrepancies in tension. Matching can be achieved by comparing the lengths of the tendons as they sit together, the direction and shape of each cut end, since they may vary in an identifiable way, and to some extent their position side by side, although this can be misleading as they can become transposed. Standard suture techniques are appropriate, such as the Kessler core stitch (4/0 non-absorbable braided polyester) and running 6/0 circumferential suture. Some extensor tendons are too flat to accommodate a three-dimensional suture such as this, and a simple mattress suture or continuous suture may be sufficient. Careful closure in layers of the surrounding gliding structures makes satisfactory excursion more likely. When treating more complex injuries, attention should be directed to the surface beneath the tendon as well as over it. Bone or fixation material must be separated from the repaired tendon, otherwise dense adhesion is very likely.

</tbody>
</table>

Wrist extensor tendons may be divided in deep lacerations in zone 7, always in association with division of more superficial tendons. Closed rupture occasionally occurs. Strong repair of the wrist extensors is essential for effective grip.

Postoperative rehabilitation (Box 12.23.6)

Following repair of a single extensor tendon, the hand and wrist are immobilized in extension. After 1 week the splint can be removed and the interphalangeal joints actively exercised under supervision. The splint is then replaced, but only extending to a point approximately 2.5cm distal to the MCP joint, so that some interphalangeal flexion is still possible. A further 3 weeks in this splint should allow tendon healing, and mobilization continues thereafter, under the care of a physiotherapist.

After primary repair of multiple extensor tendons, far superior results following early mobilization have been achieved with dynamic splintage (all excellent) as opposed to 40% excellent and 31% good following static splintage. Dynamic splintage can be started within days of repair.

Spontaneous rupture

It is not uncommon for EPL to rupture following Colles’ fracture, usually with little displacement. The EPL at the level of the distal radius is poorly vascularized, and vulnerable to disruption of what blood supply it has, perhaps combined with interference in synovial nutrition through haematoma. Tendon transfer is usually required, and either extensor indicis or a slip of abductor pollicis can be used.

Injuries involving loss of soft tissue

Injuries to the dorsum of the hand involving extensive damage to or loss of soft tissue cover present additional problems. Usually when skin is lost, parts of the extensor tendons will be missing also, and injuries involving crushing may be associated with metacarpal fractures or even bone loss. Primary reconstruction is always the goal, and if it is not possible immediately should be accomplished within 5 days. Reconstruction is geared to the precise details of the injury, and after thorough debridement may involve skeletal fixation, tendon repair or grafting, and skin replacement usually by flap cover. If there is doubt about the extent of tissue damage or viability, or the patient is not fit, it may be reasonable to bring the patient back to the operating room for a second look and definitive reconstruction after 48h. Under most circumstances, however, primary reconstruction is generally thought to be preferable.
**Box 12.23.6 Rehabilitation**

- Initial immobilization in extension
- Early dynamic splintage
- Fractures fixation must be kept separate (adhesions).

---

**Failed extensor tendon repair**

Adhesions following extensor tendon repair can be effectively treated by tenolysis. Before doing this, time should be allowed for full resolution of post-traumatic scar tissue, and maximum joint ranges should be achieved by the physiotherapist. Good skin cover is a requirement. The technique requires careful dissection of the tendons from their surrounding bed with preservation of some extensor retinaculum if possible. Early protected mobilization is essential.

Rupture of repaired extensor tendons is unusual, and should be treated by tendon transfer or grafting, according to the availability of reconstructive material.

---

**Further reading**

Summary points

- Limit initial soft tissue damage
- Reconstruct key soft tissue elements
- Functional rehabilitation.

Introduction

Normal hand function is determined by a complex, delicate interaction of soft tissue and skeletal elements. Key soft tissue structures include musculotendinous units, neurovascular bundles, and skin. When the soft tissues are damaged by trauma, infection, or burns, function is compromised. Surgical and non-surgical management of soft tissue hand injuries is therefore aimed at limiting initial soft tissue damage, reconstructing key soft tissue elements, and functional rehabilitation of the hand and patient. Complex open hand injuries present a challenging problem to all reconstructive hand surgeons.

Compartments and spaces of the hand

The pattern of swelling after trauma and burns, the spread of infection and injected substances, and the susceptibility of tissues to raised intracompartmental pressure, are all influenced by anatomy. The complex arrangement of fascia and synovium in the hand forms a number of compartments and spaces, whose walls may contain the spread of infection, channel the spread of substances injected at high pressure, and prevent the dissipation of rising intracompartmental pressure. If neglected, infections may breach these anatomical boundaries and enter adjacent spaces and compartments.

A compartment is a volume of tissue partially or completely enclosed by anatomical structures. A space lies between anatomical structures, normally occupies a minimal volume, and contains only loose connective tissue and interstitial fluid or a small volume of synovial or other physiological fluid.

Compartments

Subcutaneous

Subcutaneous compartments contain fat, a variable amount of fibrous tissue, and nerves, blood vessels, and lymphatics. On the dorsum of the hand and fingers, the skin is not bound down, allowing massive swelling after injury, and the subcutaneous fat is a single compartment within which infection spreads easily. Along the sides of the digits, in the fingertip pulp, at the flexion creases, and in the palm, the skin is bound to the skeleton, via septa, cutaneous ligaments, and other fibrous structures which limit both distension and the spread of infection.

Muscle

There are ten muscle compartments in the hand containing intrinsic muscles (Figure 12.24.1).

Fig. 12.24.1
Muscle compartments within hand and surgical access through 2 dorsal longitudinal incisions, overlying the second and fourth metacarpals (J Chan 2009).

They comprise the thenar and hypothenar eminences, adductor pollicis, four dorsal interossei, and three palmar interossei. Their fascial envelopes allow very little distension and therefore their response to injury or inflammation is predominantly a rise in pressure.

Fibrous tunnels
In the hand the main tunnels are the carpal tunnel and Guyon’s canal. Although the proximal and distal ends of these are not closed off by rigid structures, the structures within them are not capable of longitudinal displacement and so inflammation and oedema manifest themselves as raised intracompartmental pressure.

In the digits are the fibrous flexor sheaths (see Chapter 12.22). Within the fibrous sheaths are synovial spaces around the flexor tendons (a space within a compartment), where increased compartmental pressure may contribute to the damage caused by infection.

**Spaces**

**Synovial spaces**

- Joints: each joint and its synovial lining is a space where infection can develop and be contained.
- Tendon sheaths: the flexor tendons are surrounded by synovial sheaths in the fingers and at the wrist. Those of the thumb and little finger extend in continuity through the palm, known as the radial and ulnar bursae respectively, whereas those of the other fingers are absent in the palm.
- The extensor tendons at the wrist are enclosed in synovial sheaths but this is rarely a site of infection.

**Potential spaces**

**Web spaces**

In the distal palm are the web spaces—strictly these are compartments—which contain fat, digital neurovascular bundles, and the tendons of the lumbricals and interossei. Their proximal limit is where these structures enter the fibrous tunnels between the palmar fascia and deep transverse metacarpal ligament. They are bounded medially and laterally by the fibrous flexor sheaths, and dorsally and palmarly by the skin of the web, with the natatory ligament on the palmar aspect.

**Midpalmar and thenar spaces**

Deep to the most superficial, longitudinally orientated layer of the palmar aponeurosis and the transverse palmar ligament a series of vertical fibres form septa on either side of each pair of flexor tendons, and attached to the metacarpals. The best developed of these pass from the radial and ulnar borders of the palmar aponeurosis to the third and fifth metacarpals respectively. Between these, the potential space deep to the long flexor tendons and superficial to the interossei is known as the palmar or midpalmar space (Figure 12.24.2). Radial to the third metacarpal, the potential space deep to the flexor pollicis longus tendon and superficial to the adductor pollicis muscle is the thenar space (Figure 12.24.2).

**High pressure injection injuries**

**Background**

High pressure injection injuries (HPII) are caused by devices used for injecting or spraying liquids or gases, and by leaks in pressurized pipes. They are uncommon, frequently underestimated, and even with the best treatment, both short- and long-term morbidity is often severe.

**Importance**

The exact incidence of HPII of the upper limb is unknown. Around two patients per year present to large hand surgery units in the United Kingdom and China.

**Causes**

Most HPII occur in young male manual workers, and the commonest injection sites are the index or middle fingers or the palm of
the non-dominant hand. The commonest devices responsible are grease guns, spray guns, diesel fuel injectors, and leaking hydraulic pipes; the commonest substances injected are grease, paint or paint solvent, diesel oil, and hydraulic fluid, though other substances including water, oil, dry cleaning solvents, and gases have been reported. The most common mechanism identified is a break in a high pressure hose, followed by cleaning or adjusting the equipment, inadvertent triggering, and gun malfunction.

Pathophysiology

Fluid materials at a pressure of $7 \times 10^5 \text{ Nm}^{-2}$ (100PSI) or more penetrate the skin and spread within the tissues; contact between ejection point and skin is not necessary. Many devices operate at much higher pressures.

The extent of spread depends on site of entry, anatomical barriers, and the volume and pressure of the substance injected. Material penetrates tissue in its line of fire until it reaches a resistant structure, such as bone, tendon, or fibrous flexor sheath, and is deflected. In the finger, injection over the main annular pulleys prevents penetration of the sheath and material spreads proximally and distally, particularly along the neurovascular bundles. The thinner parts of the sheath are less resistant, and material enters and spreads throughout the synovial space. Joints are usually not penetrated. In the palm the palmar fascia and all deeper layers are penetrated through to the dorsum, with spread of material at all levels. Spread may be very extensive, and substances injected into the finger can reach the proximal forearm.

Early tissue damage is due both to direct physical and chemical effects, and to secondary ischaemia. Injections of paint rapidly dissolve in fat lobules, causing tissue necrosis and an intense necrotizing acute inflammatory reaction. This leads to fibrinoid degeneration of blood vessel walls and vascular thrombosis. The immediate toxicity of grease is less severe, but it may lead to more chronic fibrosis and other problems, particularly discharging granulomas.

Regional and systemic effects can occur, and lymphangitis, lymphadenitis, tachycardia, hypotension, pyrexia, confusion, leucocytosis, anaemia, and impaired renal function, have been reported after injection of paint, solvents, and diesel fuel. The pathophysiology of these effects is not understood, but both direct toxicity and the embolic effects of fatty materials have been suggested.

Clinical features

History

- Occupation
- Hand dominance
- Time of injury
- Site of injury
- Material injected
- Pressure of device.

Examination

- Puncture point usually trivial
- Circulation
- Sensation.

Investigations

Plain radiographs in two planes help delineate the extent of involvement, particularly if the injected material is radio-opaque; however, radiological and clinical findings must be correlated. Haematological and biochemical parameters should be monitored if systemic effects are noted.

Classification

The authors propose a modified classification of HPII (see Table 12.24.1), based on our review of the literature.
Table 12.24.1 Classification of HPIIs.

a Modified from Wong et al. (2005).

Treatment

Non-surgical

For all injuries, analgesia should be administered. Intravenous opiates should be given but may be inadequate and a brachial (not digital) nerve block may be necessary. If systemic effects are present, monitoring of vital signs and urine output should be started. Antibiotic prophylaxis against secondary infection and both steroidal and non-steroidal anti-inflammatory drugs have all been recommended, but none are of proven value. Mild injuries may be treated initially with elevation and observation, however, the threshold for surgical exploration should be low, and the patient prepared for surgery.

Surgical

Moderate and severe injuries, as well as patients with mild injuries who complain of increasing pain, require urgent exploration, decompression, and removal of as much of the injected material as possible. This is performed under tourniquet without forced exsanguination. Starting at the entrance wound the incision is extended proximally and distally until the full extent of spread is revealed—the smell of solvents can be a useful sign. Removal of all foreign material may be facilitated by use of the operating microscope and helps preserve vital structures. The skin should be left open, or at most partially and loosely closed. Inevitably some material is left, and repeat debridement at 48h should be performed.

Postoperative management

After operation the hand is elevated and splinted in the position of safe immobilization, and aggressive active and passive mobilization begun within a few days. Delayed primary amputation is necessary if the digit becomes clearly non-viable. Late reconstruction may include tenolysis, tendon grafting, neurolysis, nerve grafting, scar contracture release, and skin replacement.

Outcomes

Two factors have been shown to predict amputation in HPII: site of injection in the finger compared to the thumb or palm; and injection of an organic solvent (paint, paint thinner, diesel, or oil) compared to other substances. In addition, a delay to debridement of more than 6h lead to significantly more amputations when organic solvent injections were considered alone, but not when all HPIIs were analysed. Furthermore, there was a trend towards higher amputation rates with higher pressures of injection. The presence of infection and the use of steroids have not been shown to affect amputation rate significantly. In one series, all fingers which were noted to be poorly perfused at presentation were subsequently amputated.

Functional outcome of the hand is also poor. At an average 8.5 year follow-up a significantly decreased range of motion has been demonstrated at affected metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints compared to the unaffected side. In addition, decreased grip and pinch strength, and increased two-point discrimination threshold has been recognized. Furthermore, 78% of patients complained of continuing cold intolerance, 61% of hypersensitivity, and 22% of constant pain in the affected digit. The average time to return to work was 7.5 months, and over half of patients had changed jobs or remained unemployed after the injury.

Compartment syndrome of the hand

Background
Compartment syndrome exists when the pressure within an anatomical compartment is increased to a level where the viability of the tissues within the compartment is compromised. The increase in pressure causes tissue ischaemia, especially of muscles and nerves within the compartment, and may lead to permanent loss of function. The fascial compartments of the hand are illustrated in Figure 12.24.1.

### Importance
Incidence varies with aetiology and severity of the primary injury; in severe upper limb burns for example it is up to 70%.

### Causes
The commonest causes are crush injuries and burns, but there are a large variety of potential causes, many of which can occur in patients who are unconscious and therefore do not display classical symptoms and signs (Box 12.24.1). Compartment syndrome is an important cause of iatrogenic morbidity as a complication of tight casts or dressings, intravenous drug administration, and arterial lines.

**Box 12.24.1 Examples of causes of compartment syndrome in the hand**
- Tight dressings or casts
- Crush injury—acute
- Crush injury—lying on hand
- Reperpusion injury—revascularization
- Burns
- Cold injury
- Snakebite
- Intra-arterial injection.

### Clinical features

#### History
- Injury known to cause compartment syndrome
- High index of suspicion (especially in unconscious patients, or those with an insensate upper limb, for example, brachial plexus injuries)
- Pain out of proportion to injury
- Pain not controlled by immobilization and analgesics.

#### Examination
- Hand held in intrinsic minus position: MCP joints extended, PIP joints flexed
- Swelling and turgor of the compartment
- Pain on passive stretch
  - Interossei: MCP joint extended, PIP joint flexed, abduct and adduct digit
  - Adductor pollicis: palmer abduction of the thumb
  - Thenar: radial abduction and extension of the thumb
  - Hypothenar: extension and adduction of the little finger
- Paraesthesia in the distribution of nerves passing through the compartment
- Paresis of muscles supplied by nerves passing through the compartment
- Alteration of pulses and perfusion: late sign, muscle necrosis usually present.

#### Investigations
The diagnosis of compartment syndrome is clinical, and once made mandates immediate surgical intervention. Direct measurement of intracompartmental pressures can be achieved by a variety of methods, all of which involve the principle of placing a column of fluid between the compartment and a measuring device. Normal compartment pressure in an uninjured extremity is 0–8mmHg, and normal capillary perfusion pressure is 20–25mmHg. No consensus exists as to a threshold for compartment decompression, and indeed the threshold may vary depending on patient factors such as blood pressure, which affects capillary perfusion pressure. Furthermore, the multiple compartments in the hand make measurement a complex process even with the simplest techniques. We therefore recommend the measurement of intracompartmental pressures only where there is strong doubt about the presence of a compartment syndrome and a strong contraindication to surgical treatment, which is a rare situation.

#### Treatment
Non-surgical

The treatment of a suspected compartment syndrome is surgical decompression without delay. In the meantime, any external pressure, such as tight bandages or casts, should be removed. The hand should be placed level with the heart to maximize perfusion pressure whilst minimizing swelling and hypovolaemia should be corrected.

Surgical

The exact site of incisions is not critical, and all compartments can be reached through two dorsal incisions (see Figure 12.24.1). Should any doubt remain as to whether a particular compartment has been decompressed, a further incision over the compartment should be made. The carpal tunnel should also be released. Decompression of digits is not necessary unless the digit itself has been injured; the commonest indication is after burns (see later). The wounds should be left open and dressed.

In circumstances where the probability of a compartment syndrome is very high, such as after revascularization after a long ischaemia time, or following a severe crush injury, fasciotomies of the intrinsic muscles and carpal tunnel decompression should be performed prophylactically.

Postoperative care

After decompression, the hand should be elevated and splinted in the position of safe immobilization. After 3–5 days the patient should be returned to theatre and the skin closed if this can be done easily. If not, dorsal wounds should be covered with thin partial thickness skin grafts and the hand mobilized soon afterwards.

Outcomes

In a retrospective study of nineteen patients who had undergone hand and/or forearm fasciotomy for raised intracompartmental pressure, a good outcome in 13 patients and a poor result was recorded in four. In those four patients, the time from diagnosis to decompression was over 6h, and all four were obtunded or under general anaesthesia when the compartment syndrome developed. However, good results were achieved in three patients decompressed over 12h after diagnosis, so fasciotomy should still be performed when there is a late presentation.

Complications

Intrinsic tightness leading to intrinsic contracture is the characteristic complication of unrecognized or under treated compartment syndrome of the hand. This is caused by fibrosis of the affected lumbricals and interossei. Intrinsic tightness can be diagnosed clinically by increased resistance to flexion of the IP joints when the MCP joint is held extended compared to when the MCP joint is flexed. Symptomatically, patients with mild intrinsic contractures complain of persistent limited interphalangeal (IP) joint flexion months after injury. In more severe cases, flexion contractures of the MCP joints and extension contractures of the IP joints may develop. Severe complications of untreated compartment syndrome include digital necrosis, and persistent nerve dysfunction.

Burns

Background

Burns of the hands require specialist assessment and treatment. The British Burn Association recognizes that burns to the hands involving dermal or full thickness skin loss are more likely to follow a complex clinical course and therefore should be referred to a specialist burn care facility. Furthermore, the need for skin grafting of hand burns is independently correlated with reduced quality of life in burn survivors.

Importance

Hand burns are common, and occur out of proportion to their percentage body surface area. Many small injuries are treated as outpatients and the total incidence is unknown but high. In diverse countries such as the United Kingdom, United States of America, and Iran, two to three patients per 10 000 population per year are admitted to hospital with burns, and ten times this number may be treated without hospital admission; the arms and hands are involved in around 45% of cases. Both incidence and cause vary markedly with age, geography, and sex.

Causes and classification

The causes of burns are thermal, chemical, and electrical. The majority are thermal, caused by hot liquids, fire, and contact with hot objects. Chemical and electrical burns have their own special effects, and are not discussed further. The amount of damage in a thermal burn depends on the temperature and duration of burning.

Burns are classified clinically according to depth of skin necrosis (Table 12.24.2). Four grades of burn are clinically recognisable: epidermal, superficial partial thickness (SPT), deep partial thickness (DPT), and full thickness (FT) (Figure 12.24.3). Full thickness burns may also involve deeper tissues.

Fig. 12.24.3
Skin anatomy. A schematic diagram of skin anatomy with levels of injury corresponding to burn depth is shown. Epidermal and superficial partial thickness burns are more painful than deep partial thickness and full thickness owing to the preservation of more nerve endings. Superficial partial thickness and deep dermal burns heal without surgery because of epithelial cells lining adnexal structures such as hair follicles and sweat glands.

Burn depth forms the basis for decisions about management as it indicates whether the skin will heal and the likely degree of scarring. Epidermal burns, for example sunburn, heal spontaneously within 2–3 days and require treatment with moisturizer and mobilization. SPT burns heal in 7–14 days without scarring. DPT burns may heal in 14–21 days or more but often produce hypertrophic scars that contract and may interfere with function. FT burns heal by secondary intention, which is only acceptable if they are small. In the hand a distinction should also be made between palmar skin, which is thick, specialized, and more likely to heal well after apparently deeper burns, and dorsal skin, which is thinner, non-specialized, and less likely to heal well after anything more than SPT injury.

For all burns deeper than epidermal, oedema occurs in nearby tissues, and swelling reaches its maximum at 24–36h. A swollen, unsplinted hand takes up a position of wrist flexion, MCP joint extension, IP joint flexion, and thumb adduction, exactly the opposite of the position of safe immobilization, and if this is allowed to persist then secondary joint changes make mobilization difficult and can result in permanent joint contractures.

Coagulated protein contracts, and FT burns have lost their ability to stretch because of destruction of elastin within the dermis. Therefore, circumferential FT burns of the hand or digits, together with increased interstitial pressure due to oedema, may cut off the distal circulation and necessitate emergency release by escharotomy. With extensive FT burns a muscle compartment syndrome can also develop, especially if escharotomy is delayed.

### Clinical features

**History**
- Obtain history from patient, witnesses, emergency personnel
- Identify likelihood of associated airway burn, inhalation injury, carbon monoxide or hydrogen cyanide poisoning—usually burns from a fire in an enclosed space
- Identify likelihood of associated escape injuries
- Estimate temperature and duration of contact, therefore depth of burn.

**Examination**

- ATLS principles, assess hand as part of secondary survey
- Determine distribution and depth of burn (see Table 12.24.2).

**Investigations**

No special investigations are needed for hand burns. Various imaging techniques have been tried for measuring burn depth, but none has proved to be of practical clinical use.

**Treatment**

**Non-surgical**

Hand burns may occur as part of a larger burn, the systemic effects of which dominate the clinical picture at first, although the hands must be considered in the overall management plan from the start. The initial management of major burns follows ATLS principles. Analgesia is important, and thermally burned hands should be protected from desiccation and contamination. Clingfilm is useful for temporary cover.

Once the patient is stable a decision about wound protection must be made. For the hand, either dressings or plastic bags can be used. It is important at this stage not to apply creams, ointments, or liquids, for example silver sulphadiazine cream that will make depth assessment by the burn surgeon difficult.

Elevation to reduce swelling is important, except when escharotomy and/or fasciotomy is planned, when the hand should be kept at heart level. Active mobilization should be pursued if the burn is treated in a plastic bag or glove, combined with resting night-splints. If the burn is treated with dressings, the hand should be splinted in the position of safe immobilization.

Most chemical burns should be treated by immediate and copious lavage with water, although there are exceptions. Emergency workplace showers are available in many factories, along with specific antidotes for particular chemicals.

Domestic electrical injuries can cause cardiac arrhythmias and myocardial damage, and if evidence of either is found the patient should be monitored for at least 24h. High voltage electrical injury, often from industrial source, is a major emergency requiring immediate resuscitation and surgical exploration, fasciotomy, debridement, and vascular reconstruction, with amputation if the limb is irretrievably damaged.

**Surgical**

Escharotomy and fasciotomy, if indicated, are emergencies. Distal circulation in the burned hand may be difficult to assess, and the indication for escharotomy is a full thickness or possibly full-thickness burn that is circumferential or almost circumferential and might cause ischaemia. Both escharotomy and fasciotomy should be performed under general or regional anaesthesia, and if anything more than one hand requires escharotomy blood should be available for transfusion.

Apart from escharotomy and fasciotomy, the decision about operative or non-operative treatment and timing of surgery should be taken by a specialist burn surgeon. Decision making depends on the depth and distribution of the burn and on other injuries. SPT burns do not need surgery, but should be re-examined after 48h to make sure they are truly SPT and have not become deeper.

Definite FT burns, dorsal or palmar, should be excised and grafted in a specialist unit. In large burns the hands are second only to the face and neck in order of priority for grafting.

The management of DPT burns is less clear cut. On the dorsum, the results of early tangential excision and skin grafting are so good that there is an argument for early surgery in all but definite SPT wounds, but this is controversial and good results can also be obtained by grafting only wounds that have not healed by 2–3 weeks. Grafts to the dorsum should be applied with the wrist and finger joints fully flexed in order to maximize the amount of skin applied and therefore prevent subsequent dorsal contracture. On the palmar surface depth is more difficult to assess and, because of the thickness of the skin, healing frequently occurs after burns that appear at first to be deeper than SPT. This is specialized skin and if it is capable of healing in 2–3 weeks or even longer without grafting, then this is likely to produce the best result.

**Postoperative care**

After grafting the hand is elevated and splinted until the graft is stable enough to tolerate mobilization, usually 4–7 days. Mobilization should be started as soon as possible. If the patient is unable to mobilize themselves, passive mobilization by the therapist should be continued until they are.

Wounds that have taken more than 14 days to heal, and grafted areas once they are healed and stable, benefit from compression gloves, which help to minimize scar hypertrophy and accelerate scar maturation.

**Outcomes**

The outcome of a SPT burn should be a normal hand, although stiffness can occur if it has not been exercised or splinted. The outcome of deeper burns depends on the severity of injury and the timing and adequacy of surgical treatment, splintage, mobilization and post-burn therapy. When burns are very deep, and involve the extensor mechanism, the results are poor, with loss...
of motion and difficulty performing activities of daily living.

Complications

Complications of hand burns are often a consequence of delayed healing with subsequent adverse scarring and contracture, or poor cooperation with therapy and splintage resulting in stiffness. Even with the best management, complications occur. Frequently seen problems include: first webspace adduction contracture, other webspace contractures, dorsal skin contractures, little finger abduction deformity, MCP joint hyperextension, PIP joint flexion contracture, extensor tendon adhesion, Boutonnière deformity, median and ulnar nerve compression neuropathy, amputation secondary to gangrene. Secondary surgery to release scars and reconstruct skin and soft tissues may be required. The growing hand is especially vulnerable and likely to need multiple secondary procedures.

Infection

Background

Hand infections are common, and the consequences of poor or delayed treatment can be severe. Infections may be acute or chronic, bacterial, viral, fungal, or protozoal. Most are acute, and most of these are bacterial. The following discussion applies to acute bacterial infections. The majority are due to trauma, including animal and human bites (usually the patient has punched someone in the mouth), but a few are haematogenous.

Importance

The total incidence is not known because many minor infections are treated by primary care physicians and accident departments, but large hand surgery units in the developed world may admit 40–100 patients per year with more serious infections. Accurate worldwide figures are not available.

Causes and classification

A large variety of bacteria have been cultured from hand infections. The most common organisms are flora of the mouth or skin, especially the gram-positive aerobes streptococci and staphylococci. However mixed infections are common and anaerobes are present not infrequently, particularly after human bites and in paronychia. Human bites have a high incidence of Eikenella corrodens and dog and cat bites of Pasteurella multocida. The majority of acute hand infections occur in immunocompetent hosts. However, a significant minority occur in patients with predisposing immunocompromise, caused by diabetes mellitus, HIV infection, or steroid treatment, for example. Immunocompromise may not be diagnosed prior to the onset of infection, and can predispose to infection with unusual organisms, including Gram-negative and mixed organisms, and mycobacteria. Clinicians must also be aware of the possibility of hand infection caused by community-acquired meticillin resistant Staphylococcus aureus (MRSA). This may be particularly important as the delay before receiving appropriate antibiotics for patients with MRSA hand infections has been shown to be increased compared to those with non-MRSA hand infection.

Most infections are confined, at least initially, to a particular anatomical site, space, or compartment, and are classified accordingly. The classification and relative incidence of those infections requiring operative treatment are listed in Table 12.24.3. This is necessarily a biased estimate of the true frequency of different types of hand infection, as already it has been noted that many infections are treated successfully in a primary care or emergency department setting.

Data from Wein zweig and Gonzalez (2002)

Clinical features

History

Most patients give a history of trauma, with a penetrating injury that may have been trivial, or a more severe injury that has been neglected. The history may suggest likely pathogens, but sometimes the history is unreliable, such as after a human ‘bite’. A full
general history should be taken, particularly regarding predisposing conditions and tetanus immunity. The duration of symptoms and severity of pain, particularly pain that has prevented sleep, indicate whether the infection is early or whether a localized collection of pus is likely.

**Examination**

**Cellulitis**

Cellulitis alone occurs most commonly on the dorsum of the fingers or hand, often following a minor wound, and is usually due to beta-haemolytic streptococcus. Erythema and swelling may spread rapidly, sometimes with associated lymphangitis and systemic illness, and there may be skin damage ranging from blistering to frank necrosis. Necrotizing fasciitis is uncommon but can affect the hand and upper limb as elsewhere.

**Nail-fold (paronychia/eponychia)**

Mixed infections, particularly with *S. aureus* and anaerobes, are common. It starts with swelling, erythema, and tenderness around the nail-fold, usually on one side (paronychia), or at the base of the nail (eponychia). After 24h pus may be detectable, in the nail-fold and sometimes under the nail. In late cases the whole of the nail-fold, both sides and the base, may be involved.

**Pulp-space (felon)**

This is commonly due to a puncture wound and a foreign body may be present. Diabetics can get pulp infections caused by pricking their fingers for blood glucose monitoring. *S. aureus* and anaerobes are the commonest pathogens. Early on there may be localized cellulitis or a small collection of pus, but soon the whole pulp becomes swollen, tense, and very tender.

**Other subcutaneous abscesses**

Localized subcutaneous infection may occur anywhere in the hand. In the palm the infection may extend via a narrow channel through the palmar fascia to form a subfascial abscess, which together with the subcutaneous component is known as a collar-stud abscess.

**Tendon sheath infection (Box 12.24.2)**

Infective tenosynovitis affects almost exclusively the flexor tendons. Most cases are caused by penetrating trauma, but some are haematogenous, and in these gonococcus is a likely pathogen. Kanavel’s four cardinal signs are: digit held in slight flexion, fusiform swelling of whole digit, tenderness over the flexor sheath, and severe pain on passive extension. In early disease, the signs may be subtle. In tenosynovitis of the thumb and little fingers tenderness may extend proximally to the wrist and into the distal forearm via the radial and ulnar bursae.

**Deep spaces**

The potential spaces in the hand (Figure 12.24.2) can become actual spaces, occupied by pus, most often following a penetrating injury or extension of infection from a tenosynovial sheath or an adjacent deep space.

**Web space**

The fingers on either side of the web are abducted away from the web, and there is swelling and tenderness on dorsal and palmar aspects.

**Thenar space**

The thumb is held abducted, with tenderness and swelling over the thenar eminence, first web (palmar and dorsal), and index metacarpal, and pain on thumb extension or attempted opposition.

**Box 12.24.2 Signs of tendon sheath infection**

- Digit held in slight flexion
- Fusiform swelling of whole digit
- Tenderness over the flexor sheath
- Severe pain on passive extension.

**Midpalmar space**

The normal concavity of the palm is lost, there is dorsal swelling that may be more prominent than the palmar swelling, and finger movements, especially of the middle and ring fingers, are painful.

**Joint**

Septic arthritis may be caused by penetrating injury (when it may co-exist with tenosynovitis caused by the same injury).
extension of another infection (most commonly tenosynovitis), or haematogenous spread from an infection elsewhere. In children
*Haemophilus influenzae* is a likely pathogen, and in sexually active adults gonoccocus should be considered. Bite wounds caused
by punching someone in the teeth can result in septic arthritis of the MCP joints of the fingers if the joint is penetrated. An
important anatomical point is that the wound occurs with the joints in maximum flexion, and if explored with the joints in extension
the defects in the different layers (skin, extensor apparatus, joint capsule) will be out of line and the involvement of the joint missed
if not looked for.

There is swelling and erythema around the joint, which is held in the position that maximizes its volume (MCP joint extension and
IP joint partial flexion). The joint is tender, and any movement is painful.

**Bone**

Osteomyelitis of the hand is uncommon and affects almost exclusively the long bones. It may follow infections in adjacent tissues
or compound fractures (including for example, a Seymour fracture) or may be due to haematogenous spread. *S. aureus* is the
commonest pathogen, and *Haemophilus influenzae* is common in young children. There is local swelling, erythema, and
tenderness over part of the affected bone.

**Investigations**

In acute infections the decision to operate is a clinical one. Plain radiographs in two planes may show foreign bodies, including
broken teeth, but apart from these and soft tissue swelling most radiographs of infected hands are normal at the time of
presentation. Microbiological specimens usually have to await surgical exploration, though in septic arthritis joint aspiration may
confirm the diagnosis. Microbiology for osteomyelitis is best by bone biopsy. Blood cultures should be done in the presence of
systemic illness.

Relevant biochemical and haematological tests should be done if an underlying cause such as diabetes or immune compromise is
suspected.

**Differential diagnosis**

Many conditions can mimic acute hand infections, the more common differential diagnoses being acute arthritis, acute gout,
herpetic whitlow, compartment syndrome, hand fracture, and rarely primary hand tumour.

**Treatment**

The principles of treatment are the same for all acute bacterial infections: surgical drainage of localized infections, elevation,
splintage, antibiotics, and mobilization as infection is controlled and swelling subsides.

**Non-surgical**

Cellulitis and early osteomyelitis may be treated with elevation and intravenous antibiotics. Patients awaiting surgery for other
acute hand infections are treated with elevation and analgesia. Antibiotic administration should be delayed until microbiological
specimens have been obtained, unless there is a strong indication for starting them immediately, such as spreading infection or
systemic illness.

**Surgical**

The decision to operate depends on history, examination, and suspected site of infection. Visible pus or fluctuation in nail-fold
infections and subcutaneous abscesses may be obvious, but at other sites severe pain and/or loss of sleep strongly indicate
localization and the need for drainage. Suspected septic arthritis and tenosynovitis require urgent drainage. Necrotizing fasciitis is
a life-threatening emergency requiring immediate resuscitation and radical excision. Cellulitis needs surgery if an abscess develops
or there is skin necrosis requiring excision. Haematogenous osteomyelitis is treated by operation if there is no improvement in 24h,
and osteomyelitis due to compound fractures or extension of soft tissue infections is drained and debrided along with the primary
lesion.

Surgical drainage should be performed in an operating theatre, under tourniquet control but without forced exsanguination. Incisions
for localized infections at different sites should conform to general principles of hand incisions. Wounds should be left open or
drained, and a planned wound inspection at 48h is recommended. If infection is severe, or the symptoms do not improve after initial
treatment, earlier wound inspection and further exploration is indicated.

**Postoperative care**

Antibiotics should be started intravenously, the choice depending on likely pathogens, and local sensitivity patterns in consultation
with microbiology colleagues. In most cases the choice should cover *Staphylococcus aureus*, beta haemolytic *Streptococcus*, and
anaerobes. *Eikenella corrodens* and *Pasteurella multocida* are both usually sensitive to penicillins. Initial antibiotic treatment
should be reviewed depending on clinical response and the results of microbiological investigation.

Hands should be splinted in the position of safe immobilization until acute inflammation is subsiding. Active mobilization should then
be started, with resting splintage during the intervening periods and at night. As swelling diminishes, passive mobilization
should be introduced with increasing active use and decreasing periods of splintage.

**Outcomes**
The outcome of a hand infection treated early and adequately should be a normal hand. Stiffness is the commonest complication
(10–30%), and late or inadequate treatment can lead to irreversible damage to the tissues involved, spread to other tissues
(including systemic and metastatic sepsis), and chronic infection both with the primarily infecting agent and other secondary
organisms.

Complications

Cellulitis and pulp infections can cause skin and fat necrosis with exposure of deeper structures, especially extensor tendons, loss
of pulp padding over distal phalanges, and osteomyelitis. Paronychia can lead to nail deformity, and sometimes chronic infection,
often a secondary fungal infection. Tenosynovitis can cause scarring and adhesions between sheath and tendons, with loss of
mobility, necrosis of the flexor tendons, extension into adjacent bone and joints, and more proximally into the deep spaces of the
palm and wrist. Septic arthritis can result in secondary osteoarthritis or fusion. Septic PIP joint arthritis may lead to a septic
boutonniere deformity caused by rupture of the dorsal capsule and destruction of the central extensor tendon slip. Osteomyelitis
can lead to loss of bone and skeletal collapse.

Principles of management of open injuries

Background

Open hand injuries can present one of the most challenging problems to the reconstructive hand surgeon. Severe soft tissue
injuries complicate the management of underlying fractures, and carry a worse functional prognosis. Adherence to the principles
outlined in Box 12.24.3 will help to optimize long-term functional outcomes after these potentially devastating injuries.

Box 12.24.3 Principles of management of open injuries

♦ Treat life-threatening injuries—ATLS®
♦ Aggressive early treatment allows functional rehabilitation
♦ Excise non-viable tissue
♦ Stabilize bony elements
♦ Early definitive soft tissue cover
♦ Total reconstruction may not be appropriate
♦ Soft tissue management takes precedence.

Reconstructive techniques used for gaining soft tissue coverage have traditionally been conceptualized as a 'reconstructive ladder',
whereby each rung of the ladder represents a more complex reconstruction, and the surgeon chooses the simplest possible
reconstructive option. More recently, the concept of the 'reconstructive toolbox' has become more widely accepted, whereby not
the simplest, but the most appropriate option from a toolbox of reconstructive techniques is applied to a particular clinical problem.
This concept is particularly important in dealing with severe open hand injuries, where stable vascularized soft tissue coverage is
vital to allow early mobilization and functional rehabilitation.

Importance

The incidence of all open hand, wrist and forearm injuries has been calculated as 966 per 100 000 person-years in a population-
based study in Norway. Males were affected over twice as commonly as females, and this bias was more evident in more severe
injuries. Furthermore, open fractures constituted 37.9% of hand fractures presenting to a hand surgery service in Hong Kong over a
10-year period.

Causes

The history indicates the type and degree of damage to both soft tissues and skeleton. Common injury mechanisms vary with
geography, work and social factors. Industrial injuries commonly involve crushing and shearing forces, while domestic injuries are
more frequently due to sharp cuts.

Clinical features

History

♦ Time, place, and mechanism of injury
♦ Determine functional needs and goals of patient—age, handedness, occupation, hobbies
♦ General medical history
♦ Smoking, and use of drugs.

Examination

♦ ATLS® principles, assess hand as part of secondary survey
- Vascularity
- Bony injury
- Musculotendinous integrity—examination may be compromised by bony injury
- Nerve injury—sensory, motor, autonomic.

Investigations

Plain radiographs in two planes, guided by the results of clinical examination, will demonstrate bony injuries. Occasionally, special views will be required in order to diagnose specific injuries. Laboratory studies as dictated by the clinical condition of the patient should be obtained.

Classification

We favour the classification described in Table 12.24.4, though other similar classifications have been described.

Table 12.24.4 Classification of open hand injuries

Treatment

Planning

The ultimate goals of reconstruction in relation to the individual patient should be determined in order to formulate a reconstructive surgical plan. For some patients, early amputation is the most appropriate reconstruction, allowing early functional rehabilitation, and early return to work.

Non-surgical

A rapid initial assessment and resuscitation following the principles of ATLS should be undertaken. Wounds should be irrigated, and dressed with a non-adherent layer and saline-soaked gauze in order to prevent desiccation of the wound. If there is no suspicion of a vascular injury or compartment syndrome, the limb should be elevated. The open hand injury should receive the same tetanus and antibiotic coverage that any open fracture would receive.

Surgical

Wound excision

Wound excision is initiated at the skin surface and carried towards the depths of the wound. Any non-viable or grossly contaminated tissues should be excised. Marginally vascularized tissue, especially muscle, should be excised. Particular attention should be paid to the intrinsic muscles of the hand, as necrosis and subsequent fibrosis can lead to significant functional impairment. Critical structures, such as vessels, nerves and tendons should be retained. Any bone fragments which are maintained on a soft-tissue pedicle should be retained if not grossly contaminated. Any extensive wound in the palm should be extended to decompress the carpal tunnel. This extension not only prevents the development of acute carpal tunnel syndrome, but allows a reference to the planes of the palm.

Primary excision is undertaken under loupe magnification with the limb exsanguinated and tourniquet inflated. Secondary excision is carried out immediately afterwards with the tourniquet deflated to further trim any remaining devalized tissue. Special attention should be paid to the soft tissue envelope after release of the tourniquet. Any parts which are to be amputated during the initial excision should be assessed for use as ‘spare parts’ in primary reconstruction, for example, a fillet flap may provide vascularized soft tissue coverage; a digit may provide bone graft.

After excision, the wound should be thoroughly irrigated with normal saline. If soft tissue reconstruction cannot be immediately performed, or if doubts remain as to the viability of some tissues, a ‘second look’ procedure at 24–48h should be undertaken. Subsequent skeletal stabilization and soft tissue reconstruction should be undertaken at the time of definitive soft tissue coverage.
Skeletal stabilization

The initial reconstructive step is skeletal stabilization. The most important consideration for skeletal reconstruction in the hand is obtaining stability. A stable bone base allows early rehabilitation, and a lack of rigid fixation is associated with a worse outcome. Anatomical length maintains the extrinsic and intrinsic relationships necessary for function. The particular form of stabilization undertaken depends on the precise fracture pattern. Segmental bone gaps can be primarily reconstructed with corticocancellous bone grafts.

Soft tissue reconstruction

Next, tendons should be trimmed and repaired using standard core and epitendinous suture techniques (Chapters 12.22 and 12.23). The A2 and A4 pulleys should also be repaired or reconstructed. If primary repair is not possible, silicone rods can be placed and a second stage reconstruction subsequently performed. The next procedure is vascular reconstruction, which is discussed in Chapter 12.27. Nerve reconstruction is undertaken next. Crushed nerve should be excised back to healthy fascicles, and the nerve repaired using an epineural technique under the operating microscope. If there is a nerve gap, conduits (reversed vein, muscle) or nerve graft—often harvested from amputated parts—can be utilized.

Definitive soft tissue coverage

Finally, vascularized soft tissue coverage should be obtained. The range of options available is large (Table 12.24.5), but some basic principles emerge:

- Skin grafts (full or partial thickness) can be used on vascularized beds, especially in non-critical areas
- Exposed tendon, nerve, bone, ligament, or joint requires flap coverage
- Flaps may be local, regional, or distant; pedicled or free. They may utilize an entire vascular pedicle, or be raised on a perforator.

Postoperative care

The hand should be elevated and splinted in the position of safe immobilization. A well-planned therapy regimen should be instituted in order to achieve maximal functional rehabilitation. The use of custom made thermoplastic splints from a few days postoperatively facilitates wound care and therapy. Skin grafts require immobilization for 5 days to prevent shear and allow adequate take, but otherwise skeletal fixation and soft tissue repair should be stable enough to allow early active motion. Desensitization therapy should also be started early following nerve repair.

Outcomes

The final outcome after treatment of open hand injuries depends on the extent of the injury, the surgical management, and the postoperative rehabilitation. This rehabilitation includes psychological and social support. Open fractures of the fingers and thumb have a significantly worse outcome than closed fractures. In the fingers, 46.6% of open fractures and 80.7% closed fractures have been reported as having a good or excellent outcome. For the thumb, the equivalent figures were 78.8% and 97.8%.

Complications

The complications of open injuries depend on the tissues injured. Failure to recognize the true zone of injury and perform adequate wound excision can lead to infection, sepsis, and even death. Skeletal fixation can result in non-union, malunion, or osteomyelitis. Joint contractures and stiffness can occur. Tendon repairs may rupture, or become adherent to scar tissue. Vascular repairs may thrombose. Nerve injury often leads to cold intolerance, hypersensitivity, and painful neuromas may form, in addition to incomplete sensory and motor recovery. Scars may become hypertrophic, and soft tissue ulceration may be problematic. Secondary procedures to address these complications include osteotomies, joint replacement, nerve grafting, sensory reconstruction, tendon transfers, tenolysis, arthrolysis, and contracture release.
Summary

Soft tissue hand injuries comprise a wide variety of pathologies. All share a common theme, in that optimization of outcome depends on early diagnosis and timely, adequate treatment. Non-surgical management, especially splintage and therapy, is a crucial component of a successful outcome, and a team approach is necessary. Even with optimal treatment, long-term results following some injuries are suboptimal, and mechanisms to rehabilitate the patient into society, work and leisure are important.

Further reading

Nerve injuries

Summary points

- Nerve injuries are common
- The history is usually clear but the examination may be less so
- Neurophysiology is only useful after 3 weeks
- Imaging is of limited value as yet
- Treatment is removal of the cause/repair as appropriate
- Recovery is dependent upon many factors especially patient age, severity of the injury, how proximal the injury is and the type of nerve
- Post operative therapy is crucial
- Late reconstruction is primarily for motor function.

Introduction

Nerve injuries are common. They may occur simply such as a laceration of the finger, dividing a digital nerve, or may be part of a more complex picture such as a brachial plexus injury in a polytraumatized patient. The consequences of the injury are dictated by the likely recovery and the functional distribution of the nerve.

Incidence

The incidence of nerve injuries is not recorded. However, there are certain situations where there should be a very high suspicion that a nerve injury has occurred, such as dysfunction in the structures innervated by that nerve following an open injury, including a surgical wound. Certain orthopaedic injuries are commonly associated with nerve trauma, particularly shoulder dislocation, humeral shaft fractures, and supracondylar fracture of the humerus in the upper limb, and dislocations of the hip or knee and trauma around the fibula head in the lower limb.

Classification (Box 12.25.1)

The main classifications in use are those of Seddon (1942) and Sunderland (1978).

Seddon (1942) described three lesions: neurapraxia, axonotmesis, and neurotmesis.

Neurapraxia is a block to the conduction of electrical impulses without disruption of the nerve itself. It is essentially a physiological rather than an anatomic disruption, and thus secondary (Wallerian) degeneration does not occur. Typically, it is due to a blow, such as by bone fragments at the time of fracture, or short-term compression, such as by a tourniquet or plaster cast. The prognosis is excellent if the cause is removed. Typically, recovery is full, beginning within days and usually complete by 6 weeks.

Axonotmesis is a disruption of the axon itself but not of surrounding nerve tissue. It is usually caused by a more severe blow to the nerve, typically in a closed injury. Initially there is Wallerian degeneration proximally to the next proximal node of Ranvier and distally for the whole length of the distal axon. After about 10 days the distal end of the proximal axon starts to grow down its myelin sheath. Subsequently recovery occurs at a rate of about 1mm/day. Again, the prognosis is good if the cause is removed. However, recovery may not be full if there is fibrosis at the injury site, shrinkage of the nerve sheath distally, and/or end-organ degeneration. The further the distance from the site of injury to the site of recovery the less reliable the recovery.

Neurotmesis is a division of the axon and nerve sheath, typically following an open injury although it can occur with traction injuries such as to the brachial plexus. Any nerve palsy following an open wound must be assumed to be neurotmesis until proven otherwise. Wallerian degeneration will occur. Without surgery there is little hope of any nerve recovery. Even following expert surgical repair, recovery is rarely complete.

Sunderland (1978) classified nerve injuries into five subgroups on an anatomical basis. These are graded I-V: grade I is equivalent to neurapraxia, grade II is equivalent to axonotmesis, and grades III-V represent differing degrees of neurotmesis.

Box 12.25.1 Nerve injuries

- Common
- Three types:
  - Neurapraxia (physiological disruption only)
Axonotmesis (disruption of axons)
Neurotmesis (disruption of nerves).

Each system has its advocates and neither is perfect.

**Associated pathology**

Various pathologies are associated with nerve injury and each has particular features depending on the site and type of injury, e.g. open digital nerve injuries are typically associated with injury to the contiguous digital artery. The main structures that can be injured in association are skin and soft tissue, blood vessels, bone, and spinal cord.

- **Skin and soft tissue:** contaminated wounds with soft tissue injury may lead to infection and a poor environment for nerve healing
- **Vascular injuries:** the repair of a major blood vessel will be a priority
- **Bone fractures:** can cause any grade of nerve injury from neurapraxia to neurotmesis. Stabilization of the fracture by a plaster cast or operatively by internal or external fixation is important to provide a stable environment for the nerve to recover
- **Spinal cord injuries:** are associated with traction injuries, typically to the brachial plexus and rarely to the sacral plexus. As nerve roots are avulsed these become essentially an irreparable lesion, and there will be injury to the spinal cord with consequences in terms of both pain and dysfunction distally.

**Clinical evaluation (Box 12.25.2)**

The general features of clinical evaluation are described, with those specifically related to each nerve being referred to in detail subsequently.

**History**

The history is often clear cut. Important details to elicit are whether the wound is open or closed, the level of injury involved, and the time delay. A nerve injury associated with an open wound should always be assumed to be a neurotmesis until proven otherwise, typically at surgery. Low-energy closed injuries are associated with neurapraxia, and high-energy injuries are associated with axonotmesis and even nerve rupture. The time from injury is important, as this will also give guidance to the severity of the injury to the nerve and the appropriate treatment.

**Box 12.25.2 Assessment of nerve injuries**

- **History:**
  - Mechanism
  - Time from injury

- **Examination:**
  - Motor function
  - Sensory function
  - Autonomic function

- **Investigation:**
  - Neurophysiology (after 3 weeks)
  - MRI scan.

**Examination**

Examination for any nerve injury should look at motor function, sensory function, and autonomic function. With neurapraxia the dysfunction may be partial, but with axonotmesis or neurotmesis it will be complete. Autonomic dysfunction is the one truly objective sign in the early phases. Thus absence of sweating in the distribution of the nerve can only be associated with significant dysfunction, typically neurotmesis or axonotmesis. If there is doubt at initial clinical examination, the patient can be reviewed within 48h. Obviously, this presumes that there are no other major injuries dictating against this course of action.

The examination needs to be detailed and well documented. Pain can confuse the examination. Ideally, muscle function should be isolated and tested specifically. Sensory testing should be with light touch, pinprick, and two-point discrimination, if there is doubt.

**Investigations**
Investigation of the nerve injury

The main modalities for investigating nerve injuries are neurophysiology and magnetic resonance imaging (MRI) scanning.

Neurophysiology

Neurophysiology relies upon the secondary changes associated with Wallerian degeneration, particularly spontaneous muscular activity which shows as fibrillation potentials. This occurs from about 3 weeks after injury. Prior to this, neurophysiology has a limited role. Thus neurophysiology is mainly used about 6–8 weeks postinjury to assess nerves whose initial recovery was anticipated to be good but where this has not necessarily been the case. A typical example would be radial nerve dysfunction following a humeral shaft fracture which was believed to be either neurapraxia or axonotmesis from which a good recovery was anticipated, but at 6 weeks there had been little recovery. There seems to be no useful role for neurophysiology in assessment of acute injuries.

MRI scanning

In theory, MRI scanning will provide images of nerves and delineate their degree of disruption. At present this has not been achieved, although research is continuing.

Imaging of associated injuries

Bone

Plain radiographs usually suffice to delineate underlying fractures. If there is gross disruption of fracture fragments, this suggests a high-energy injury often associated with more severe nerve injuries.

Vascular injuries

If there is a doubt about vascular function, arteriography should be performed but not at risk of delaying exploration and repair of a major arterial injury.

Spinal cord injury

Spinal cord injuries can be imaged by MRI scanning, but the interpretation of these is difficult acutely.

Management (Box 12.25.3)

Management can be divided into initial management, conservative measures, operative repair, and secondary reconstruction.

Initial management

With closed injuries the limb should be rested, preventing further damage to the nerve. Associated fractures should be stabilized appropriately. With open injuries the wounds should be cleaned and dressed and preferably not reinspected too often as this leads to increased contamination. An alternative is to suture the wound under local anaesthetic without tension and await formal early surgical exploration as appropriate. With contaminated wounds debridement within 6h is considered essential with cover from appropriate antibiotics to minimize the risk of infection.

Conservative measures

Conservative measures are designed to provide an optimal environment for nerve recovery. This is also true following surgical repair. The two main modalities to address are motor and sensory dysfunction.

For motor dysfunction it is important to have a programme of physiotherapy and splintage to ensure that the muscle–tendon complexes continue to have good passive excursion and that joints also go through a full passive range of motion. This should ensure that whatever motor function does recover will work optimally. Splints such as those for radial nerve palsies may also allow continuing use of the arm.

The main concerns over sensory dysfunction are the risk of injury in anaesthetic areas and working on desensitization and retraining exercises as nerve function recovers. Thus patients are instructed in protection of anaesthetic areas and advised that, if injured, the wound should be covered as they often heal more slowly. Desensitization needs to be performed by the patient supervised by a hand therapist.

Nerve surgery

Surgery on nerves is best performed early, i.e. within 10 days of injury. Many series have shown that a delay in treatment causes a worsening of the prognosis, and in certain injuries, such as those to the brachial plexus, surgery becomes much more difficult once extensive local fibrosis has occurred. However, emergency nerve repair is not necessary; rather surgery is better performed by an experienced surgeon within several days rather than acutely by an inexperienced surgeon. At operation the nerve should be inspected; if it is found to be intact, it can simply be left, and the wound cleaned and closed; if the nerve is divided, and the environment is suitable, i.e. the skeletal structures are stabilized and the wounds are clean or cleanable, end-to-end repair should be performed using magnification. If there is doubt as to the cleanliness of the wounds, guided by the Rank–Wakefield classification, nerve repair should be delayed until asepsis can be guaranteed.
Management of nerve injuries

**Box 12.25.3 Management of nerve injuries**

- Rest
- Debride contaminated wounds within 6h
- Physiotherapy to maintain range of motion
- Splints (e.g. for radial nerve palsy)
- Surgery:
  - Repair nerves within 10 days
  - Delayed repair for contaminated wounds
  - Line up nerve
  - Multiple small sutures
  - Repair contiguous major artery
  - Nerve graft for defect in nerve
  - Secondary surgery within 12–18 months.

At nerve repair it is important to line up the nerves accurately either by inspecting the nerve bundles or by using external markings such as longitudinal blood vessels. Multiple sutures are applied, allowing good apposition without tension and preventing bulging of nerve fascicles. Typically 6.0 monofilament nylon sutures will be used for sciatic nerve injuries, 8.0 for median and ulnar nerve injuries in the forearm, and 10.0 for digital nerve injury. Any contiguous artery of size, i.e. any in the upper limb proximal to the wrist or in the lower limb proximal to the ankle, should be repaired even if the viability of the limb does not depend on this. It has been shown that the results of nerve injury are improved by repairing the neighbouring artery, presumably because of the increased blood supply locally but perhaps simply because of local splintage.

Where there has been extensive injury to the nerve or delay preventing a tension-free repair, nerve grafting should be performed. Classically, this is performed with nerve grafts from ‘expendable peripheral nerves’ such as the medial cutaneous nerve of the arm or the medial cutaneous nerve of the forearm in the upper limb, or the sural nerve in the lower limb. The nerve is cut to appropriate lengths, glued together with a fibrin glue, and sutured end-to-end to the nerve stumps after they have been trimmed back to healthy nerve ends. This provides a conduit down which the nerves can recover. Extensive work during the 1980s showed that freeze-thaw muscle grafts can also provide a suitable conduit over short distances (i.e. up to 5cm). This avoids sacrificing other peripheral nerves. However, they have largely fallen out of favour. Primary suture gives better results, and even with small gaps is preferable to grafting not least as the latter has to cross two anastomosis sites. Moreover, the results with long grafts (i.e. over 5–10cm) are not good, particularly if there is a poor vascular bed.

Recent laboratory and clinical studies have shown that bridging nerve gaps with a silicone tube, leaving a gap of 3–5mm between the nerve ends, gives comparable results to primary repair. At the end of the operation, meticulous haemostasis must be achieved to prevent haematoma formation. The limb is splinted to prevent any tension on the nerve for 6 weeks whilst it is recovering except for digital nerve injuries where early mobilization gives better results. During this period and thereafter appropriate conservative measures must be instituted to optimize end-organ function.

**Secondary surgery**

Where a nerve repair has failed or recovery has been incomplete it may be appropriate to re-explore and graft the nerve. This can be of value for up to 6 months and sometimes up to 1 year following injury, but rarely thereafter. This is because of a combination of shrinkage and fibrosis in the distal nerve trunk, failure of the end-organs, particularly the motor endplates, progressive and irreversible changes in the central nervous system with loss of the parent motor neuron, changes within the receptor fields of sensory neurons, and, if therapy has not been adequate, distal secondary stiffness. At this point reconstructive surgery should be considered rather than further nerve surgery. This can address motor and sensory function.

It is difficult to improve sensory function, although for limited areas, such as the distribution of an important digital nerve (e.g. to the ulnar pulp of the thumb), innervated skin from another area can be transferred as in the Littler transfer or Foucher’s modification. This will require some re-education, and although function will not return to normal it may be improved. This procedure is only infrequently performed and is very rarely indicated for more proximal lesions.

**Motor function** is the mainstream of secondary reconstructive surgery following nerve injury.

**Pain**

The treatment of pain following nerve injuries is difficult, particularly proximally involving the spinal cord, as with brachial plexus injuries (see later). For peripheral nerves it may occur with terminal sensory nerves such as digital nerves and the superficial branches of the radial nerve. The pain is typically localized to the distribution of the nerve, with burning pain and hypersensitivity. There is usually a neuroma at the site of nerve injury which is very sensitive. These can be extremely difficult to treat.

Prevention of pain by avoiding damage to nerves is best. If the nerve is damaged, primary repair should effect some restoration in
nerve function which should prevent/minimize hypersensitivity and pain. Adequate postoperative analgesia and desensitization exercises also help. If pain is established, desensitization exercises and simple measures such as transcutaneous electrical nerve stimulation should be tried first. If these fail, nerve-suppressant medication such as amitryptyline, or gabapentin in increasing doses may help. If the pain is sympathetically mediated guanethidine or steroid and local anaesthetic blocks, may help but are becoming less common. Sometimes surgery is necessary, which aims at either burial of the neuroma in a less sensitive site, such as deep in a muscle or bone, or restoration of continuity in the nerve which appears to give better results. This can be performed with a nerve graft, although obviously the concern here is that one painful nerve site will be replaced by another. Cryotherapy to the injured nerve may help the pain and hypersensitivity but usually at the expense of some further loss of sensibility.

Results

The results of nerve surgery are very variable. However, grading is well classified according to the Medical Research Council (MRC) grading of 1954 and its 1975 modification (Table 12.25.1). It is important to note that, although this grading is quite sensitive when there is very little function, such as only a flicker of motor function, it gives only a crude indication of the loss of the first 50–70% of function. In the section on motor function a plus sign can be added to M4 to indicate some improved function, but this should not be used elsewhere in the grading.

Table 12.25.1 MRC grading of nerve surgery results

Factors affecting nerve recovery (Box 12.25.4)

- **Age**: The results of nerve repair decrease with age from as young as 10 years upwards
- **Nature of the injury**: Recovery will be better in clean injuries than in extensive injuries such as closed traction injuries or where there is gross soft tissue loss. The results in gunshot wounds are particularly poor, with only 40% of patients having any return of function
- **Level of injury**: The more proximal the injury, the less good is the recovery. This represents a number of factors including a decay in the quality of nerve recovery distally with time and particularly distal end-organ failure, as nerve recovery may take up to 2 years to reach end-organs such as the hand or foot. Recovery is rarely complete with distal injuries, however, and digital nerve repair in adults never gives normal sensibility.

Box 12.25.4 Results of nerve surgery

- **Better prognosis:**
  - Young patient
  - Clean injury
  - Distal
  - Large muscle group
  - No defect
  - Early repair
- **Worse prognosis:**
  - Older patient
Contaminated injury
• Proximal
• Small muscle group
• Large defect
• Delayed repair.

Type of nerve
Motor nerves to large muscle groups not requiring fine control have a good prognosis, whereas motor nerves supplying small muscles in the hand rarely have a good outcome. With pure sensory nerves, there is a significant risk of long-term chronic pain.

Length of injured nerve
If a large segment of nerve has been injured or there has been a delay leading to nerve retraction and prevention of primary repair, the results of surgery will be less good as the results of nerve grafting are less good.

Associated injuries
Associated skeletal injuries must be stabilized or the chances of a repair remaining intact are negligible. Significant vascular injuries should also be repaired even if this is not essential for limb viability, as nerve recovery is improved.

Delay
It has been shown that primary nerve repair is much more successful than delayed repair. Ideally, nerve injuries should be repaired within a few days of injury (a maximum of 10 days), provided that local tissue conditions are favourable.

Technical skills
It has not been proved that the skill of the surgeon results in improved outcomes. Nonetheless, it is widely believed that better results are achieved by experienced nerve surgeons using magnification than by occasional surgeons.

Complications (Box 12.25.5)
The main complications of nerve surgery are failure of recovery, pain, stiffness, and crossover sensation.

Failure of recovery
If sepsis is present, nerve recovery is very unlikely. It is also unlikely in the presence of ischaemic or hypovascular tissue where nerve repair and particularly nerve grafting are less successful. It can be difficult to decide when to re-examine a nerve following primary repair or grafting. It should normally be obvious within 3 months that there has been some progression of nerve recovery distal to the repair site. This will be indicated by return of function in the local motor or sensory supply and particularly by an advancing Tinel sign. This should be documented and is a very useful assessment of progressing nerve function. If there is a strongly advancing Tinel sign, the prognosis for nerve recovery is good. However, if there is also a Tinel sign at the repair site, this is less optimistic, and a strong Tinel sign at the repair site with none distally is a poor prognostic feature. Neurophysiological assessment may be able to indicate whether there has been nerve growth across the repair site. The main assessment of failure is clinical. If there is doubt, then re-exploration and revision nerve grafting should be undertaken. Nerve grafting is almost always required at revision surgery. It is unclear how many times nerve grafting can be undertaken following failure. However, if there is no recovery after two attempts, further success is unlikely. Again, the likelihood of successful nerve grafting after 12 months is minimal except in treating pain.

Box 12.25.5 Complications of nerve surgery

- Failure to recover
- Pain
- Stiffness
- Sensory crossover.

Pain
Pain is a significant problem as a complication of nerve injury and failure of recovery and was discussed earlier.

Stiffness
Stiffness is essentially a failure of therapy in the postinjury period although some stiffness will inevitably follow major nerve injuries. It is very debilitating as it will reduce the benefit from any motor recovery.

Crossover
Trophic nerve factors from the distal nerve stump will attract sensory and motor nerves from the proximal stump to the appropriate sensory and motor tubules distally. However, there will be crossover with motor nerves destined for one muscle going to another, and motor and sensory crossover. This reduces the efficacy of nerve recovery and can lead to problems of re-learning, particularly if there is sensory crossover. This can be reduced by retraining and is less of a problem in young patients who have greater cerebral plasticity.
Upper-limb nerve injuries

Accessory nerve (Box 12.25.6)

The accessory nerve is particularly prone to injury by surgeons at biopsy of masses in the posterior triangle. The motor loss is to the trapezius with no significant sensory loss. However, there is often a significant problem with pain. The diagnosis should be obvious on the principle of nerve dysfunction in the line of an open wound although, sadly, referral and repair are often delayed especially following iatrogenic injuries.

Nerve grafting is almost always required. Good recovery in the nerves occurs in 80–90% of operations performed within 3 months, with no useful recovery after 1 year. If nerve repair has failed or not been attempted, pain may be a problem. Treatment of this is extremely difficult. If nerve repair fails, the scapula may be supported by a sling or transfer of levator scapulae and rhomboids. This may improve function but does not generally improve pain.

Box 12.25.6 Accessory nerve

♦ Posterior triangle surgery
♦ Usually requires nerve graft
♦ 80–90% success with surgery.

Box 12.25.7 Long thoracic nerve

♦ Iatrogenic/brachial plexus injury
♦ Nerve repair or muscle transfer.

Long thoracic nerve (Box 12.25.7)

The long thoracic nerve is typically injured in association with brachial plexus injuries (see later). The next most common cause is iatrogenic, at the time of axillary clearance. The motor dysfunction is paralysis of the serratus anterior causing loss of control of the thoracoaxial movements. There is no sensory loss, but there is often a dull aching pain following injury. There are no reported series of repair of the long thoracic nerve, although sporadic cases show some value. If primary repair is not possible, local nerve transfer may be of value. If nerve surgery fails, muscle transfer of the pectoralis major or pectoralis minor to the lower part of the scapula improves thoracoscapular movement and diminishes pain.

Axillary nerve (Box 12.25.8)

The common causes of axillary nerve injuries are, again, brachial plexus injuries (see later), dislocations and fracture dislocations at the shoulder, and open wounds, particularly iatrogenic injuries. The motor loss is of deltoid paralysis. Patients with deltoid paralysis can often still achieve a full range of shoulder movement, particularly by using the rotator cuff muscles. Strength is reduced by about 50% in abduction and slightly less in flexion and extension. The area of sensory loss is the ‘badge’ area on the lateral aspect of the upper arm and is a minimal problem. Pain is not typically a problem.

Open injuries require exploration. Treatment of axillary nerve injuries following shoulder dislocation is less clear cut. Most surgeons wait for 6 weeks, anticipating a neurapraxic lesion and early recovery. If this does not occur, neurophysiological assessment should be performed together with a careful review to exclude a rotator cuff lesion which can present both similarly or in conjunction with an axillary nerve injury. If there is continuing doubt, the axillary nerve should be explored and, where possible, repaired using a nerve graft. This should be within 3 months of injury. The results of early surgery suggest that recovery to M4 or better should occur in about 80% of cases.

Radial nerve (Box 12.25.9)

Radial nerve palsy is one of the most frequent acute major nerve palsies in the upper limb. The most common cause is fracture of the shaft of the humerus with the nerve injured in the spiral groove. In most cases this is a neurapraxic lesion, or at worst an axonotmesis, and good recovery is anticipated. With high-energy injuries the nerve can suffer significant stretching and have an extensive lesion in continuity (see later) or even rupture.

Box 12.25.8 Axillary nerve

♦ Iatrogenic/brachial plexus injury/shoulder injuries
♦ Explore/repair open injuries
♦ Closed injury recovery usually by 6 weeks.
The motor loss is to the extensors of the wrist and hand, giving a classic wrist-drop posture. Sensory loss is in the dorsum of the first web space and is of little significance. Pain from these injuries is rare, in contrast with more distal radial nerve injuries.

**Box 12.25.9 Radial nerve**

- Common
- Humeral fracture (80% recover within 6 weeks)
- Nerve repair success 80%
- Tendon transfers work well.

The natural history of most radial nerve injuries following humeral fractures is recovery. Radial nerve palsy was reported in 57 of 765 fractures of the humerus (an incidence of 7.4%) of which 47 (82.5%) underwent full spontaneous recovery.

For low-energy injuries the wrist and hand should be mobilized with static or dynamic splintage. If there is no evidence of recovery at 6 weeks, neurophysiological assessment should be undertaken. If there is continuing doubt, open exploration should be performed. Whenever the fracture is opened primarily, the radial nerve should be inspected and repaired if ruptured. In all cases of high-energy injury there should be a high suspicion of a significant nerve injury and consideration should be given to early exploration.

A number of surgeons have reported on the results of radial nerve repair, particularly of military injuries which tend to be worse than civilian injuries. In civilian experience about 80% of repairs achieve M4 recovery or better distally. If nerve repair fails, tendon transfers give an excellent result. It is usual to wait for at least 18 months after nerve repair to see if there is any recovery in motor function, but such is the excellence of flexor-extensor transfers for radial nerve palsies that these may often be undertaken earlier.

**Musculocutaneous nerve (Box 12.25.10)**

This nerve is most commonly injured as a result of brachial plexus injuries (see later), and next most commonly via open wounds including iatrogenic injuries. The loss of motor function results in paralyse of the biceps, brachialis, and brachioradialis. The loss of sensation is to the lateral aspect of the proximal forearm and is of minimal consequence. This is primarily a motor nerve and as such does well with 80% of patients recovering at least M4 elbow flexion if repaired within 3 months.

If primary nerve repair fails, intercostal nerve transfer (neurotization) sometimes works well at providing some elbow flexion but the preferred transfer is the Oberlin transfer. A few of the motor fascicles from an intact ulnar nerve are transferred side-to-end to the musculocutaneous nerve. The nerve recovery is over a short distance and has minimal surgical morbidity. If neurotization is either not contemplated or fails, tendon transfer can be performed. This is sometimes required for simple injuries, but is more common following brachial plexus injuries (see later).

**Box 12.25.10 Musculocutaneous nerve**

- Brachial plexus injuries/iatrogenic
- Repair/nerve graft usually successful.

**Box 12.25.11 Median nerve**

- Self-inflicted/accidental lacerations
- Primary repair/nerve grafting better than delayed repair
- Tendon transfers can be used.

**Median nerve (Box 12.25.11)**

The median nerve is commonly injured via self-inflicted lacerations at the wrist, accidental injury, or secondary to surgery. If the lesion is very proximal in the forearm, the median-supplied forearm flexors will be paralysed, namely the pronator teres, the flexor carpi radialis, all the flexor digitorum superficiales, and classically the profundus tendons to the index and middle fingers. Obviously this gives major dysfunction of the hand, particularly the radial side. More distal injuries would exclude the long flexors, but would include the median-supplied muscles of the thenar eminence which are primarily the abductor pollicis brevis and opponens pollicis, although there may be some ulnar supply to these. The loss of sensation is even more harmful, as it is in the radial three digits and includes the most important areas of the pulp of the thumb and the index and middle fingers. With distal injuries there is often only partial division of the nerve, in which case the loss is less and is variable.

The best results are with primary surgery, although very good results can be obtained from nerve grafting. Wrist injuries are often
accompanied by injuries to the flexor tendons which also need to be repaired. If the injuries to the median nerve are within a few centimetres of the carpal canal, it is usual to release the carpal canal to avoid any local compartment problems.

The results of median nerve surgery very much reflect the factors discussed above. In a series of primary and delayed median nerve repairs, better results were achieved with primary repair (Table 12.25.2).

Data from Birch and Raji (1991).

The results of nerve grafting are good; 100% of patients achieve good or fair sensory results and 80% good or fair motor results after median nerve repair. The most important factors for nerve grafting are age, closely followed by gap length, level of injury, and delay. Gap length and delay are of greater significance in sensory recovery than in motor recovery, whereas the level of injury has a greater effect on motor recovery than sensory recovery. This is also true for ulnar nerve grafts (Table 12.25.3).

Data from Frykman and Gramyk (1991).

Full recovery following median nerve injury will not be achieved in children over 10 years of age and adults. However, good functional recovery should be achievable. If there is very poor sensory recovery even after revision surgery, it is unlikely that complex nerve skin transfers would be performed to regain sensation, but this is always a possibility. Most secondary reconstructive procedures are aimed at tendon transfers.

Box 12.25.12 Ulnar nerve

- Self-inflicted/accidental lacerations
- Primary repair/nerve grafting better than secondary repair
- Tendon transfers/tenodeses sometimes useful.

Ulnar nerve (Box 12.25.12)

The ulnar nerve, like the median nerve, is commonly injured through open wounds, particularly at the wrist, which are either self-inflicted or due to a fall on glass. The sensory loss is less marked than the motor loss, particularly to the small muscles of the hand which tend to recover at best only incompletely, especially in adults.

Again, treatment is primary suture where possible and repair of the ulnar artery. The results of repairs of the ulnar nerve are similar to those of the median nerve and are shown in Table 12.25.4. If primary surgery fails, nerve grafting is worthwhile in most cases and usually gives some benefit (Table 12.25.5).

Clinical picture

Duchenne’s sign is clawing of the hand in ulnar nerve injury. If the hyperextension is passively prevented by dorsal pressure over the metacarpophalangeal joints, the extensor tendons can extend the middle and distal phalanges. This is known as Bouvier’s manoeuvre. In contrast, an attempt to extend the fingers further by flexing the wrist, in effect providing a tenodesing effect on the extensor tendons, increases rather than decreases the deformity. This is known as the André–Thomas sign. The inability to cross the middle and index fingers over each other due to loss of the interosseous function is known as the Pitres–Testut sign. An inability to adduct the little finger to the ring finger, so that the little finger tends to stay in an abducted position, is known as Wartenberg’s sign. Probably the best-known sign is Froment’s sign, described in 1915, where an attempt to perform a key pinch between the pulp of the thumb and the side of the middle phalanx of the middle finger results in marked flexion at the thumb interphalangeal joint due to weakness or paralysis of the adductor pollicis and therefore the need to bring the flexor pollicis longus into action to provide strength. The descriptions of the clinical findings are based upon the classical innervation of the ulnar nerve. However, there is considerable variation, with a number of crossover patterns from the ulnar to the median nerve and vice versa. The most common is the Martin–Gruber communication, which occurs in about 17% of forearms (range 5–34%), where there is communication between the median and ulnar nerves in the proximal forearm. There are other rarer communications.

Reconstructive surgery

If nerve surgery has failed, the modalities to be addressed are sensation and motor function. It is rare to perform any surgery to improve sensation in the ulnar-supplied distribution to the hand. The main treatments are tendon transfers.

Digital nerves (Box 12.25.13)

In theory the repair of digital nerves should give excellent results, as these are pure sensory nerves often with only a short recovery distance. Unfortunately this is not the case.

Digital nerves are typically injured by lacerations, often in domestic situations but regrettably also iatrogenically. The concomitant digital artery is generally injured as well but does not normally require repair provided that the finger is viable. There is often associated injury to flexor tendons and even bone, and obviously these need appropriate primary treatment.

Repairs are performed using a microscope with fine sutures such as 10.0 nylon. Unlike for most repairs the results are better following early mobilization, primarily due to less stiffness. In children, full recovery can occur. In adults, even though normal two-point discrimination can be achieved, no patient achieves full recovery of sensation in the digit. Moreover, even if the nerve is not repaired there is often considerable recovery due to crossover sensation from the contralateral digital nerves. This does not indicate that digital nerve repair should not be performed, as a good recovery will improve function and reduce the risk of a painful neuroma at the injury site. Typically patients with injuries to the radial digital nerve to the index finger will bypass to the middle finger for fine sensibility.

Box 12.25.13 Digital nerves
Lacerations (domestic and iatrogenic)

- Primary repair of nerve but not artery
- Mobilize early
- Crossover sensation common.

Lower-limb nerve injuries

Nerve injuries in the lower limb are less common than in the upper limb and have been less widely reported. The main reported nerve injuries are to the sciatic and common peroneal nerves. Less frequently nerves of the sacral plexus are injured particularly usually in association with pelvic fractures.

Sacral plexus injury (Box 12.25.14)

The sacral plexus is typically injured at the time of a pelvic fracture, often with fracture of the sacrum. Rarely, it will be injured by an open wound. Pelvic fracture is often associated with other life-threatening injuries, but it is important to try to delineate nerve injuries preoperatively as there is also a significant incidence of perioperative nerve injuries. Sciatic nerve injuries may also occur in these complex fractures and it is important to differentiate the two. The sensory loss following sacral injuries is over a much greater area proximally, and the motor loss will involve the hip flexor and knee extensors and there may be sphincter dysfunction.

Typically the sacral plexus suffers a traction injury like the brachial plexus and at present does not appear to be amenable to surgery, although with clean division successful repair has been performed. In the long term, recovery is at best incomplete and is often associated with pain.

Sciatic nerve (Box 12.25.15)

The sciatic nerve is mainly injured in association with pelvic fractures, and with fractures and dislocations of the hip. Regrettably, it can also be associated with hip replacement surgery. The injuries may be traction or division injuries and occasionally are due to compression. The incidence of pelvic injuries and fracture dislocations of the hip is reported at 8–12%, with the greatest risk in those involving injuries to the posterior column. Recovery appears to be improved by early reduction and stabilization of the fractures, with a good result expected in about 40–50% of patients, although the results are poor in at least one-third.

Box 12.25.14 Sacral plexus

- Traction injuries usually with fracture
- Surgery rarely indicated
- Recovery often poor.

Box 12.25.15 Sciatic nerve

- Pelvic fractures/hip dislocations/hip replacement
- Severe in children
- Early reduction/stabilization improves results
- Fracture/surgical injuries should be explored early and repaired.

The incidence of nerve injury at hip arthroplasty appears to be about 1% (range 0.6–3.7%) after primary hip replacement, 2–3% after revision arthroplasty, and 6% in patients treated for congenital dislocation of the hip.

The treatment of nerve injuries in association with fractures or hip replacement is early exploration. Division of the nerve, compression of the nerve from a suture, or even a cement burn can occur. Appropriate treatment of these results in a much greater likelihood of good recovery.

The consequences of sciatic nerve injuries in children are particularly severe where there are limb-development problems as well as sensory and motor abnormalities. In particular, functionally significant leg-length discrepancy may occur. The lack of sensibility on a weight-bearing area leads to increased risk of skin breakdown, and the lack of muscle balance leads to risk of contractures.

Tibial and common peroneal nerve injuries (Box 12.25.16)

In the largest series reported on injuries of the sciatic nerve, the nerve was classified into the common peroneal and tibial divisions —345 injuries of the common peroneal nerve and 229 injuries of the tibial nerve were reported, and 145 nerve repairs were performed. One-third of the 72 cases of repair of the common peroneal nerve achieved functional dorsiflexion of the ankle. Eighty per cent of the 47 cases of repair of the tibial nerve regained functional plantar flexion of the foot. Recovery of sensation ranged from S2 to S4 and occurred in about two-thirds of cases. The main fixed deformities were equinus of the heel and clawing of the toes.
Trophic ulcers were present in 14%, and pain and hypersensitivity of the foot were major problems in 50%. The discrepancy between function and neurological deficit is greater for the sciatic nerve than for any other nerve injury (Table 12.25.6).

Data from Seddon (1975).

The common peroneal nerve itself is typically injured around the knee, particularly as it winds around the fibula neck where it is both superficial and relatively immobile. It may be injured by local trauma to the knee, with knee surgery, and by open injuries. The most common injury is a rupture. Injury results in lack of anterior and peroneal compartment muscle function. The nerve has less supportive connective tissue and fewer autonomic fibres than the tibial nerve. Hence in traction injuries the motor and sensory nerves bear more of the injury. Open lesions should be repaired primarily and ruptures should be grafted. The results of surgery depend on both the severity of the injury to the nerve and the quality of local soft tissue. The results are generally good with clean simple wounds, but are less good with traction injuries. Delay is a significant problem following traction injuries, and a delay of over 6 months almost always leads to poor results. Early treatment can give significant recovery in about two-thirds of cases, but overall about 50% gain useful ankle dorsiflexion and a little over 50% gain protective sensation.

Box 12.25.16 Common peroneal nerves

♦ Common peroneal:
  • Often traction injuries
  • Lacerations recover best with surgery
♦ 50% success with surgery
♦ Tendon surgery works well.

If there has been no adequate recovery after 1 year, further nerve surgery is probably not of value unless there was considerable doubt over the initial operation. Thereafter tendon transfer should be performed if static splintage is not adequate. The most useful is a tibialis posterior to tibialis anterior transfer which has been widely reported and in most cases gives a significant improvement in function.

Iatrogenic nerve injuries (Box 12.25.17)

There are four main types of iatrogenic nerve injury: surgical division, injection injuries, irradiation injuries, and compression neuropathy.

Direct surgical injuries are typically lacerations, although occasionally sutures will be placed around nerves or plates put upon nerves. If, following surgery, as for any open wound, there is dysfunction, particularly complete dysfunction in the line of the nerve, this should be explored as a matter of some urgency unless the surgeon identified and preserved the nerve right up to the end of the procedure. Even incomplete nerve dysfunction should be considered for early exploration, especially if there is a risk of partial compression such as around metalwork.

Box 12.25.17 Iatrogenic nerve injuries

♦ Surgical: explore early
♦ Injection: early decompression
Tourniquet: usually recover

Compression:
- Usually recover
- Up to 25% do not resolve
- Consider decompression.

Fortunately, injection injuries are rare, and most commonly occur through injections near peripheral nerves in the upper limb now that the risk of sciatic nerve damage caused by buttock injections is well recognized. Any substance injected into a nerve causes an intense fibrotic reaction and early decompression is recommended. This can usually be avoided by checking whether the patient has tingling and pain in the distribution of the local nerve at the time of injection. If this is identified upon insertion of the needle, it can be withdrawn normally with no damage, but if injection continues then permanent damage will almost always occur.

There are two main risks from irradiation injuries. The most common is irradiation neuritis with intense fibrotic reaction which can occur many years after the irradiation. Symptoms occur typically 6–8 months after treatment, initially with pins-and-needles and sometimes with progression to severe and intractable pain. Operations rarely seem to improve function, particularly in the region of the brachial plexus where so many of these injuries occur following irradiation for breast carcinoma. There is a limited hope for free vascular grafting to bring in an increased blood supply on the basis that this is an ischaemic injury.

Most iatrogenic compression neuropathies are caused by tourniquets or pressure on nerves on the operating table.

Tourniquet neuropathies are infrequent. It is estimated that their incidence is between 1 in 5000 and 1 in 8000 cases. Although neurophysiological studies have shown that nerve abnormalities occur within as short a period as 20 min, it appears that 2h is a safe upper limit for the use of a tourniquet in both upper and lower limbs. Although many surgeons have experience of using longer times without problem, this should be the exception and not the rule. Typically these lesions are neurapraxia or axonotmeses and recovery is full, but rare cases of permanent injury have been reported.

The most common perioperative injuries are to the common peroneal nerves in the lithotomy position, the brachial plexus in cardiac surgery, and the ulnar nerve as in the supine position. These have previously been felt to be benign lesions, which recover well, but this is not always so and a permanent deficit appears to occur in 5–25% of patients with brachial plexus lesions and 10–27% of patients with common peroneal lesions. Once these patients are identified, they should be assessed with early neurophysiology and if there appears to be a severe lesion consideration should be given to decompression of those sites where it may have occurred, most particularly the ulnar nerve at the elbow.

Further reading

Brachial plexus injuries

Summary points

- Serious injury, usually closed
- C5/C6 injuries commonest
- More proximal injuries have best results
- Early treatment leads to better results
- Direct repair if possible
- Arthrodesis or muscle transfer may be useful.

Introduction

Brachial plexus injuries are uncommon but very serious (Box 12.26.1). They may be closed or open, or occur as part of birth trauma. The treatment of these injuries has progressed but in most cases long-term disability persists due to the unpredictability of nerve regeneration. Secondary reconstruction is only of partial benefit. These injuries typically affect young males and they present a major challenge both to medicine and society as a whole.

Box 12.26.1 Brachial plexus injury

- Uncommon
- Serious effects
- Usually closed injury.

Aetiology

The majority of brachial plexus injuries are closed, usually as a result of motorcycle accidents. This is demonstrated in Table 12.26.1 which shows experience from a tertiary referral centre in Switzerland. Open injuries occur more commonly in violent societies such as parts of South Africa and the United States of America. A significant percentage are iatrogenic lesions following removal of a lump from the posterior triangle of the neck.

Incidence

The incidence of brachial plexus injuries is not known. There were estimated to be about 300–350 patients who suffer severe and permanent damage as a result of closed supraclavicular brachial plexus injuries each year in the United Kingdom. Recently the frequency appears to have diminished. There are many other milder lesions of the brachial plexus that recover well. The patients are typically inexperienced motorcyclists under 25 years old.

Anatomy

Normal

The brachial plexus is made up of five nerve roots from C5 to T1, but there is considerable variation and the plexus may be pre- or postfixed, i.e. coming from C4 or from as low as T2. The typical brachial plexus is shown in Figure 12.26.1.

Box 12.26.2 Four types of injury

- Neurapraxia—good prognosis
- Rupture—postganglionic can recover
- Lesion in continuity—poor prognosis
- Avulsion:
  - Preganglionic
  - May be treatable surgically.
Pathological (Box 12.26.2)

Four types of injury can occur to the structures of the brachial plexus:

- Neurapraxia
- Rupture or division (neurotmesis)
- Lesion in continuity (a combination of anoxotmesis and neurotmesis)
- Nerve root avulsion.

**Neurapraxia**

Complete recovery should occur.

**Rupture or division**

This is a postganglionic lesion, i.e. one distal to the dorsal root ganglion. Therefore it represents a peripheral nerve injury with an opportunity for recovery provided macroscopic continuity is re-established, such as at surgery.

**Lesion in continuity**

This is also a postganglionic lesion. It represents stretching of a large segment of nerve but without rupture. This should, in theory, be a favourable lesion, but intense peri- and intraneural fibrosis leads to poor results.

**Avulsion**

This is a preganglionic lesion, i.e. a central lesion often associated with a direct spinal cord injury. Typically both dorsal and ventral roots are avulsed from the spinal cord but one or other alone may be avulsed. Historically this has been an irreparable lesion, but there are now some opportunities for surgical repair (see later). Preganglionic lesions are commonly associated with severe neuralgic pains.

**Associated pathology**

The main associated injuries are to bone and blood vessels.

**Bone injuries**

Typically there may be one or more fractures of the head or shaft of the humerus, fracture of the scapula, clavicle, or ribs, or a dislocation of the shoulder. There may also be other limb injuries associated with severe polytrauma.

**Blood vessels**

Major vascular injury, namely rupture of the subclavian artery, occurs in about 10% of supraclavicular and over 20% of infraclavicular lesions of the brachial plexus. The incidence is even higher in open wounds.

**Other injuries**

Head, spinal cord, and chest injuries occur in up to 10–15% of severe brachial plexus injuries.

**Classification**
The purpose of classification of brachial plexus injuries (Table 12.26.2) is to delineate the severity of the lesion. Two questions to be addressed are: Which nerve roots are involved? Are the injuries pre- or postganglionic? These are mainly addressed to closed injuries, as open injuries, typically with knives, are almost always postganglionic divisions of some or all of the brachial plexus.

**Clinical evaluation (Box 12.26.3)**

The diagnosis of a brachial plexus injury is usually obvious—typically a young traffic accident victim with a flail insensate arm. In some patients, however, the diagnosis may be less clear cut, for example patients after reduction of an anterior dislocation of the shoulder who cannot abduct their shoulder, which may be due to pain, a rotator cuff lesion, or an axillary nerve or infracavicular plexus injury.

**Box 12.26.3 Clinical signs**

- May not be immediately obvious (e.g. head injury)
- Assess motor/sensory function
- Tinel’s sign (especially C6 root)
- Bruising along nerve trunks
- Swelling in posterior triangle (poor prognosis)
- Severe pain down arm (avulsion injuries).

**History**

In severe brachial plexus injuries the history is often incomplete, especially from patients who have suffered a concomitant head injury. There will often be a history of high-energy trauma.

**Examination**

The initial examination will often show a completely flail insensate limb, but is often not very specific and is complicated by associated pathology. There may be rapid return of function within 7–10 days after the initial neurapraxia has resolved. Nonetheless, with the severe injuries that often require early surgical intervention, the picture rapidly becomes clear. Specifically, sensory testing should be done as per the dermatome map (Figure 12.26.2).
Muscle testing should ideally be done for each muscle in the upper limb but there are general patterns which can be recognized (Table 12.26.3).

Certain clinical findings are of particular significance.

- A positive Tinel sign radiating to the hand is indicative of rupture. This is valid at 24h and is especially reliable for the C6 root
- Linear bruising along the course of the nerve trunks in the arm implies rupture of those trunks
- Severe swelling and deep bruising in the posterior triangle is a poor prognostic indicator
- Weakness of the trapezius, disturbance of sensation above the clavicle, and paralysis of the ipsilateral hemidiaphragm suggest that the upper root to the brachial plexus has been avulsed. Homer's syndrome is associated with avulsion of the brachial plexus, particularly the C8 and T1 nerve roots
- Severe pain radiating down the arm is associated with avulsion injuries.

Investigation (Box 12.26.4)

Investigations can be subdivided into those for the neural injury and those for associated pathology. Obviously patients involved in severe polytrauma will require appropriate blood tests and other investigations.

**Neural investigations**

**Plain radiographs**

The key radiographs are those of the chest and cervical spine. Elevation of the ipsilateral hemidiaphragm on the chest radiograph suggests a phrenic nerve injury and possible C5 and C6 nerve root avulsion. Fracture or dislocation of the first rib or fracture of the transverse process of the seventh cervical vertebra are associated with C8 and T1 root avulsions. On the anteroposterior radiograph the cervical spine may be abducted away from the site of injury suggesting root avulsion.

**Imaging of the cervical spinal cord**

Myelography, computed tomography (CT) scanning with enhancement, and magnetic resonance imaging (MRI) scanning are all of value but have significant false-positive and false-negative rates and so are not yet regularly used. Ultimately, however, MRI scanning to look at both the spinal cord and the brachial plexus may be of value.

**Box 12.26.4 Investigations**

- Chest radiograph—diaphragmatic elevation/transverse process/rib fracture, neck abduction
- Neurophysiology has little acute role
- MRI scan may become valuable
- Consider:
  - Plain radiograph for skeletal injuries
  - Vascular studies
  - CT scan for head injury.

**Neurophysiological studies**
These are of little value for 2–3 weeks until Wallerian degeneration has begun. Most severe brachial plexus injuries require surgery. This is recommended earlier than 2–3 weeks, hence neurophysiology has little role acutely.

Neurophysiology has been extended to use intraoperatively with scalp or cervical electrodes. These are of assistance in evaluation of the injured nerves at surgery. They are, however, not entirely reliable.

Investigation of associated injuries

Plain radiographs of skeletal injuries: these should be done as part of standard polytrauma assessment.

- Vascular studies: an arteriogram or digital subtraction arteriogram may be used for suspected subclavian artery or even aortic arch injuries
- CT scan for head injuries: where doubt persists as to the severity of the head injury this is an essential prerequisite to surgical intervention.

Management (Box 12.26.5)

The treatment of brachial plexus injuries can be divided into initial, non-operative and primary, and secondary operative treatments.

Initial management

The initial management of the brachial plexus injured patient is along advanced trauma life support guidelines. Vascular injuries are emergencies and require accurate diagnosis and urgent surgery. Surgical approach depends upon the site of injury. The vascular injuries specifically to the subclavian artery should be repaired with reversed vein grafts. Prosthetic grafts have a high incidence of thrombosis and lead to extensive local fibrosis. Skeletal injuries should be stabilized early, usually with rigid internal fixation. Humeral nails for humeral shaft fractures are easier and quicker to use but associated with higher non-union rates and do not permit examination of the radial nerve which can be ruptured in association with a brachial plexus injury.

Box 12.26.5 Management

- Treat vascular injuries
- Stabilize associated skeletal injuries
- Non-operative management for neurapraxia
- Surgery:
  - Direct suture for clean sharp injuries
  - Conventional nerve grafts
  - Nerve transfer for motor power or pain relief in preganglionic injuries.

Non-operative treatment

Neurapraxic lesions should be treated conservatively. It may be difficult to delineate these lesions absolutely. Indicators include mild lesions with a limited number of nerve roots involved. There is often patchy sparing of sensation or motor function and early recovery within the first 7–10 days. The treatment aims to prevent further damage to the brachial plexus by keeping the arm adducted to the chest for 4 weeks whilst preventing distal joint stiffness with physiotherapy.

A conservative approach should not be adopted for too long because of the much greater benefit of early over late operative repair. Thus, if the anticipated recovery is not occurring at 2–3 weeks, neurophysiological studies should be performed in conjunction with spinal cord imaging, and the decision for further treatment based upon these findings and the clinical progress.

Operative treatment

Primary operative treatment aims to restore nerve function whilst secondary operative treatment is that of muscle transfers and bone operations to overcome specific problems. There is only a very limited role for late nerve surgery.

Primary operative treatment

The standard surgical approaches are the transverse supraclavicular incision for proximal lesions and the deltopectoral approach for infraclavicular lesions (Box 12.26.6).

Box 12.26.6 Results of primary surgery

- Best results with more proximal lesions
- Delay is detrimental
In the supraclavicular approach flaps of skin and platysma are raised, then after division of the omohyoid between stay sutures, whilst avoiding damage to the cervical plexus and vessels and the phrenic nerve, the brachial plexus is delineated posterior and lateral to the scalenus anterior muscle.

In the infraclavicular approach the deltoid and the pectoralis major are separated, the pectoralis minor is detached from the coracoid and reflected, and the plexus is then seen wrapped around the subclavian arteries.

Once the plexus has been displayed the lesions may be obvious. With increasing time from injury, however, this is less so and may be complicated by the degree of recovery that is shown. Diagnosis may be enhanced by intraoperative electrical testing both stimulating orthodromic across the lesion and antidromic recording from cervical or scalp electrodes. For neuromas and lesions in continuity, when there is a partial response to electrical stimulation across the lesion, the decision to resect and graft, or to leave is very difficult.

The following specific surgical treatments are available:

- Direct suture
- Conventional nerve grafts
- Vascularized nerve grafts
- Nerve transfers.

Direct suture

Direct suture is rarely used and is only a possible option in early treatment of clean sharp injuries of the plexus. Even in such injuries, grafting is usually recommended. In clean injuries suitable for either direct suture or small grafts, the best results are achieved.

Conventional nerve grafts

The technique is as for standard nerve grafting (see earlier). The nerves used are typically one or more of the medial cutaneous nerve of the forearm, medial cutaneous nerve of the arm, and the sural nerve. It is essential that these are put in without tension. They are typically secured with fibrin glue and sutures. Postoperatively the arm is immobilized in a sling full time for 6 weeks to protect the repairs. Thereafter, physiotherapy is begun.

Vascular nerve grafts

Vascular grafts were first used in 1976 to provide a well-vascularized tube for nerve regeneration. It was hoped that this would overcome the problem of ischaemic scarred nerve beds. The reported results show that vascular grafts are only equivocally better than conventional grafting. The surgery is more complex and, therefore rarely used except in very scarring recipient sites.

Nerve transfers

These were first performed in the 1950s and are now well established. The most common are the accessory to suprascapular nerve transfers and transfers of intercostal nerves to median or musculocutaneous nerves. Their role is twofold. One is to provide further motor input to nerves distally to improve function. The accessory to suprascapular transfer can result in significant improved shoulder control and intercostal nerve transfer to the lateral cord can give grade III and even grade IV elbow flexion. They do require some relearning, but most patients manage this. The other role is to increase the sensory input to the distal nerves which can have a dramatic benefit in relief of pain especially with preganglionic injuries.

Results of nerve surgery

The results of nerve surgery are very variable and depend upon many factors, as with all peripheral nerve repair work (see Chapter 12.25). In essence, the recovery of the proximal muscles is best because there is the shortest distance from the nerve to recover and these muscles have a mass action so that fine innervation is not as important as in the finer actions of the smaller muscles of the hand. Furthermore, with nerve recovery to distal muscles there is often significant end-organ failure prior to the nerve reaching the muscle. Sensory recovery in the hand is at best protective.

The reported results are mainly with conventional nerve grafting and nerve transfers.

Nerve grafting

Of particular importance for the recovery after brachial plexus injury is the delay from treatment. Delays over 3 months are especially detrimental and after 6 months the chances of worthwhile regeneration are minimal. Repair of C5 and C6 by conventional nerve grafting gives functional flexion of the elbow and some control of the shoulder in 60% of cases.

Nerve transfer

Useful functional gain is achieved with the shoulder and elbow with significant relief of pain in over 60% of patients operated on within 3 months. Nerve transfers are particularly successful for preganglionic injuries of C5 and C6 and sometimes C7. They are
much less effective for preganglionic injuries of C8 and T1.

Reconstructive surgery (Box 12.26.7)

There are various techniques of secondary operative reconstruction of brachial plexus injuries. The main ones are muscle transfers, arthrodesis, amputation, and surgery for the treatment of pain. These are always second best for ‘good nerve regeneration will result in far better function than musculotendinous transfers’.

- Muscle transfers: the standard rules apply as for elsewhere (see Chapter 6.9). Muscle transfers are particularly useful for regaining elbow flexion and wrist and finger extension
- Arthrodesis is mainly used at the shoulder when there is good proximal shoulder girdle control so that the scapula muscles can support the weight of the arm and provide some movement. It can also help reduce the dragging on the brachial plexus from a very unstable shoulder, which can increase pain. Arthrodesis in the rest of the upper limb is rarely performed
- Amputations are now uncommon except in severe acute lesions with extensive vascular injuries. Later indications are for a flail and useless limb in a well-rehabilitated patient and occasionally for marked shoulder pain, particularly that associated with dragging on the plexus. Most of the amputations are proximal humeral amputations to maintain some shoulder contour.

The role of each reconstructive procedure is considered further in terms of the four main areas of use: the shoulder, elbow, forearm, and hand.

Shoulder

The complexity of surgery at the shoulder is often dictated by the level of function in the rest of the upper limb. Hence in injuries of C5 and C6 only, when nerve recovery has been poor, considerable efforts at improving the shoulder are worthwhile in order to use the very good hand and forearm function that the patient will have. For impaired shoulder function muscle transfer particularly of latissimus dorsi into the external rotators may be of value in regaining some active external rotation. If this is not possible, an external rotation osteotomy of the humerus may allow a more functional range for use of a good forearm and hand. For the flail or very weak shoulder arthrodesis is the most useful treatment. Gleno-humeral arthrodesis can be performed with internal or external fixation. Rarely, scapulothoracic fusion may be performed for poor thoracoscapular control.

Elbow

The lack of elbow flexion is a major disadvantage to patients who still have a good hand. Lack of elbow extension is less disabling as gravity can be used to achieve extension. The patients most troubled by lack of elbow extension are those who can abduct their shoulder above 90 degrees as the forearm then tends to fall, or those patients who need extension strength to get out of a chair or wheelchair.

Most elbow surgery is directed at regaining elbow flexion. The three main types of transfer are the triceps to biceps transfer, the pectoralis major to biceps transfer, and the Steindler flexorplasty, advancing the brachioradialis proximally up the arm. The triceps to biceps transfer gives the best results but with loss of elbow extension. The Steindler flexorplasty tends to give the worst results with weakness and risk of damage to the ulnar nerves.

Recently there have been cases of use of contralateral latissimus dorsi as a free muscle graft and in Japan in particular, surgeons are using gracilis as a free muscle transfer for both elbow and wrist and hand flexion. The latter typically gain M4 or M3 elbow flexion.

Forearm

The main problem is lack of forearm rotation. Active forearm rotation is very difficult to re-establish although re-establishing some pull on the distal tendon of the biceps may give some active supination. Surgery is mainly directed at improving the position of the rest of the forearm with a rotational osteotomy.

Hand

The most common problem that is treated is loss of finger and wrist extension. The extensors of the arm generally have more proximal root values than the flexors so for proximal brachial plexus injuries there may be retention of wrist and hand flexion but loss of extension. Tendon transfers are based upon the Robert Jones transfer (see Chapter 6.9) but obviously directed to which muscles are functioning well. Failure is more common that with peripheral nerve injuries as there is often partial involvement of the
Pain can be the most severe consequence of a brachial plexus injury. It is more common with preganglionic injuries and with injuries of C8 and T1 than C5 and C6. It can lead to depression, opiate dependence, and suicide. It is typically crushing, burning, and vice-like often with superimposed shooting or lightening pains. These patients are difficult to treat and involvement in other activities such as work and the major role of successful rehabilitation back into the community. Specific treatments include analgesics, transcutaneous electrical nerve stimulation, nerve transfers, and spinal cord intervention.

**Box 12.26.8 Pain treatment**

- Analgesics especially nerve irritant suppressants, e.g. amitriptyline
- Transcutaneous nerve stimulation (50% success)
- Nerve transfers (up to 80% success)
- Spinal cord surgery
- Rehabilitation.

Analgesics range from simple oral analgesics up to opiates. The latter, however, should be avoided if possible as they tend not to be that effective and are associated with dependence. Neuralgial pains may respond in particular to carbamazepine, phenytoin, or amitriptyline.

Transcutaneous electrical nerve stimulation gives a significant reduction in pain in up to 50% of patients.

Nerve transfers, particularly intercostal nerve transfers, have been shown to be effective in reducing neuralgic pain. This was felt to be only with early surgery but even late surgery is of benefit in up to 80% of cases.

Attempts have been made at spinal cord intervention with interruption of spinal tracts and thermocoagulation of the dorsal root entry zone. Some patients have dramatic relief of symptoms and up to two-thirds are improved but there is a significant risk, of up to 10%, of lasting neural deficit, particularly affecting the lower limbs and possibly sexual function. Therefore spinal cord surgery is mainly used as a last resort.

Rehabilitation of patients following brachial plexus injuries is fundamental to their long-term function and integration back into their former lives. The key is a multidisciplinary approach with the surgeon or rehabilitation physician as the coordinator. Other team members include physiotherapists, occupational therapists, nurses, and retraining officers. The physiotherapists strengthen muscles, mobilize joints, and set up the transcutaneous electrical nerve stimulation. Occupational therapists make and fit splints and organize the retraining activities of daily living. The nurses provide ongoing support on the ward. The retraining officer is crucial in planning return to future work.

**The future**

Predictions about the future of brachial plexus injuries are difficult and unreliable. Adult brachial plexus injuries are becoming less common as motorcycle use appears less frequent especially in poor weather. Nonetheless as the evidence continues to accumulate of the efficacy of early intervention it is hoped that these patients will be referred earlier and will have more effective nerve surgery.

Recent work from Sweden has shown regrowth of implanted ventral rootlets into the spinal cord. This allows some regeneration of motor function into preganglionic injuries. Initial work in humans has shown some promise.

Nerve growth factors have recently been studied and shown to be present only in low levels in brachial plexus neuromas. In future, application of nerve growth factors at the time of operation may improve nerve recovery.

In reconstructive surgery the role of free muscle transfers has not been fully evaluated but is likely to broaden the scope of reconstruction.

**Conclusion**

Brachial plexus injuries sadly affect some of the youngest and most active members of the population and are a severe and debilitating drain on both patients and society. Too often they have been treated with a degree of therapeutic nihilism based on the belief that surgery has no role, as espoused at the SICOT Meeting in Paris in the 1960s. However, there is no doubt that early aggressive treatment of these patients can give significant benefit and even late attention to their problems can be very helpful.

When a man has nothing a little is a lot.

Replantation

Summary points

♦ Digital replantation is the best reconstruction available for the correct indications
♦ Amputated thumbs, multiple fingers, and paediatric replants are the strongest indications
♦ A functional result requires a mobile, stable, sensate digit of adequate length
♦ Replant survival and functional results are dependent on multiple factors including microsurgical expertise
♦ Spare part surgery is a unique opportunity to salvage tissue in an unreplantable limb.

Introduction

One of the guiding principles of reconstruction espoused by the father of modern plastic surgery Sir Harold Gillies was to replace like with like. In the successful replantation of an amputated part using microsurgery this principle is taken literally. Since the first reports of an arm replantation and the first thumb replantation, the reattachment of amputated parts has become commonplace and includes almost any extremity of the body.

Unfortunately successful replantation does not mandate satisfactory function, with the aim of survival alone being useless without a functional appendage. The potential adequacy of bone, tendon, and nerve repairs and joint flexibility must be predicted preoperatively before embarking on an attempt at replantation.

Mechanisms of amputation

The mechanism greatly influences the degree of damage caused to all anatomical structures and will have significant implications on survival and long-term function. It is prudent to give the patient a guarded outcome as occasionally even in ideal circumstances results can be disappointing.

The industrial machinery which cause amputations are many and varied and the injury can be further influenced by the reflex withdrawal response of the victim. A detailed description of the mechanism of injury combined with examination of the amputated part and radiographs will give clues to the extent of tissue damage but ultimately surgical exploration must determine the technical feasibility of replantation.

Box 12.27.1 Principles

♦ Replace like with like
♦ Give guarded outcome to patient
♦ Sharp injuries best
♦ Crush/avulsion worst.

Sharp or guillotine injuries

Sharp or guillotine injury is the most favourable mechanism of amputation although it is the rarest. Unfortunately it is seen most often at very distal levels where replantation is technically difficult.

Crush injury

Localized

Localized or moderate crush injuries caused by power saws and many industrial press-type machines are the most common form of injury. The tissue damage occurs over a wider area and often occurs at multiple levels. Following conservative trimming of damaged structures, this type of injury can usually be converted to the sharp type and whilst prognosis is worse than a sharp injury, in the absence of an avulsional component, a high survival rate can still be achieved.

Diffuse

Diffuse crush injuries caused by blunt squashing or high-velocity cutting machines reveal extensive contusion of skin and soft tissue as well as ragged tendon and nerve ends and often comminution of bones. There may be frank loss of tissue especially bone and skin and this may necessitate either local, regional, or free flap coverage.
Avulsion

Avulsion amputations result from a degloving or longitudinal force and are compounded by the natural withdrawal reflex of the victim. Typically, the vascular structures rupture and protrude from the proximal amputation stump while long tendon and nerve ends protrude from the distal part. Extensive damage occurs to the digital arteries over a variable length, often extending proximally to the next branch point and even into the palmar vessels, and may include skip lesions of thrombus. If the mechanism included a torsional component the arteries can look macroscopically normal in the absence of flow and this is due to intramural spiralling seen clearly with more proximal dissection under the microscope. In contrast, veins rupture rather than avulse. The veins are sheared at the same level of the skin and can be anastomosed primarily whereas the arteries nearly always require vein grafting.

Characteristic of avulsion is the extensive degloving of skin which remains with the amputated part, creating poorly vascularized distally based flaps following replantation. The ultimate fate of the skin depends on the extent of distal resection of the arteries in order to restore blood flow. It is possible to be left with an alive digit distally surrounded by a coat of necrotic skin requiring further reconstruction. In general the long-term functional prognosis is poor given the injury to nerves and tendons, especially if the latter have disrupted at their musculotendinous junction. One caveat to this is the classic isolated ring avulsion which often leaves the skeleton and flexor sheath intact and requires revascularization or replantation of the soft tissues alone thereby permitting early active mobilization and a more favourable outcome.

Confounding factors

Physical trauma may be combined with thermal or chemical burns which in the absence of blood supply to the amputated part can be impossible to assess. Incorrect storage can cause fossible of the amputated part. Gross contamination requires widespread debridement of all tissues including bone and necessitates vein grafting of all vessels.

**Indications for replantation (Box 12.27.2)**

There are no absolute indications to replant. The decision whether or not to replant isn’t always easy and demands experience both in replantation and hand surgery in order to maximize the chance of a successful functional outcome. The aim is to restore function, growth, and cosmesis. Stiff, cold, or painful fingers may be excluded from everyday use and also interfere with the function of the remaining undamaged hand. There remains a subgroup of patients who for religious or cultural reasons will categorically insist on replantation. Similarly some patients prefer to keep a non-functional digit as it affords a better cosmesis than a bothersome prosthesis. Thus whilst the delayed amputation of a finger at 12 months does not constitute a success, if there is any doubt, it is generally better to err on the side of replantation than primary amputation.

**Box 12.27.2 Aims of replantation**

- Aim to restore function, growth, cosmesis
- Within ischaemia time
- More distal injuries more favourable
- Thumb strongest indication in upper limb
- Multiple digits strong indication
- Better in younger patients.

Ischaemia time, level, mechanism of injury, number of digits amputated, associated hand injury, and age will all influence the potential for recovery.

**Ischaemia time**

The amount of muscle contained in the amputation is the critical determinant with respect to time to revascularization. Amputations containing minimal muscle generally present well before their maximum permissible ischaemia time has elapsed (warm 12–16h; cold <28h). More proximal amputations, particularly those in the forearm or the lower limb, contain significant portions of muscle and therefore have a much more limited warm ischaemia time than digits (6–8h). With viability unlikely and potentially life threatening consequences these replantations should probably not be attempted if the warm ischaemia time exceeds 8h.

**Level of amputation**

There are numerous classifications for the level of amputation but from a practical viewpoint there are five distinct types –

1. Type 0 (Distal) = distal to the distal interphalangeal (DIP) joint, or thumb interphalangeal (IP) joint
2. Type 1 = insertion of flexor digitorum superficialis (FDS) to DIP joint (Zone 1)
3. Type 2 = A1 pulley to insertion of FDS (Zone 2)
4. Type 3 = wrist to A1 pulley
5. Type 4 (major) = proximal to wrist or lower limb.

Although technically difficult, it has become obvious that distal replantations, only have to survive to be functional. They have the potential for the best results of any replant.
Only sharp type replantations in Type 1 have the potential to restore function, especially when they are multiple and to the ulnar side of the hand. Even with limited distal interphalangeal joint movement or sensation, the intact proximal interphalangeal joint will restore considerable palmar grip function and balance with the outstretched hand. Paradoxically, Type 2 amputations, with more to gain by replantation, are the poorest indication in a single digit because of the complexity of the structures involved. In practice very good function following a single digit non-guillotine injury in Types 1 and 2 levels is rare and replantation is generally contraindicated.

Replants in Types 0–2 have the relative advantage of not requiring any motor neural re-innervation. Amputations proximal to Type 2 in the hand are strong indications for replantation. Replantation of a clean-cut wrist-level amputation is the most rewarding. At the mid forearm level and above the prognosis worsens.

Whilst an amputation through a joint obviates the need for osteosynthesis and bony union and potentially allows for earlier mobilization, the range of motion resulting is universally disappointing. Repair of the unique stabilizing structures of the joint (usually the proximal interphalangeal joint) cannot hope to replicate the pre-injury status and therefore mobility.

Digit involved

The thumb contributes 40% of function to the hand and is the strongest indication for replantation at any level and at any age (Figure 12.27.1). The mobility in three planes of the trapeziometacarpal joint also compensates for the stiffness postreplantation in the interphalangeal or metacarpophalangeal joints without a significant diminution in function. Replantation of a single finger should only be done in special circumstances, but single-digit amputations with a concomitant injury to another finger or part of the hand, magnify the disability and is a stronger indication (Figure 12.27.2).

Fig. 12.27.1
(A) Total thumb amputation—a strong indication for replantation even in a 76 year old. B) Normal sensation and good function is attained.

Fig. 12.27.2
Postoperative view of multiple distal replants of middle and ring fingers. These have the best functional and cosmetic results of all amputations.

Multiple-digit amputations are a strong indication for replantation. The barest use of the hand requires a stable, mobile thumb and a pillar against which it can oppose. The radial three digits are concerned with pulp pinch grip, and therefore sensory excellence is of greater importance than mobility. On the ulnar side of the hand however, power grip is the prime function and this requires digital length and mobility; sensation is relatively less important. The potential for joint movement, especially the proximal interphalangeal joint, is of prime importance. Amputations in Types 0 and 1 do not need sophisticated function as simple restoration of length will
allow them to contribute to ulnar power grip.

Where multiple digits have been amputated and not all are suitable for replantation, the opportunity to select the least traumatized of them and transfer to the most appropriate stump should always be kept in mind. Most commonly this will involve the thumb.

Age

Young patients carry a better prognosis than the elderly. Due to the remarkable plasticity of the immature brain to create cortical reorientation, replantation of any digit at any level is strongly indicated in children. Beyond the age of 20, nerve regeneration occurs variably and unpredictably, and all but distal amputations should be expected to have significant limitations in their neurological function in terms of both motor and sensory modalities.

Clinical evaluation (Box 12.27.3)

History

The history should include the calculation of the ischaemic time, the nature and mechanism of the injury, and the presence of any contaminating agents. The patient's age, occupation, hobbies or sporting skills, and hand dominance should be noted. The status of the patient's tetanus prophylaxis should be checked. Any life-threatening medical comorbidities may make the decision to replant foolish.

Box 12.27.3 Clinical evaluation

- History/mechanism of injury/handedness
- Comorbidities
- Avoid unnecessary meddlesome examination of wound
- Hb/xmatch
- X-ray of amputated limb and injured limb.

Examination

The purpose of emergency examination is to evaluate the technical feasibility of restoring circulation and the potential for functional recovery so that an informed discussion with the patient can proceed prior to surgery. The amputated part will reveal the type of injury and its level. By deduction the proximal stump(s) should mirror the pattern of the distal segment, so that it is generally possible to avoid painful unwrapping of the proximal wound. In the more complex major limb and multiple-injury categories, it is important to exclude more proximal multiple-level injury, extensive tissue loss and particularly brachial plexus injury. Even in these situations it is evident that some form of surgery is inevitable, so that meddlesome explorations prior to anaesthesia should be avoided.

Consent

Problems often do not appear until intraoperatively and therefore preoperative consent should be as broad as possible and include grafts of veins, skin, nerve, and bone as well as local and free flaps.

Specific investigations

Most amputations have undergone some haemorrhage and therefore a haemoglobin/hematocrit and a blood group cross match should be performed routinely. Plain radiographs of both the injured limb and the amputated parts should be obtained and should demonstrate the joint proximal to the injury.

Management (Boxes 12.27.4 and 12.27.5)

Preoperative principles

Management of the patient

Although most amputations are isolated injuries the emergency management of the patient should be along trauma guidelines. As there are no absolute indications for replantation, other life-threatening injuries take priority. The patient should be adequately stabilized and resuscitated. There are numerous reports in the literature of digital replants being done hours or days later when the patient is stable.

Box 12.27.4 Management 1

- Stabilize and resuscitate
Store amputated part cool and moist
- Haemorrhage control with compression
- Two-team approach to surgery
- General anaesthesia favoured.

### Box 12.27.5 Management 2

- Debride
- Tag structures
- Bone shortening essential
- Repair extensor tendons
- Venous anastomoses first
- Then volar repair.

#### Amputated part

Preparation of the amputated part in a saline-soaked sterile gauze, placed in a sealed plastic bag, and packed in an ice-water slurry should be done immediately. Despite intensive research, no perfusate has been shown to be convincingly beneficial in cytoprotection of limb tissue.

#### Proximal limb stump

Haemorrhage can mostly be arrested by a compression bandage, with a tourniquet only used as a last resort. In cases of incomplete amputation with devascularization, the appendage should be splinted in an anatomical position to maximize any residual circulation.

#### Digital replantation

##### Operative principles

Ideally replantation should be performed as soon as possible by a two-team approach, with one operating on the amputated part and the other on the stump. Much time can be wasted unless a disciplined sequence of repair is followed shown in Table 12.27.1

##### Anaesthetic requirements

General anaesthesia is favoured but if time permits an axillary block and catheter may be performed preoperatively which has the dual advantage of assisting with vasodilation due to a sympathetic blockade and providing postoperative analgesia. Although there is now evolving data in the anaesthetic literature that regional anaesthesia may cause a steal phenomenon to an already sympathectomized digit or free flap and may be counterproductive. Distal replants (Type 0) may be done under local anaesthesia only.
Elements of the anaesthesia are vital to optimize success and unfortunately replantations often occur after hours when experienced anaesthetists may not be available. It is incumbent upon the surgeon to ensure perfusion requirements to the digit are achieved. This includes a gentle induction and extubation, maintenance of a core body temperature of 37°C, a urine output of 1mL/kg/h, avoidance of vasopressors and diuretics, normovolaemia, and a haemoglobin of approximately 10. In our experience packed red blood cells followed by concentrated albumin are the best colloids to maintain intravascular volume, and with the use of depth of anaesthesia brainwave monitors, often volatile anaesthetic gases can be reduced with a subsequent improvement in systemic blood pressure.

Evaluation and exposure

Contaminating foreign material should be removed and conservative debridement of damaged tissue carried out. All vital structures should be systematically identified and tagged. Proximal damage and retraction of the digital artery and/or nerves will mandate a skin incision for exposure. A Bruner type incision is preferable, so that flap closure is possible over the microvascular anastomosis even if the incision itself cannot be fully closed because of swelling. The ends of the flexor tendons are located and a core suture is inserted into each.

Skeletal shortening and fixation

Bone shortening is an essential and frequently underrated initial step in replantation. Guillotine injuries and distal replants are the exception to the rule. The prime reasons for shortening are to allow good quality tension-free wound closure for primary healing, extensor tendon apposition, and nerve approximation. Although skeletal shortening does assist in vascular end to end repair, this is the least valid reason and in fact can lure the operator into inadequate resection of damaged vessels. In cases of disarticulation where shortening is not possible this may necessitate vein graft lengthening.

Rigid fixation to allow early movement is a vital operative step and the most difficult to achieve. Too often the functional benefit of successful revascularization is reduced by malunion although non-union is unusual. The dilemma resides in the balance between rigid low-profile plate fixation with its ensuing widespread periosteal stripping and the less invasive pin fixation favouring maximization of vascularity to the fracture but a consequent decrease in rigidity. Properly placed crossed K-wires carry a number of significant advantages as a method of skeletal fixation in replantation providing stable but not rigid fixation, minimal periosteal stripping and easy removal (Figure 12.27.3).

Dorsal repair

The extensor tendon, including the lateral bands and intrinsics, should be repaired with a continuous running technique. It is preferable to perform the venous anastomoses prior to the arteries to avoid unnecessary and prolonged bleeding if the reverse sequence is followed. In distal replants, some severe crush injuries and those with prolonged ischaemia where revascularization is doubtful then it is advisable to perform the arterial repair first. The dorsal digital veins are usually easily located in the subcutaneous tissue by the presence of small blood clots and the location of the veins on the distal amputation stump will mirror their position on the proximal stump. Occasionally adequate sized veins can be seen on the volar aspect. Radical resection is rarely necessary so direct anastomosis is common. The dorsal skin is closed cautiously over the venous anastomoses. Inadequate skin closure due to insufficient bone shortening or degloving risks venous exposure, desiccation, infection, secondary haemorrhage and late thrombosis after 4–5 days.

Volar repair
After periosteal repair the flexor tendons should be repaired by tying the core sutures previously placed and in so doing restoring the natural posture of the finger thus reducing tension on the neurovascular repairs. Digital arteries are identified by their constant dorsal relationship to the nerves in the fingers. Towards their termination in the distal phalanx they converge towards the midline to form an arcade with often a single midline artery deeply placed on the bone. The proximal vessels must be resected until pulsatile flow is encountered. If the vessel spasms, manoeuvres to restore flow include distraction of the vessel to its physiological length, a bolus of intravenous heparin, dependency of the limb, topical antispasmodics, and warm saline irrigation. Experience dictates an adequate distal artery seen under the microscope. Vein grafts should be harvested from the flexor aspect of the forearm and should be placed under mild tension in order to avoid redundancy. Where access is difficult, it is helpful to anastomose the distal end of the vein graft into the amputated part prior to skeletal fixation. Increased survival is directly proportional to the number of anastomosed vessels.

If no useful arteries and/or veins can be located for revascularization, afferent arteriovenous anastomosis may provide adequate perfusion or efferent arteriovenous anastomosis may provide outflow.

Both digital nerves should be repaired using an epineural suture technique. The medial cutaneous nerve of the forearm, the posterior interosseous nerve, or an interpositional vein graft are convenient donor sites if no rejected amputation segments are available. Skin closure should be tension free and designed so that vascular pedicles are covered. This may necessitate flap transpositions with skin grafts to the secondary defects (Figure 12.27.4). Circumferential dressings should be avoided when placing a volar plaster.

Major limb replantation (Box 12.27.6)

The capacity of replanted tissues to develop sensory reinnervation gives limb replantation a unique advantage over any contemporary prosthesis. The mixed nature of the proximal nerves involved, the large bulk of muscle, the local tissue destruction, and sometimes the avulsive mechanism of injury all weigh heavily against an ideal outcome. Larger vessels make vascular repair relatively simple, but permissible ischaemia times are severely reduced. The prognosis for significant recovery following repaired brachial plexus or proximal peripheral nerve injuries, even in ideal circumstances, is poor. In general, above-elbow replantations are contraindicated except in children. Double-level injuries, especially an associated brachial plexus avulsion are a contraindication.

In the lower limb the replanted foot or leg is likely to remain insensate and will cause difficulties for the patient during ambulation and with footwear. Patients tolerate below-knee prostheses well and rehabilitate rapidly. Therefore, except in children, replantation of lower limbs should be reserved for incomplete amputations where the posterior tibial nerve is in continuity.

Operative principles

There are several principles in major limb replantation that are not pertinent to the replantation of digits. Major limb replantation is a true surgical emergency. Contrary to traditional earlier credos, all major limb replantations should be revascularized prior to any bony fixation or other soft tissue repair. Temporary endarterectomy shunts can be used to rapidly restore arterial and venous
continuity. Venous repair should always be delayed to allow toxins in the venous effluent to dissipate prior to reconnection into the circulation. Intraoperative cooling is also important in these large-muscle-containing parts.

**Musculoskeletal repair**

The objectives of bone shortening in major limb replantation are different from those in digital replantation. The priority is the permission of end-to-end nerve and musculotendinous repair and this may necessitate quite radical resections of 10cm or more. Fixation depends on level and site of the fracture and should be performed along AO guidelines. Despite the shortening, free flaps are frequently necessary to obtain wound closure.

Musculotendinous divisions are repaired in the same way as injuries in a non-replant situation. Side to side tenorrhaphies, secondary tendon transfers, or even secondary free muscle transplants may be indicated.

**Neurovascular anastomoses**

Adherence to microvascular technical principles is important. Only those vessels with demonstrable flow should be anastomosed. Grafts will almost always be necessary for arterial reconstruction. Because of high flow rates and high pressure demands over many years, the long-term fate of vein grafts in these sites is uncertain and consideration may be given to primary arterial grafts, for example from the thoracodorsal or opposite radial artery.

**Reperfusion**

If any doubt exists about the compartment pressures, prophylactic fasciotomies should be performed. These may include the interossei and a carpal tunnel release in the hand. Systemic reperfusion toxicity and myoglobinuria are theoretical grave risks after revascularization and are proportionate to the length of ischaemia of the part.

**Postoperative principles (Box 12.27.7)**

The patient should be kept warm, well hydrated, and comfortable with the limb elevated on pillows. Broad-spectrum systemic antibiotics are indicated for prophylaxis. Smoking is totally prohibited given its proven association with vascular spasm and increased risk of thrombosis. Visible access to the region of the amputation site is particularly important to detect early signs of local necrosis, sepsis, or vessel exposure. Given the propensity for myonecrosis in major replants it may be prudent to perform a ‘second-look’ operation after 24–48h in order to ascertain muscle viability.

**Monitoring**

Monitoring of capillary return, colour, and temperature should be hourly for the first 24h and every 2h for the next 24h. Healthy revascularized tissue should have a capillary return of 2s. Venous congestion is detected by a violet-blue colour and a rapid capillary return. When pricked the part will bleed briskly with dark blue blood. Absolute arterial obstruction is obvious. The digit is pale white and cold with no capillary return, the pulp is empty, and there is absence of bleeding on needle puncture. Partial arterial insufficiency is more difficult to recognize and may be misinterpreted as a venous problem. In this situation the finger may appear blue; however, the capillary return will be very slow or absent, and bleeding on needle puncture will be either absent or a delayed slow ooze of dark blue deoxygenated blood.

**Anticoagulation**

The paucity of human studies and conflicting animal studies make decisions regarding anticoagulation arbitrary. Anticoagulation regimens differ from centre to centre and range from no anticoagulation to full therapeutic heparinization varying on a case by case basis. We have experienced numerous cases of digital replantation that have clearly been salvaged by heparin. It is particularly valuable as a static dose intraoperatively in cases where reperfusion is protracted.

**Mobilization**

The goal of early active movement of replanted fingers, although theoretically tempting, is difficult in practice because of repairs on both extensor and flexor surfaces. Complete immobilization for approximately 3 weeks is the best option in most cases.

**Box 12.27.7 Postoperative principles**

- Keep patient warm
- Visible access
- Second look 24–48h
- Monitor vascularity
- Heparin may be used
- Immobilize for 3 weeks.
(A) and (B) Attaining a good functional result in devastating hand injuries requires surgical skill and expertise, and a hint of luck. (C) Postoperative result of 3 finger replantation – even minimal function is beneficial to the patient.

Results

Digital replantation

Adults

Results in the literature are numerous and relatively consistent

Based on a meta-analysis the following results can be expected.

Survival of replants

- Overall: 85%
- Guillotine: 90%
- Avulsion: 65%

Functional results

- Bone: non-union is uncommon
- Nerves:
  - Two-point discrimination, 2mm to >20mm
  - Average, 9mm
  - More distal replants have superior two-point discrimination
- Vasomotor:
  - Incidence of cold intolerance is dependent on climatic conditions
  - Is due to the injury and not the replantation
  - Partial improvement occurs over years
- Subjective:
  - Overall 80% have subjective benefit
  - Older patients have lower satisfaction rates
- Rehabilitation: except for distal-tip replants, at least 4 months can be expected to elapse Before return to work.

Children

Results of digital replantations can be summarized as follows.

Survival

- Overall 70%.

Functional results
Nerves:
- Average two-point discrimination, 5mm
- Normal sensation with one nerve repair only

Motion:
- 25% have a totally normal movement
- The majority of the remainder have functionally useful digits

Growth:
- Depends on presence or absence of epiphyseal injury
- Nearly all show growth commensurate with the child.

Major replantation
A number of reports of major replantation have been published. In an eloquent analysis the functional results of major replantation were superior to prosthetic reconstruction.

Complications (Box 12.27.8)

Arterial insufficiency
Arterial insufficiency requires prompt return to the operating room and results from inadequate shortening of damaged vessels thus revision is usually with vein grafts. If revision is unlikely to be successful, full systemic heparinization, warming, and placing the hand below heart level may be beneficial, but expectations should be guarded. Late vascular occlusion is rare but may occur in proximal amputation due to intimal hyperplasia.

Venous insufficiency
This is rapidly lethal and early detection is vital for salvage. Relative congestion may be relieved by elevation above heart level, but if this is not successful then exploration and revision should be undertaken. If this is not possible then either medicinal or ‘chemical’ leeching may be used.

Medicinal leech (*Hirudo medicinalis*)
Leech bleeding is due to release of hirudin which is a potent anticoagulant. Leeches should be applied as required when the digit takes on a bluish hue. Tetracycline or ceftriaxone should be administered to prevent *Aeromonas hydrophila* infection which is resident in the gut of *H. medicinalis*.

Chemical leech
This technique involves making a chevron-shaped pulp incision and the injection of 500IU heparin into the subcutaneous tissue. Regular milking (every 30min) is required to ensure continued bleeding. Injections need to be repeated several times daily.

Infection
Despite the insalubrious manner in which many amputations occur, frank wound or bone infection is surprisingly rare. Haematoma and necrotic skin margins are the harbingers of infection which will threaten vascular patency. Thrombosis occurring after 4–5 days is ominously infective in origin and is generally unsalvageable, highlighting the essential need to obtain primary healing of skin. Early intervention with flap coverage is the only hope.

Late complications
Non-union, malunion, stiffness, and tendon rupture
It is very important to make detailed notes of any variation in neurovascular anatomy that has been created by the initial surgery to minimize risk during essential secondary surgery. Revision surgery on replanted parts is the most technically challenging of all hand surgery and may be threatening to the survival of the part. Arthrolyses and tenolyses are frequently unrewarding. Therefore it is essential to perform optimal repairs at the time of the initial operation, even to the extent of primary nerve grafting if gaps are present. Silicone joints and tendon rods may also be considered to avoid reoperation through the replanted area, even though this risks infection.

Box 12.27.8 Complications
- Arterial insufficiency
- Leeching can be used for venous insufficiency
- Infection rare
- Arthrolysis tenolysis for stiffness
- Cold intolerance.
Cold intolerance

The incidence of cold intolerance is initially high but improves with time. In our practice only a very small number of patients have sought reamputation although it has been a major problem in colder climates. It is highly likely to be due to the injury and not the amputation per se.

Opportunism

In replantation opportunity strikes but once and it is of little use to realize later that some part of a non-replantable limb could have been used for an imaginative reconstruction. The durable sensate weight-bearing skin from the sole of the foot is ideal for resurfacing denuded upper tibial skeletal structures (Figure 12.27.6) and thereby avoiding above-knee amputations.

Future developments

The ultimate dream for the replantationist is the transfer of human limb allografts. Surgical enthusiasm is currently in a state of flux following recent events. The first transplant was rapidly rejected. A more recent French attempt led to a second wave of hand transplants around the world.

There is precise documentation of the outcomes of at least 25 cases over several years. Most have had complications from the immunosuppression including transient rejection episodes, diabetes, and avascular necrosis of the hip; however, this has necessitated only two secondary amputations. The spectacular functional results from bilateral cases as well as a face transplant have tempered the chorus of objections from early hardliners. The achievement of lymphohaematopoietic chimeraism is the Holy Grail as it will allow composite tissue transplantation without the inherent risks of immunosuppression.

In the longer term xenotransplantation of joints, muscles, tendons, and nerves from transgenic pigs may have a role in secondary reconstruction.

Further reading

## Summary points

- Proximal phalanx unicondylar and spiral fractures most unstable
- If axially stable can be considered for non-operative treatment
- Kirschner wires offer stability without excessive soft tissue dissection
- Ring and little finger metacarpal flexion deformity is well tolerated, but this is not the case for the radial metacarpals
- Displaced proximal and middle phalanx fractures are a common cause of stiffness
- Displaced condylar fractures are usually best reduced and fixed.

## Incidence

Metacarpal and phalangeal fractures have a combined incidence of approximately 380 per 100,000 per year and are most common in 10- to 39-year-old males. They are frequently caused by sporting injuries or fights. Little finger metacarpal fractures account for 30% of all metacarpal and phalangeal fractures.

## Classification

There are a variety of classifications systems which describe the site and pattern of the fracture, all of which have advantages and disadvantages. Whatever classification system is used it is important to classify fractures according to their stability.

Stable fractures are those which present in acceptable alignment and will not displace into unacceptable alignment if the hand is left free and mobilized. Thus most undisplaced fractures and most displaced little finger metacarpal neck fractures are stable.

There are two subtypes of unstable fractures. The first includes fractures which present in acceptable alignment though are at risk of displacing into unacceptable alignment if mobilized. Undisplaced unicondylar and spiral fractures of the proximal phalanx are examples of this type. The second subtype includes all displaced fractures which present in unacceptable alignment and require reduction, after which they must be stabilized (splinted or internally fixed) in order to prevent redisplacement. Virtually all displaced fractures which need to be reduced are unstable, and for these it is also important to consider their likely axial stability after fracture reduction.

Axial stability describes a fracture’s ability to oppose the constant tension in the digit’s flexor and extensor tendons which attempt to shorten the fracture: transverse fractures have good axial stability while long oblique fractures have poor axial stability. The axial stability of a fracture, once reduced, is one factor which determines its suitability for non-operative treatment. Fracture stability should be viewed as a spectrum with absolute stability (undisplaced transverse third metacarpal fracture) at one extreme and absolute instability (severely comminuted open proximal phalangeal fracture with bone loss) at the other.

## Clinical evaluation

### History

The patient as well as the fracture must be assessed. Hand dominance, employment, and recreational activities, as well as ability to comply with the proposed treatment, must all be considered.

The mechanism and time of injury should always be ascertained. Twisting injuries are likely to cause fractures with rotational deformity and fifth metacarpal neck fractures are much more serious if there is a dorsal wound which was caused by a tooth (punching someone in the face). For open fractures it is important to determine the environment in which the injury was sustained (farmyard or clean environment).

### Physical examination

The whole hand must be examined for swelling and bony tenderness so as not to miss multiple injuries (Figure 12.28.1), and skin sensation and perfusion distal to the fracture should also be examined, especially in crush injuries. Alignment should be carefully assessed though significant amounts of radial/ulnar and dorsal/palmar angulation can be masked by soft tissue swelling. It is of utmost importance to look for rotational deformities as these are poorly tolerated in the fingers and usually indiscernible on radiographs. Although obvious if the patient can make a fist, most with fresh fractures cannot and rotational deformity is best assessed by examining the alignment of the fingernails with the fingers extended (Figure 12.28.2).
This man punched a wall and sustained a little finger metacarpal neck fracture. Examination also revealed marked tenderness over the little finger carpometacarpal joint. There is no visible little finger carpometacarpal joint space on the posteroanterior radiograph, which suggests an injury, but this could easily have been missed but for the clinical findings. Further radiographs showed an impacted fracture–subluxation of the carpometacarpal joint.

The ring fingernail lies in a different plane to the other fingernails indicating a rotational deformity.

**Investigations**

**Radiographs**

Radiographs should be considered as a continuation of the clinical evaluation. Rather than simply requesting radiographs of the injured finger (or worse still the injured hand) one should request radiographs centred on the area of clinical tenderness where the fracture is suspected. The standard radiographic views for individual fingers are posteroanterior and lateral. Posteroanterior oblique views should also be obtained for finger metacarpal and proximal phalangeal fractures as dorsal angulation is frequently masked on the lateral view by the adjacent digits (Figure 12.28.3).
Fig. 12.28.3
A) Posteroanterior, B) oblique, and C) lateral views of fractures of the bases of the ring and little finger proximal phalanges. The fracture displacement is difficult to assess on the lateral view. The fingers are not superimposed on the oblique view which shows the dorsal angulation of the ring finger fracture.

Anteroposterior and lateral views in the plane of the thumb (Gedda views) are usually sufficient for thumb fractures. Computed tomography (CT) scans, and other complex imaging techniques are rarely required.

Management

Initial management

If a closed fracture requires operative treatment or a manipulation and this cannot be performed immediately, the fracture should be temporarily splinted for pain relief. Patients with open fractures should always receive antibiotics and, if necessary, tetanus immunization.

All hand fractures should be screened by a surgeon with an interest in hand fractures. Such a policy reduces the prevalence of unsatisfactory results and prevents overtreatment of simple fractures, which in itself can cause stiffness and generate poor results.

Definitive management

The majority of fractures can be treated equally successfully with a variety of techniques. Both conservative management and operative fracture fixation can produce stunningly good results and humiliating failures. Although fracture factors such as alignment and stability are important determinants of treatment, consideration should also be given to the following.

1) The patient’s expectations of treatment and motivation: although some patients cannot tolerate any cosmetic deformity, many are prepared to accept considerable malunion, provided that normal function is restored. This is especially if acceptance of malunion allows an earlier return to work
2) Rehabilitation resources: aggressive operative fracture fixation should only be performed if appropriate therapy services are available
3) Technical difficulty: trainees and assistants must be shown treatment methods which they will be able to perform independently and safely in the future
4) Cost: do the potential benefits of operative treatment over conservative management justify the extra costs?

Extra-articular fractures (Box 12.28.1)

The treatment goal is union in an alignment which permits normal hand function and provides a cosmetic result which the patient finds satisfactory. Rotational deformity is unacceptable, particularly for metacarpal and proximal phalangeal fractures, and is a strong indication for operative fracture fixation. Metacarpal fractures can tolerate considerable shift and palmar angulation, and some radial/ulnar angulation without loss of function. Proximal phalangeal fractures are much less tolerant of malunion with acceptable limits of about 10 degrees of radial/ulnar angulation and 20 degrees of dorsal/palmar angulation.

Undisplaced and minimally displaced extra-articular fractures

The majority of undisplaced or minimally displaced fractures are stable and should be treated by early mobilization. For phalangeal fractures, this is usually achieved by buddy strapping (Figure 12.28.4) or a Bedford gaiter which holds the injured finger to an adjacent one so as to protect it from unexpected knocks. After 3 weeks most fractures are sufficiently sticky to discard all strapping. Alternatively, if the fracture is very painful or the hand is very swollen, stable fractures can be safely rested on a palmar slab in a comfortable position for 1 or 2 weeks and then mobilized once the pain and swelling have subsided. Stable fractures almost invariably achieve a good result.
However, minimally displaced spiral and long oblique fractures of the proximal and middle phalanges have little axial stability, are potentially unstable and may displace if mobilized (Figure 12.28.5). These fractures should be immobilized on a palmar slab or on an aluminum splint with the hand in the Edinburgh position for 3 weeks.

Displaced extra-articular fractures

The surgeon should assess the configuration of the fracture (transverse, oblique, etc.), so as to predict its axial stability following a closed reduction. If the reduced fracture has little or no axial stability (spiral and long oblique fractures) and accurate fracture alignment is vital, then the fracture should be treated operatively. If the fracture reduction has good axial stability (transverse and short oblique fractures) then the fracture may be treated non-operatively.

Conservative treatment methods

Unstable metacarpal fractures can be immobilized in plasters (Colles plaster, ulnar slab, or hand cast) which allow metacarpophalangeal and interphalangeal joint movement. Unstable proximal and middle phalangeal fractures require immobilization of the injured digit until the fracture becomes sticky (3 weeks). The position in which the injured hand is immobilized and the period of immobilization are of great importance. Fingers should be immobilized in the Edinburgh position (Figure 12.28.6), with the metacarpophalangeal joints flexed to at least 60 degrees and the interphalangeal joints virtually fully extended. In this position the collateral ligaments of these joints are taut and cannot shorten as a result of post-traumatic inflammation. Immobilization of fingers with the metacarpophalangeal joints extended and the interphalangeal joints flexed is a potent cause of interphalangeal joint flexion deformities and reduced metacarpophalangeal joint flexion. It is also a position in which most phalangeal fracture reductions are unstable and will redisplace.

Fractures treated conservatively should be followed up with weekly check radiographs to ensure that the splint does not slip and the fracture does not displace.

Although fracture union, as assessed by bridging callus on radiographs, takes many weeks to occur, firm clinical union is usually achieved after 3 weeks. It is thus rarely necessary to immobilize a finger fracture for longer than 4 weeks.

Operative treatment

Kirschner wires
These are widely used to stabilize fracture reductions and can be inserted following either a closed (percutaneous insertion) or open reduction. Two K-wires are usually used. Crossed K-wires can distract fractures and increase the risk of non-union (Figure 12.28.7).

![Crossed K-wires](Fig. 12.28.7)

Open fracture of the shaft of the proximal phalanx. This was treated with crossed K-wires which held the fracture in distraction and a non-union developed. The X-rays also show the track from another K-wire which was inserted and removed: this may also have contributed to the non-union by causing additional thermal injury.

The advantage of K-wires, especially if inserted percutaneously, is that they provide fracture stability without an extensive surgical exposure. However they may be difficult to insert and are provide relatively unstable fixation thus, if an extensive surgical exposure with peristomeal stripping is required to reduce a fracture, it is probably better to consider rigid internal fixation which allows early mobilization. Another disadvantage is that their tips inevitably protrude into the surrounding soft tissues and can cause irritation and pain, and interfere with rehabilitation. Furthermore, if their ends are left protruding through the skin, troublesome pin site infections can occur. Although these usually resolve once the K-wires have been removed, serious finger infections and osteomyelitis occasionally occur.

**Rigid internal fixation**

This is a demanding technique. Spiral and long oblique fractures can usually be fixed with lag screw fixation whereas transverse and short oblique fractures require plate fixation. The treatment aim of rigid internal fixation is to make an unstable fracture stable enough to allow early mobilization. Although the benefits of rigid internal fixation are obvious for some fracture types such as the unicodylar fracture of the proximal phalanx, it is uncertain for others whether internal fixation brings about an earlier return of useful function or a better end result than less invasive treatment methods. Tendon adhesions and joint contractures readily develop and the surgeon, therapist, and patient must all be motivated to ensure that the finger is actively mobilized within 1 week in order to prevent these complications. Deep infections following rigid internal fixation are only rarely seen in the hand.

**External fixation**

External fixation is not widely used for closed hand fractures though it is a useful technique for open fractures (Figure 12.28.8). It causes little soft tissue damage and usually provides sufficient stability to allow early fracture mobilization. There are numerous commercially available hand external fixators, and it is possible to manufacture one from Kirschner wires, the barrel of a syringe and bone cement. Pin site infections can cause troublesome deep infections. External fixators are usually removed after 3 or 4 weeks, once the fracture is sticky.
Dynamic traction

There are many dynamic traction devices, some of which are expensive and manufactured, while others are assembled out of K-wires by the surgeon during surgery. The principle aim of all these devices is to counteract the tension in the finger extensor and flexor tendons which will cause shortening of injuries without axial stability. This is achieved by applying a distraction force. Dynamic traction is commonly used for the treatment of complex intra-articular fractures of the base of the middle phalanx (Figure 12.28.9).

Specific extra-articular fractures

Extra-articular metacarpal fractures

Metacarpal base fractures of the thumb

Extra-articular fractures of the base of the thumb metacarpal displace into flexion. Provided that there is reasonable contact between the fracture surfaces, considerable deformity (up to a rather arbitrary 30 degrees) can be accepted without loss of thumb function. Most of these fractures are managed quite adequately in a scaphoid-type plaster for 3 weeks. However, if there is gross fracture displacement, comminution, or shortening, closed reduction and percutaneous K-wiring or open reduction and internal fixation (plate or K-wires) should be considered.

Finger metacarpal base and shaft fractures

These fractures, and all other metacarpal fractures, displace into palmar angulation and are most common in the ring and little finger rays. The intermetacarpal ligaments usually prevent rotational deformity though this can occur in all rays. It most commonly occurs with spiral fractures of the distal shaft of the little finger metacarpal.

Palmar angular malunion is well tolerated in the ring and little fingers which have mobile carpometacarpal joints and ‘metacarpalgia’ (synonymous with metatarsalgia) when gripping objects is most uncommon. However, it is more likely to occur following index and middle metacarpal fracture malunions as these rays do not have mobile carpometacarpal joints. Thus, although over 30 degrees of palmar angulation can be accepted in ring and little fingers without fear of significant functional disability, index and middle finger metacarpal shaft fractures with more than 30 degrees of angulation should be reduced. Although 30 degrees of palmar angular malunion of a ring or little finger metacarpal does not cause functional disability, it inevitably causes cosmetic deformity which is more prominent than that following metacarpal neck fracture malunion. For this reason the author usually offers to reduce and immobilize in plaster fractures with 30 degrees or more angular deformity. Fractures with less than 30 degrees of palmar angulation need not be reduced and should be treated conservatively, either by early mobilization or, if painful, by immobilization on a palmar slab for 3 weeks.

Treatment methods for fractures in unacceptable alignment include closed reduction and plaster immobilization (Figure 12.28.10) or percutaneous K-wiring, external fixation and open reduction and internal fixation with K-wires, screws, or plates. Although these fractures are easily reduced closed, it is difficult to maintain the reduction in plaster and redisplacement can occur, either during
plaster immobilization or after the plaster has been removed at 3 or 4 weeks. For this reason, operative fixation should be considered for all fractures with rotational deformity and those which have completely ‘stepped off’ and telescoped (causing shortening). Operative fixation should also be considered when the cosmetic result is important, though one is trading in a bony bump and a sunken knuckle for a scar. Percutaneous K-wiring can be performed by reducing the fracture and passing three transverse K-wires, two distal and one proximal to the fracture, across from the fractured metacarpal into the adjacent metacarpal. Alternatively, these fractures can be stabilized by one to three intramedullary K-wires which are inserted through a small cortical window in the metacarpal base or neck. This technique is particularly suitable for the little finger metacarpal but is not as easy as it may appear (Figure 12.28.11). Most patients rapidly regain hand function and, if the K-wires are buried in the metacarpal shaft, they rarely migrate and require removal.

Lag screws can be used to fix spiral metacarpal shaft fractures but, if open reduction and internal fixation is the chosen treatment option, plate fixation is usually required. If plates are used, early postoperative mobilization is essential so as to prevent adhesion formation.

It is not unusual for patients with little finger metacarpal shaft fractures which have been reduced and stabilized in plaster to default from clinic and remove their plasters. Although such fractures may unite in gross palmar angulation (up to 60 degrees) and the cosmetic appearance may be unsightly, function is good.

Finger metacarpal neck fractures

Little finger metacarpal neck fractures are usually self-inflicted in a fight and displace into palmar angulation. Although this angular deformity is readily reduced, it is virtually impossible to maintain the reduction with closed methods. Excellent functional results can be achieved within 3 weeks by ignoring the fracture displacement and mobilizing even the most severely displaced fracture. The patient should be warned that he will be left with a bony bump and a sunken knuckle and initially may have a
metacarpophalangeal and even a proximal interphalangeal joint extension lag. Operative fixation is reserved for fractures with complete step off or patients who cannot accept deformity. Metacarpophalangeal joint stiffness is not an infrequent complication of operative fixation, especially if blade plates are used.

Considerable palmar angulation can also be accepted in ring finger metacarpal neck fractures. However, index and middle finger metacarpal neck fractures must unite in reasonable alignment as these digits do not have mobile carpometacarpal joints which can extend and prevent the metacarpal head becoming prominent in the palm. Fortunately, metacarpal neck fractures in these rays are rare and they are usually only minimally displaced. Thus, most finger metacarpal neck fractures are treated conservatively.

Extra-articular phalangeal fractures

Extra-articular proximal and middle phalangeal fractures

Displaced fractures of the proximal and middle phalanges are a common cause of finger stiffness. This occurs either as a result of malunion or adhesion formation between the fracture and the flexor tendon or the extensor hood which enshrouds the dorsal and lateral surfaces of the proximal phalanx.

Proximal phalangeal fractures displace into dorsal angulation and are easily reduced by traction and flexion of the metacarpophalangeal joint. Fractures of the distal third of the middle phalanx also displace into dorsal angulation whereas proximal third fractures displace into palmar angulation. Middle phalanx fractures tolerate angular and rotational malunion better than fractures of the proximal phalanx.

Extra-articular fractures of the base of the proximal phalanx.

These displace into dorsal angulation which is frequently missed on radiographs as the fracture is obscured by the other fingers on the lateral view (Figure 12.28.5). Malunion with dorsal angulation disrupts the fine balance between the extensor mechanism and the flexor tendons, and may result in a boutonnière deformity. In addition, an apparent loss of metacarpophalangeal joint flexion may occur. These fractures usually have a transverse configuration though there may be considerable dorsal comminution, especially in the elderly.

They readily reduce with metacarpophalangeal joint flexion and the reduction can then be maintained in a well-fitting plaster cast or Zimmerman splint which holds the finger in the Edinburgh position. It is vital that the plaster/splint is checked and the fracture is radiographed weekly for 3 weeks, as the plaster/splint all too readily slips distally allowing metacarpophalangeal joint extension, fracture redisplacement, and proximal interphalangeal joint flexion (Figure 12.28.12). This is a potent combination for finger stiffness, and boutonnière deformities often develop. Because of these difficulties, some surgeons prefer to treat these fractures operatively, either with percutaneous K-wires, rigid internal or external fixation. A condylar blade plate provides good stability, but is uncompromising, very difficult to apply and may result in stiffness due to extensor tendon adhesions, especially if the patient is reluctant to move his or her finger postoperatively. It is not known whether any form of operative fixation produces better results than careful non-operative management.

Phalangeal shaft fractures.

The majority of displaced transverse and short oblique fractures of the phalanges can be treated satisfactorily by closed reduction and immobilization in the Edinburgh position for 3 weeks. Spiral fractures have no axial stability after reduction, tend to redisplace and are a common cause of rotational malunion. Long oblique fractures may produce a bone spike which blocks proximal interphalangeal joint flexion (Figure 12.28.7). These fractures may be treated satisfactorily by closed reduction and K-wire fixation (Figure 12.28.13), or open reduction and lag screw fixation (Figure 12.28.14) with similar outcomes (Horton et al., 2003). Percutaneous K-wiring under radiographic control is not as easy as it may appear as the phalangeal shaft cortices are thick. Lag screw fixation is readily complicated by proximal interphalangeal joint fixed flexion deformities which can cause cosmetic deformity and loss of function, but are not usually severe if appropriate rehabilitation is provided.
Phalangeal neck fractures.

Fractures of the neck of the proximal phalanx in adults are almost always transverse and can be treated non-operatively by closed reduction and immobilization in the Edinburgh position which is modified slightly to incorporate slight flexion of the proximal interphalangeal joint (Figure 12.28.15). However these injuries often occur in young children who have caught the finger in the hinge-side of a door and these cannot be safely managed non-operatively due to poor compliance and chubby small fingers. These injuries will not remodel as they are away from the growth plate. Closed reduction and percutaneous K-wire fixation which transfixes the proximal interphalangeal joint is recommended in this situation. If the child presents late (more than 1 week, then it may be impossible to manipulate the fracture back into normal alignments, but an open reduction can usually be avoided by inserting a green hypodermic needle into the fracture (introduced dorsally) and using this to lever the distal fragment back into place: the fracture can then be K-wired (Figure 12.28.16).

Fracture of the neck of the proximal phalanx. This was treated by closed reduction and placement in a dorsal splint which held the metacarpophalangeal joint flexed (60 degrees) and prevented full proximal interphalangeal joint extension. The interphalangeal joints could be flexed within this splint which was worn for 3 weeks.
Fracture of the neck of the proximal phalanx in a child who presented 1 week after injury. The fracture could still be levered back into position with a hypodermic needle which was inserted into the fracture.

Extra-articular distal phalangeal fractures

These can involve the tuft or the metaphysis. Tuft fractures are usually caused by crush injuries and often have associated painful subungual haematoma. These fractures should be treated conservatively though associated soft-tissue injuries (nailbed and skin lacerations) may require surgery and painful subungual haematoma should be drained. They are best treated by early mobilization but can be splinted for 1 or 2 weeks if very painful.

Metaphyseal fractures also usually occur following crush injuries and again overlying nailbed injuries are common. If undisplaced, these fractures should be treated by early mobilization. If displaced, these fractures should be reduced in order to prevent cosmetic deformity and abnormal nail growth, and reduce the risk of non union (Figure 12.28.17). The reduction can usually be maintained by a dorsal or palmar splint though some prefer percutaneous K-wires.

Intra-articular fractures

Joint stiffness, joint instability, and post-traumatic osteoarthritis are specific complications of intra-articular fractures. These complications, as well as fracture alignment and stability, should always be considered when planning the treatment of intra-articular fractures. Furthermore, the likely outcomes of non-operative treatment (early mobilization or splintage) and operative fixation should be compared and the feasibility of worthwhile fracture fixation should be assessed.

Box 12.28.1 Non-articular fractures—general principles

- Beware of rotational deformity
- A malunion following conservative management is usually easier to treat than a stiff joint after operative fixation
- Metacarpals angulate palmarly; proximal phalanges angulate dorsally
- Metacarpals are more tolerant of deformity than phalanges
- The ring and little metacarpals are more tolerant of deformity than the index and middle metacarpals.

As a general rule, the thumb and finger carpometacarpal, metacarpophalangeal, and distal interphalangeal joints tolerate articular...
incongruity reasonably well and rarely develop troublesome post-traumatic osteoarthritis or stiffness. In contrast, troublesome post-traumatic osteoarthritis and stiffness are well-recognized complications of some intra-articular fractures of the proximal interphalangeal joint.

**Trapeziometacarpal joint fractures**

Bennett’s fracture of the thumb metacarpal is a two-part fracture-dislocation of the trapeziometacarpal joint without significant articular comminution (Figure 12.28.18). The palmar metacarpal fragment retains its attachment to the strong ulnar ligament of the thumb trapeziometacarpal joint and thus joint stability is restored following fracture union in anatomic alignment. Although Bennett’s fractures are easily reduced thumb traction and abduction, the reduction is unstable and redisplacement often occurs if the fracture is treated conservatively in a Bennett’s plaster. Such malunion causes persistent stiffness, weakness and pain and these fractures are more reliably treated by closed reduction and percutaneous K-wiring. The K-wire(s) may either pass between the bases of the thumb and the index finger or across the trapeziometacarpal joint. The thumb should then be immobilized in a scaphoid plaster for 4–6 weeks, thus allowing fracture union in good alignment. Of thumbs treated in this manner 80% are painless at 6-year follow-up and few of the remaining 20% experience significant pain or disability. However, 50% have radiological post-traumatic arthritis.

**Click to view larger**

Fig. 12.28.18
A) Bennett’s fracture treated by B) closed reduction and percutaneous K-wiring.

For Bennett’s fractures with large palmar fragments, open reduction and lag screw fixation is not inappropriate, though care must be taken not to damage sensory branches of the radial nerve or the palmar cutaneous branch of the median nerve.

Intra-articular fractures of the base of the thumb metacarpal with articular comminution are more difficult to treat. If the articular congruity and fracture alignment are reasonable, cast immobilization for 3 weeks may be the best option. Displaced fractures with two main articular fragments (Rolando’s fracture) can be treated by open reduction and internal fixation with either K-wires or a T-plate. If there is a metaphyseal defect caused by cancellous bone impaction, this should be bone grafted. Operative fixation of these fractures is never simple and becomes technically much more demanding with increasing comminution. Ligamentotaxis using a small external fixator attached to the thumb and index metacarpal shafts is a worthwhile option for fractures with severe comminution.

Fractures of the base of the little finger metacarpal with carpometacarpal joint subluxation are similar to the Bennett’s fractures. The small radial fragment retains the strong intermetacarpal ligament attachment and the little finger metacarpal base displaces ulnarly or, more usually, dorsally. Axial traction on the little finger readily reduces these fractures, which can then be stabilized with percutaneous K-wires which is passed through the base of the little finger metacarpal, either into the hamate bone or the ring metacarpal base.

**Metacarpophalangeal joint fractures**

**Metacarpal head fractures**

These usually occur as a result of an axial force (punch) and are most common in the index finger. Unless there is a large articular step (not gap), these fractures can be treated by active early mobilization with good results. If there is considerable articular incongruity and a single large fracture fragment (usually a palmar fragment), open reduction and internal fixation is indicated. However, many of these fractures are comminuted and difficult to fix as the bone is thin and friable. For such fractures conservative management with early mobilization is probably prudent.

**Fractures of the base of the proximal phalanx**

Collateral ligament avulsion fractures from the bases of finger proximal phalanges usually involve less than one-third of the articular surface. Such fractures should be mobilized in buddy strapping without fear of subsequent joint instability as persistent symptoms are unusual. Displaced avulsion fractures with larger articular fragments (more than 30% of the articular surface) should be treated
by open reduction (palmar approach) and internal fixation, using either a K-wire or a lag screw.

Avulsion fractures of the thumb ulnar collateral ligament with less than 3mm of displacement can be satisfactorily treated by immobilization in a scaphoid-type plaster for 3 weeks. Avulsion fractures with greater displacement or marked rotation should be treated by open reduction and internal fixation, using a K-wire or a single lag screw if the fragment is sufficiently large (Figure 12.28.19). Avulsion fractures of the thumb radial collateral ligament are treated conservatively unless they involve a large portion of the articular surface. This rationale for treatment is based on the fact that ulnar collateral ligament stability is vital for pinch grip whereas radial collateral ligament stability is not critical to thumb function.

![Click to view larger](Fig. 12.28.19)

Displaced avulsion fractures of the ulnar collateral ligament of the thumb metacarpophalangeal joint. These can be treated by open reduction and lag screw or by K-wire fixation.

Proximal interphalangeal joint

Condylar fractures of the proximal phalanx

There is almost universal agreement that displaced unicondylar fractures of the proximal phalanx are best treated by open reduction and internal fixation. These fractures usually have no axial stability and, if treated conservatively, almost inevitably unite with shortening and palmar or dorsal displacement. This causes a radial/ulnar angulation when the finger is extended and a rotational deformity when it is flexed. The unicondylar fracture fragment is usually sufficiently large to permit open reduction and internal fixation with a 1.5-mm or smaller lag screw (Figure 12.28.20) which should be placed just proximal to the origin of the collateral ligament. Alternatively, these fractures may also be stabilized with one or two K-wires. Proximal interphalangeal joint movement is usually slightly diminished following unicondylar fracture fixation and a 10-degree fixed flexion deformity and an 80-degree arc of flexion are typical.

![Click to view larger](Fig. 12.28.20)

Displaced unicondylar fracture of the proximal phalanx of a finger. If this is not stabilized the fracture fragment may displace further in a proximal direction as the fracture configuration has little axial stability. If allowed to unite with displacement it will cause an angular deformity and stiffness of the proximal interphalangeal joint. Lag screw fixation is demanding but permits early mobilization.

Bicondylar fractures of the proximal phalanx require careful assessment. If the general alignment of the proximal interphalangeal joint is reasonable and there is no angular or rotational deformity, the position of the fracture can be accepted. The finger is then rested in the Edinburgh position for 3 weeks. Surprisingly good results can be achieved with this method though most surgeons now favour open reduction and internal fixation using multiple K-wires, lag screws, or even a condylar blade plate. The best treatment method varies from fracture to fracture and some loss of proximal interphalangeal joint movement is to be expected.

Intra-articular fractures of the base of the middle phalanx

These fractures can be classified as follows:

- Dorsal avulsion fractures of the central slip
Palmar lip fractures with or without dorsal subluxation of the proximal interphalangeal joint

Dorsal avulsion fractures

These are avulsion fractures of the central slip of the extensor mechanism and they often allow palmar dislocation of the proximal interphalangeal joint. If the fracture fragment is sufficiently large, open reduction and internal fixation may be performed, especially if the proximal interphalangeal joint is dislocated and the reduction is unstable. A 1.5-mm or smaller lag screw or a K-wire can be used though care must be taken not to split the fracture fragment as the dorsal cortex is thin and the fragments are small (Figure 12.28.21). Smaller fracture fragments are treated with good results by splinting the proximal interphalangeal joint in extension for 3 weeks. However, radiographs should always be obtained with the finger in the splint in order to ensure that the fracture fragment lies in reasonable alignment and the joint, if previously dislocated, remains congruent.

Palmar lip fractures

Small palmar avulsion fractures without associated proximal interphalangeal joint subluxation or dislocation are caused by hyperextension injuries. These are treated by early mobilization but the patient should be warned that the proximal interphalangeal joint may remain swollen and tender for many months. Full finger flexion will only be regained once the swelling has settled, and there may be a permanent fixed-flexion deformity of the proximal interphalangeal joint.

Larger palmar lip fractures of the base of the middle phalanx cause dorsal subluxation of the proximal interphalangeal joint and are often comminuted with impacted central articular fragments (Figure 12.28.22). These injuries are caused by axial compression forces and are frequently inflicted by cricket or basket balls. Their prognosis depends on patient motivation, the degree of fracture comminution, and the percentage of the articular surface which is damaged. The proximal interphalangeal joint readily reduces with traction and flexion and the injury is then stable, provided that extension of the proximal interphalangeal joint is restricted. This can be achieved with extension block splintage, percutaneous K-wiring, dynamic traction or external fixation of the proximal interphalangeal joint. Some surgeons favour open reduction and internal fixation of these fractures, particularly those with more than 50% involvement of the articular surface, but this is complex surgery which is not always successful. Extension block splints are worn for 4–6 weeks and the results for fractures involving less than 30% of the articular surface are usually good. This treatment method works well in motivated patients, but requires careful follow-up to ensure that the proximal interphalangeal joint does not resublux within the splint. Percutaneous K-wiring of the proximal interphalangeal joint in sufficient flexion to reduce the dorsal subluxation requires less patient cooperation. The K-wire is removed after 4 weeks and the finger is then actively mobilized, producing satisfactory outcomes. A few of these fracture–subluxations resublux after the K-wire, external fixator, or extension block splint is removed. All treatment methods usually produce a painless stable proximal interphalangeal joint which flexes to 90 degrees though has a 10–30 degrees fixed flexion deformity. The long-term results of non-operative treatment of these injuries are not as bad as may be anticipated and considerable joint remodelling can occur.
Distal interphalangeal joint fractures

Condylar fractures of the middle phalanx

These are treated in the same manner as those of the proximal phalanx.

Intra-articular fractures of the base of the distal phalanx

These can be classified as follows:

- Avulsion fractures of the flexor digitorum profundus insertion (covered in Chapter 12.22)
- Palmar lip fractures (avulsion fractures of the palmar plate)
- Avulsion fractures of the extensor expansion (mallet fractures)
- Other intra-articular fractures.

Palmar lip fractures

These may cause dorsal subluxation of the distal interphalangeal joint. Although large single fragments involving more than 30% of the articular surface can be treated by open reduction and internal fixation, the majority of these fractures have small fracture fragments and any associated joint subluxation can be reduced by splinting the distal interphalangeal joint in flexion for 4 weeks.

Mallet fractures

Mallet fractures can cause palmar subluxation of the distal interphalangeal joint (Figure 12.28.23). Their treatment is controversial but those with a fracture fragment which involves less than a third of the articular surface and no associated joint subluxation are reliably treated conservatively by splinting the distal interphalangeal joint in extension for 4–6 weeks. This is most easily achieved with a polyethylene Stack splint or thermoplastic which must be worn continuously. There is usually soreness at the fracture site for several months but this almost always resolves. Larger fracture fragments can also be successfully treated conservatively and some consider that this is also the treatment of choice for fractures with associated distal interphalangeal joint subluxation. Others consider that the presence of joint subluxation necessitates operative fixation, either with a lag screw or K-wires (Figure 12.28.24). Although there is a trend towards lag screw fixation of large fragment fractures, there is no evidence that this produces a better result than splintage, and the screw head is relatively bulky and the overlying skin is thin such that wound problems may occur. This is also discussed in Chapter 12.23.
This mallet fracture with palmar subluxation involved more than 50% of the articular surface but was treated conservatively. The patient complained of persistent discomfort though at 2-year follow-up did not consider this sufficiently severe to warrant surgery.

Mallet fracture causing palmar subluxation of the distal interphalangeal joint. It was treated closed by flexion of the joint and placement of a K-wire in the head of the middle phalanx such that it passed dorsal to the avulsion fracture fragment and prevented it from extending and migrating dorsally. The main fracture fragment was then reduced onto the avulsion fragment and it and the distal interphalangeal joint were transfixed with another K-wire.

**Other intra-articular fractures**

Most other intra-articular fractures of the distal phalanx are impacted and have small fragments. These should be treated conservatively with active mobilization as symptomatic post-traumatic osteoarthritis is unusual.

**Open fractures**

Open metacarpal and phalangeal fractures should be treated as other open fractures, with thorough soft tissue irrigation and debridement and fracture stabilization so that the damaged soft tissues can be inspected and gently mobilized. External fixation is particularly useful for these fractures.

**Multiple hand fractures**

Multiple fractures in unsatisfactory alignment are usually best treated by operative fixation, especially if there is more than one fracture in each ray or each ray contains a different type of fracture. This is because it is difficult to manipulate and maintain multiple fracture reductions with conservative methods.

**Box 12.28.2 Intra-articular fractures—general principles**

- Troublesome post-traumatic osteoarthritis and stiffness are most common at proximal interphalangeal joint
- Carpometacarpal, metacarpophalangeal, and distal interphalangeal joints tolerate articular incongruity well
- Bennett’s fractures and little finger carpometacarpal fracture-subluxations require reduction and pinning
- Unicondylar fractures of the proximal phalanx are treated with open reduction and internal fixation
- Beware of joint subluxation in palmar and dorsal lip fractures of the base of the middle phalanx.

**Metacarpal and phalangeal fractures in children**

These fractures heal more rapidly than their adult counterparts. Although dorsal/palmar angular malunion may improve with remodelling during growth if the fracture is in the midshaft or at the end of the bone containing the growth plate, radial/ulnar and rotational malunion do not improve with growth.

In general, paediatric hand fractures should be treated in a similar manner to adult fractures. However, most extra-articular fractures...
which require operative fixation can be managed with K-wires and plate fixation is rarely indicated.

**Complications**

The major complications of metacarpal and phalangeal fractures are as follows:

- Malunion (rotational or angular) causing loss of hand function
- Finger stiffness
- Post-traumatic osteoarthritis
- Non-union.

**Malunion**

If a rotational deformity is detected within 8 weeks of injury, it is usually possible to take the fracture down and internally fix it in satisfactory alignment with K-wires or a plate. However, this is difficult surgery and the patient should be warned of the risks of osteotomy non-union and finger stiffness. A safer option, which should be used for rotational deformities detected after 8 weeks, is to regain full finger movement, allow the fracture to unite, and then perform a rotational osteotomy, either through the base of the fractured bone or through the base of the finger’s metacarpal. The latter can be stabilized either with K-wires or a small plate, and is most unlikely to be complicated by finger stiffness.

Angular malunions which interfere with finger function are treated with a corrective osteotomy at the fracture site.

**Finger stiffness**

This can either be due to joint contracture or tendon adhesions and both can complicate either conservative treatment or operative fixation. Loss of finger extension, unless severe, usually causes little disability. Loss of finger flexion is much more disabling and can cause loss of dexterity and hand weakness, especially if it causes quadriga.

Stiffness due to joint contractures results in equal losses of active and passive movement. In stiffness due to tendon adhesions, the range of passive movement exceeds the range of active movement.

Joint contractures are difficult to treat but should initially be managed with physiotherapy and splintage. If this fails then surgical release of the contracted joint capsule and ligaments may be indicated, but the results of this surgery are unpredictable. In severe cases, the patient may be best managed with an amputation.

Tendon adhesions are also initially treated with vigorous physiotherapy. If they persist, a tenolysis should be performed once the fracture has firmly united. Postoperatively, the patient undergoes an intense course of physiotherapy.

**Post-traumatic osteoarthritis**

The treatment of this condition, if symptomatic, is no different from that of other types of osteoarthritis.

**Fracture non-union**

Fracture non-union is rare in metacarpal and phalangeal fractures, even though radiographic evidence of fracture union takes many weeks to develop. However, fractures which are treated operatively and fixed with distraction, frequently develop non-union. Non-union, if symptomatic, is treated by internal fixation and bone grafting.

**Further reading**

Summary points

♦ Commonest fracture in the wrist
♦ Immobilization and serial X-ray is no longer the preferred method of management – use MRI scan
♦ Trend towards more frequent fixation especially displaced proximal fractures
♦ Untreated non-union leads to arthritis and pain
♦ Non-unions treated with bone grafting +/- fixation.

Essentials

The scaphoid is the most commonly fractured carpal bone. The typical patient is a young male. The bone is largely articular and has a tenuous vascular supply to its proximal pole. The scaphoid geometry and orientation make it difficult to interpret on radiographs and fractures can be occult on plain films. The practice of immobilization followed by delayed radiographic examination is ineffective and inconvenient to the patient. Magnetic resonance imaging (MRI) offers a cost effective, early diagnostic alternative. Non-displaced waist fractures are effectively treated non-operatively but there is a trend towards operative fixation. Displaced fractures and proximal pole fractures are unstable and operative fixation is preferable in such cases.

Scaphoid non-union is diagnosed if healing has not occurred 6 months from injury. Presentation may frequently be late. Proximal fractures are more prone to non-union. The eventual outcome of untreated non-union is osteoarthritis and pain, although these may not occur for some time. The success of surgical treatment is dependent on the site of the non-union, the age of the non-union, and the presence of avascular changes in the proximal fragment. Standard treatment involves bone grafting with or without internal fixation. Vascularized bone grafts are gaining in popularity, particularly when bone grafting has already failed once and when avascular necrosis (AVN) is present.

A predictable pattern of degenerative change is seen following established scaphoid non-union (scaphoid non-union advanced collapse or SNAC). Several different options for surgical salvage of advanced degeneration are described.

Introduction

Scaphoid fractures tend to occur in young and active patients, many of who are uniquely dependent on the integrity of upper limb function for work and sport. The trauma specialist managing these injuries should be confident in their diagnosis, initial management and management of medium- and long-term complications.

Incidence

Not everyone with a scaphoid fracture will seek medical opinion and the true incidence is impossible to ascertain. The diagnosis is commonly made speculatively in patients presenting with wrist pain following an injury and the actual number of patients with scaphoid fracture is probably less than one might expect. For the average district general hospital serving about 250 000 people, the incidence is about 35 per year or fewer than one per week.

This said, the scaphoid is still by far the most commonly fractured (Box 12.29.1) carpal bone accounting for 60% of carpal fractures. In Bergen, Norway, the annual incidence is 4.3/10 000 people; 82% of scaphoid fractures occur in males, with a mean age of 25 years. The incidence for men is highest between the ages of 20–30 years and decreases rapidly after this age. Incidence for men is significantly higher than the corresponding rates for women up to 50 years of age, whereas over the age of 60 the rates for men and women are similar.

Box 12.29.1 Scaphoid fracture

♦ Most commonly fractured carpal bone
♦ More common in males (82%)
♦ Most common between age 20–30 years
♦ 70% occur at the waist, 20% at the distal pole, and 10% at the proximal pole.

In the United Kingdom, approximately 70% of scaphoid fractures occur at the waist, 20% at the distal pole, and 10% at the proximal pole. The fracture is rare in children and when present occurs most commonly in the distal pole.
Anatomy

The term scaphoid derives from the Greek word skaphe meaning boat. It is the only bone that bridges the two carpal rows and creates a mechanical linkage between them (Box 12.29.2). Conventionally the bone is divided into three basic regions—proximal pole, waist and distal pole.

Box 12.29.2 Anatomy

- Scaphoid largely covered with articular cartilage
- A helical, non-articular strip of bare bone forms the waist
- Feeding vessels enter the bone along the waist in the distal half
- Proximal pole blood supply is through intra-osseous retrograde flow
- Scaphoid bridges the proximal and distal carpal rows
- Scaphoid motion is complex.

Three of the six surfaces of the scaphoid are articular. The distal surface articulates with the trapezoid and trapezium, its medial surface with both capitate and lunate, and its proximal convexity articulates with a corresponding concave fossa on the distal radial surface, the scaphoid fossa. The waist represents a non-articular strip, devoid of articular hyaline cartilage, and macroscopically is seen as a roughened ridge of bare bone. It forms a helix winding from the proximal end of the dorsal surface, around the lateral surface and terminating at the base of the tubercle volarly (Figure 12.29.1).

Blood supply

The scaphoid waist has consistently been shown to be the site of multiple vascular foraminae, which serve as entry portals for feeding arteries. Obletz and Halbstein’s (1938) study of nearly 300 cadaveric specimens showed that the largest foraminae occur in the distal half of the bone. Thirteen per cent of scaphoids had no perforations in the proximal half of the bone and a further 20% had only a single foramen at or proximal to the waist (Figure 12.29.2).
The scaphoid waist is the site of multiple vascular foramina, which serve as entry portals for feeding arteries. Arterial foramina are seen here occurring at or distal to the scaphoid waist.

The major blood supply to the scaphoid arises variably from the radial artery and its superficial palmar branch, although additional anastomosis from the anterior interosseous artery is described. The main feeding vessels enter the bone along the waist. The distal portion of the scaphoid has reliable direct arterial inflow, whereas the proximal pole is supplied by intra-osseous retrograde flow. Fractures of the scaphoid waist can disrupt the tenuous flow to the proximal pole.

Ligaments

In bridging the proximal and distal carpal rows, the scaphoid spans both the lunate and capitate. Three important intrinsic ligaments secure it: the scapholunate ligament, the scaphotrapezial, and scaphocapitate ligaments. The most important of these is the scapholunate ligament connecting the proximal scaphoid pole to the adjacent lunate. The ligament prevents excessive scaphoid flexion and pronation, and lunate extension.

Wrist kinematics

The proximal carpal row (scaphoid, lunate, and triquetrum) has no direct musculotendinous insertion onto it. Its movement is determined by the shape of its articulations and ligamentous attachments.

The movement of the scaphoid is complex and varies between individuals. During normal wrist flexion–extension the scaphoid not only flexes and extends but also rotates around its longitudinal axis. In radioulnar deviation of the wrist the scaphoid moves in both the coronal and sagittal planes. With radial deviation, the scaphoid rotates in the coronal plane such that its proximal pole translates ulnarly, and in the sagittal plane it flexes. On ulnar deviation the scaphoid rotates in the coronal plane such that its proximal pole lies more radially, and in the sagittal plane it extends. The extent to which these motions occurs in radioulnar deviation differs between individuals. In some the scaphoid predominantly flexes and extends, whereas in others the coronal rotation is the principal movement (Figure 12.29.3).

Fracture

In the presence of an unstable waist fracture, the scaphoid proximal pole will have a tendency to extend through its strong ligamentous attachment to the adjacent lunate and the distal pole will have a tendency to flex. The deforming forces on a scaphoid fractured at its waist are thus directed to cause intra-scaphoid flexion, the so-called ‘humpback’ deformity. With loss of the linkage between proximal and distal carpal rows characteristic collapse of the midcarpal joint is seen (Figure 12.29.4).
In unstable fractures the distal pole of the scaphoid demonstrates relatively more movement than that seen in intact scaphoids whereas the proximal pole fragment becomes relatively fixed, and considerable motion can occur at the fracture site. This explains pseudarthrosis and cavitation seen with some non-unions and the pattern of secondary arthrosis seen with established non-unions, which is initially seen between the radial styloid and mobile distal scaphoid fragment.

**Mechanism of fracture**

The principle mechanism for scaphoid fracture is forceful wrist hyperextension, usually resulting from a fall onto the outstretched wrist. Less commonly a direct blow to the wrist may also cause fracture. In cadavers forceful dorsiflexion beyond 90 degrees results in carpal injuries and scaphoid fractures occur consistently if radial deviation is added. In this position the proximal scaphoid pole becomes locked between the distal radius and capitate, and the palmar ligaments supporting the proximal pole become taut adding further stabilization. The applied load at the distal pole thus generates bending forces within the scaphoid and failure occurs at the least supported portion, the waist.

**Classification**

Commonly, classification systems are based on the orientation of the fracture. Herbert and Fischer’s classification incorporates fracture stability as well as delayed unions and non-unions. Acute injuries are divided into stable and unstable types and subgrouped according to fracture location and associated perilunate injury (Figure 12.29.5).

Fracture morphology is more accurately assessed with computed tomography (CT) and MRI than on plain radiographs. CT is more...
Clinical features

The diagnosis of acute fracture of the scaphoid is suggested by the patient’s age, mechanism of injury, and initial signs and symptoms. Clinical signs of scaphoid injury include: tenderness in the anatomical snuffbox, tenderness over the scaphoid tubercle, and pain on longitudinal compression of the thumb. All three signs are 100% sensitive but lack specificity. The use of these three tests in combination improves specificity whilst still maintaining 100% sensitivity.

Clinical investigations

Due to its complex geometry and orientation, radiographs of the scaphoid are difficult to interpret (Box 12.29.3). A multitude of different radiographic views have been suggested for the scaphoid. Russe (1960) originally suggested four views (posteroanterior (PA), lateral and two oblique views taken in 15–20 degrees of supination and pronation respectively). Ziter (1973) popularized an ulna deviation view, which lengthens the scaphoid, and it is common to include this as a fifth view. The PA and pronation oblique are the most useful of the four Russe views in diagnosis of scaphoid fracture (Figure 12.29.6)

Box 12.29.3 Diagnosis

- Clinical signs lack specificity
- Up to 16% of fractures are occult on initial x-rays
- Repeat x-rays at 2 weeks are unreliable
- False positive results occur with bone scan
- MRI is sensitive and specific in fracture diagnosis
- MRI is cost effective in early definitive diagnosis following wrist injury.

Although the majority of fractures are diagnosed with certainty on initial radiographs, 16% of fractures may be imperceptible on initial radiographs, the so-called occult fracture. When faced with clinical findings consistent with a scaphoid fracture but having normal-appearing x-rays, the classic teaching has been to immobilize the wrist and repeat x-rays at 10 days, and even at 3 weeks if tenderness persists. However, this practice does not improve diagnostic accuracy and is inefficient in terms of the economic impact of unnecessary immobilization, need for repeat clinical review, numerous repeat x-rays, and potential time of work.

Other imaging techniques have been proposed for detection of the occult fracture. Isotope scanning, CT, and MRI have all been shown to be useful.

The sensitivity of isotope bone scan is 100%, and a negative bone scan excludes fracture. However, bone scans are not totally specific. False positive results for fracture occur in up to 25% of scans. It is possible that “bone bruising” is responsible for some positive bone scan results. Overtreatment of a significant proportion of patients occurs if based upon isotope bone scan results.

Diagnosis of fracture on CT relies on the presence of cortical or trabecula displacement at the site of injury and when no
displacement is present CT can fail to identify injury which can be seen on MRI and bone scan (Figure 12.29.7).

MRI scanning is gaining in popularity as the investigation of choice when occult fracture of the scaphoid is suspected (Figure 12.29.7). Sensitivity has been reported at 100% and it is more specific than bone scan and has greater interobserver agreement in cases of fracture. MRI may highlight other bony and soft tissue pathologies that may be the underlying cause of symptoms in the patient with wrist pain following injury. Brydie has reported the largest series to date of MRI applied in routine clinical practice in suspected scaphoid injury. One hundred and ninety-five consecutive cases referred from the Accident and Emergency department with normal scaphoid series radiographs underwent MRI scanning. Scaphoid fracture was demonstrated in 19%, and in a further 19% a fracture of the distal radius or another carpal bone, not visible on plain radiographs, was demonstrated. MRI was estimated to have changed subsequent management in 92% of cases.

From a financial perspective, early MRI and conventional clinical surveillance with repeat x-rays have roughly comparable health-care costs. However, MRI is likely, overall, to be more cost effective when productivity and income loss are considered. Earlier definitive diagnosis in cases of suspected scaphoid fracture can prevent unnecessary plaster immobilization and prevent extended time off work and thus reduce on economic losses.

**Treatment**

**Distal pole fractures (Box 12.29.4)**

The distal pole is well vascularized and fractures in this area have a high rate of union.

Distal pole fractures can be extra or intra-articular. Extra-articular, distal transverse fractures are usually included with other waist of scaphoid fractures. Intra-articular fractures have been classified by Prosser and colleagues. Two predominant patterns of injury are seen: avulsions and intra-articular impaction fractures.

Avulsion injuries are the most common and represent detachment of the radioscaphoid ligament distal insertion on the radiovolar tip of the tuberosity. Treatment consists of splintage during healing, and most will heal uneventfully.

Impaction fractures are subclassified according to whether the radial side, ulnar side or both sides of the distal articular surface are involved. Radial sided fractures are the most common, unite readily and have a good prognosis. Immobilization of distal pole fractures in a short arm cast for 3–6 weeks is recommended. The long-term prognosis of distal articular fractures needs investigation, and the role of open reduction and internal fixation in preventing degenerative change when significant intra-articular incongruity exists is not known.

**Box 12.29.4 Distal pole fractures**

- **Avulsion:**
  - Most common
  - Heal with splintage

- **Intra-articular:**
  - Impaction fractures
  - Usually heal with cast
  - Ulnar sided fractures have poorer prognosis

- Extra-articular (transverse): treat as for waist fractures.

**Scaphoid waist fractures (Box 12.29.5)**

**Stable, non-displaced fractures**

Union rates in excess of 90% and as high as 95% are reported with cast immobilization. Currently, there is no way of predicting which fractures will unite. Although controversial, internal fixation of non-displaced fractures is gaining in popularity, and will be discussed in the ‘Areas of uncertainty or controversy’ section.
Unstable fractures

Fractures where there is displacement of more than 1mm in any direction are considered unstable and require more aggressive treatment than non-displaced fractures. Cast treatment in this situation does not reliably immobilize the fracture, and when more than 1mm displacement is present, up to a 55% rate of non-union is seen with cast treatment alone.

Scaphoid fracture can occur as part of a major carpal injury, the so-called transscaphoid perilunar dislocation. The pathomechanics of such injuries is described as a sequence of injuries around the lunate resulting in differing degrees of perilunar instability. When associated with perilunar instability, scaphoid fractures should be internally fixed as part of the procedure to restore stability to the carpus.

Box 12.29.5 Scaphoid waist fracture

♦ Stable, non-displaced:
  • 90% will heal in a cast
  • Fixation is controversial
  • Performed open or percutaneously

♦ Unstable fractures:
  • >1mm of displacement
  • Displacement more readily assessed on CT
  • Non-union common
  • Treat with internal fixation.

Proximal pole fractures (Box 12.29.6)

Fractures involving the proximal pole of the scaphoid have a poorer prognosis. The retrograde blood flow and consequent precarious vascularity increase the risk of AVN. Consequently, prolonged healing times of up to 6 months have been associated with cast treatment, and non-union occurs more commonly than with fractures at other sites. Healing rates following non-union surgery on proximal pole fractures are particularly poor and this adds further weight to the importance of achieving initial union in acute fractures.

The factors outlined constitute reasonable indication for internal fixation of all proximal pole fractures. Rettig and Raskin had favourable results from fixation with a Herbert screw using the dorsal approach in 17 proximal pole fractures. None failed to unite, average time to union averaged 10 weeks and there were no cases of AVN seen at an average follow up of 37 months.

Casting techniques

Theoretical advantages for immobilizing the wrist in differing positions have been postulated, but the position does not significantly affect union rate. An extended immobilization position, as opposed to a flexed one, leads to less restriction of extension at 6-month follow-up. The practice of immobilizing the thumb is commonplace and may add some comfort for patients. However, immobilization of the thumb confers no additional benefit over Colles type casts in terms of union. In cadavers, forearm rotation causes movement at a scaphoid fracture site, with average peak displacements of 2.1mm during forearm rotation in a short-arm cast. Clinically union rates of long-arm versus short-arm casts show no convincing difference.

Box 12.29.6 Proximal pole fractures

♦ Poorer prognosis
♦ 30% non-union with cast treatment
♦ Prolonged healing times with cast treatment
♦ AVN common
♦ Treat with internal fixation using dorsal approach.

Duration of immobilization and the assessment of union

It has long been accepted that scaphoid fractures should be immobilized until union has occurred even though prolonged immobilization may be necessary. Cases have been quoted where cast immobilization of up to 60 weeks, were used before union could be diagnosed! This situation is unacceptable in today’s practice, but confidently diagnosing union continues to be a challenge.

Traditionally assessment of scaphoid union has relied upon clinical signs and serial plain radiographic examination. However,
tenderness over the scaphoid disappears early, even in fractures, which have not united. The term 'clinically united' has no meaning in the context of scaphoid fracture.

The scaphoid is mostly intra-articular, and no external callus is expected or seen with fracture healing on x-ray. Trabeculae crossing the fracture and sclerosis at the fracture line are said to indicate union. However, the shape, size and orientation of the scaphoid make it difficult to assess for these, and the appearance of trabeculae crossing the fracture may be artefactual. Radiographs taken 12 weeks after injury cannot be reliably and reproducibly used to assess union of a scaphoid fracture. Radiographs can only establish failure of union, and it is important that patients should be kept under review for a minimum of 6 months at which stage a non-union can confidently be ruled out on radiographs.

Prescribing the optimum duration of immobilization is a dilemma given that clinical and x-ray indicators of union, at or before 12 weeks, cannot be relied upon. Commonly, casting for an empirical 8 weeks is used for treating waist fractures. Extending immobilization to 12 weeks if union is doubtful at 8 weeks is acceptable, but casting should be dispensed with after 12 weeks.

CT scanning is increasingly being used to aid diagnosis of union in cases where doubt exists on plain radiographs. Continuity of trabeculae across the whole width of the bone constitutes union. One study described partial unions seen on CT scans performed at 12–18 weeks, where bridging trabeculae cross some areas of the fracture and gaps exist at other sites on coronal CT images. All 22 of the partially united fractures went on to fully unite without need of further immobilization (Box 12.29.7 and Figure 12.29.8).

Box 12.29.7 Assessment of union of scaphoid fracture

- Healing usually takes 8–12 weeks
- Clinical assessment unreliable
- X-rays not always reliable
- CT useful in doubtful cases.

Operative techniques

Method of fixation

Kirshner wires are a simple mode of fixation, but they provide less stable fixation than screws and protruding wires may cause damage to joint surfaces. Staples and plates have been described, but since fractures of the scaphoid are intra-articular, their application is limited. Standard screws have large heads, which cannot be buried and standard partially threaded screws may not be appropriately proportioned to allow compression.

Several different commercially available implants are now available, which have been specifically designed for scaphoid fixation. The original was the Herbert screw (1984), based on an original principle replacing the normal screw head with a second thread. The design allows for firm implant fixation in both proximal and distal fragments of the scaphoid and for the screw to be completely buried below the articular surface. The two threaded sections are proportioned specifically for the scaphoid, and by making the pitch of the thread at the tip of the screw greater than that of the thread replacing the head, compression is produced on screw insertion. (Figure 12.29.9).
### Box 12.29.8 Outcome of scaphoid fracture

- 20% still have some pain 2.5 years after fracture united
- Malunion:
  - May cause pain
  - Humpback deformity may limit wrist extension
  - May result in osteoarthritis
- Secondary osteoarthritis seen in 5%, 7 years after fracture united.

### Fig. 12.29.9
Scaphoid compression screw with two threaded portions, each with a different pitch. The difference in pitch between the leading thread (P2) and the trailing thread (P1) governs the rate of drawing together of the two fragments to produce compression.

Cannulated systems allow installation over a guide wire. They are easier to place and minimize exposure requirements. The Herbert-Whipple screw (Zimmer, Warsaw, IN) is a titanium device with variably pitched threads. The diameter of the non-threaded portion of the cannulated screw is larger than that of the original Herbert screw making it more resistant to bending loads.

### Prognosis (Box 12.29.8)

Union rates based on early radiographic evaluation of union at or before 12 weeks are unreliable. Studies, which have assessed for non-union at 6 months or a year, present more reliable estimates of union rate. For fractures of the waist of the scaphoid figures approaching 90% are realistic following cast treatment. For proximal pole fractures non-union occurs in up to a third of fractures treated non-operatively and for distal pole fractures this complication is rare.

Although, union is generally assumed to have a good outcome, injury to articular cartilage and altered carpal dynamics due to degrees of malunion, may result in persisting pain and secondary osteoarthritis following healing of a fracture. Persisting pain is reported by 20% of cases up to 2.5 years after fracture union. Radiographic evidence of secondary osteoarthritis is seen in 5% of wrists at a minimum follow-up of 7 years following healed fracture. The incidence of secondary degeneration is probably underestimated by plain x-rays and CT studies have suggested even greater frequencies (Box 12.29.9).

### Box 12.29.9 Algorithm for suspected scaphoid fracture management
Areas of uncertainty or controversy

With the development of less invasive methods of fixation and a proliferation of new fixation devices, there has been an increasing trend towards internal fixation of acute, non-displaced scaphoid fractures. Proponents of fixation techniques suggest that more reliable union rates, quicker time to union, accelerated rehabilitation, and earlier functional recovery, are prime advantages over cast treatment. Five randomized controlled trials have compared internal fixation with cast immobilization for non-displaced scaphoid fractures, three using percutaneous screw insertion and two an open technique. In the largest trial, non-unions, diagnosed on CT scan at 16 weeks, were reported in 10 out of 44 fractures treated non-operatively and were subsequently fixed surgically. No non-unions occurred with operative treatment. The other four trials failed to demonstrate a significant difference in union rate between the two groups. Two trials reported significantly faster times to radiographic union in operatively treated fractures, one trial reported no difference and in the remaining two, time to union was not reported. None of the authors showed significant differences in range of movement and grip strength beyond 1 year, but three did show earlier return of these parameters in operatively treated fractures. Return to work was reported as being significantly earlier with operative treatment in three of the trials, but in one no difference was found.

Common complications following operative treatment appear to be largely related to the wound and include sensitive and hypertrophic scar, wound infection and cutaneous nerve dysaesthesia. The incidence of these may be less with percutaneous techniques. CRPS occurs rarely and can complicate non-operative treatment as well. Although postoperative complications are generally minor, the need for meticulous surgical technique remains paramount. Failure of surgical technique resulting in wire, instrument or screw breakage, implant protrusion into adjacent joints and intraoperative injury to joints, nerves or tendons can result in disastrous outcomes.

The case for fixation of non-displaced fractures remains controversial. Given that the majority of these cases will heal in a cast, a policy of fixation risks over-treating many patients and exposes them to avoidable surgical complications. Potential benefits from fixation are related to reliable healing and earlier functional recovery. The later advantage is transient and functional outcome, in the medium and long term, is equivalent following operative and non-operative treatments. For young and active patients, the population in which scaphoid fractures tend to occur, these benefits may seem attractive, but in providing informed choice, this needs to be balanced appropriately against any added risk.

Author’s preferred treatment for non-displaced waist fractures

Where scaphoid fracture is suspected but not confirmed on initial good quality radiographs further clinical review is undertaken after 1–2 weeks, in which time most minor injuries will have settled. During this period the wrist need not be immobilized as long as the patient is told that the scaphoid may be fractured and they are given a clear explanation of the plan of action. The patient is asked to avoid undue wrist usage. If subsequent clinical examination still suggests fracture then MRI is performed so that a definitive diagnosis can be made.

When good quality radiographs (ideally scaphoid series consisting: PA; pronation and supination oblique; lateral and ulnar deviation views) show no evidence of displacement in all views the fracture can be treated accordingly as undisplaced. When doubt exists CT scan should be arranged.

In active patients with undisplaced waist fractures we offer operative fixation following the appropriate counselling on non-operative and operative interventions. If the patient chooses operative treatment percutaneous fixation is undertaken with a cannulated compression screw. We usually use a volar approach inserting the screw in a distal to proximal direction for waist fractures, and a dorsal approach inserting the screw from proximal to distal in more proximal fractures.

For patients with undisplaced waist fractures, who opt for non-operative treatment we adopt the “aggressive” conservative approach.
suggested by Dias. Patients are treated in a below elbow cast with the wrist in a functionally extended position and the thumb left free. The cast is removed after 6–8 weeks and scaphoid series radiographs repeated and compared to the initial series. If the fracture line can no longer be seen on views comparable to those in which diagnosis was made and the appearance on all views is satisfactory, the fracture is considered united. Immobilization is discontinued but the patient is warned of the possibility for non-union. Follow-up is arranged at 3 and 6 months with radiographic examination being performed at each visit to establish no change has occurred.

If doubt exists regarding union CT is performed. In cases where union or partial union is demonstrated by CT wrist immobilization is discontinued. Follow-up with radiographs should continue for a minimum of 6 months.

If CT demonstrates no union operative fixation is undertaken. In cases where there has been no collapse or cystic change and at operation no movement exists at the fracture site then bone grafting is not used and a percutaneous technique can be performed. Conversely, cancellous or corticocancellous graft is used in cases where collapse or cystic cavitation is present.

**Non-union**

A non-union exists when, given adequate time, the fracture has not united and healing activity has ceased, so that it will not unite without intervention. For the scaphoid, if non-union is defined as a persisting, clear gap at the fracture 1 year following injury, then the incidence of non-union following conservative treatment is 12.3% (Box 12.29.10).

**Box 12.29.10 Non-union**

- Persisting fracture gap at 6 months
- Males in their 20s
- 30% symptom free at time of diagnosis
- Eventually symptoms will develop, although this may be decades later
- Secondary osteoarthritis rare before 4 years
- Secondary osteoarthritis inevitable in all patients.

**Clinical presentation**

The typical patient is male and in their twenties. Presentation may occur in four different ways:

1) Patients treated and followed up adequately in whom non-union occurs
2) Patients treated but followed up inadequately. The patient is discharged prematurely in the belief that the fracture has united, and represents with a non-union
3) Patients who were never treated because the diagnosis was not made following injury. They present later with symptomatic non-union, often after a further injury
4) Patients in whom scaphoid non-union is an incidental finding when examination is undertaken for another reason.

**Clinical features**

Not all non-unions are initially symptomatic. At time of diagnosis up to 30% are free of symptoms. Left untreated, symptoms eventually develop in almost all patients, although this may not be for several decades after injury.

Clinical examination usually reveals tenderness over the scaphoid, although this is not specific for non-union. Stressing the scaphoid as described by Watson, by preventing the bone flexing in wrist radial deviation, may cause pain, but again is not specific for non-union. A loss of wrist movement is usually present, and loss of 25% or more is predictive of non-union.

**Investigation**

Diagnosis is usually made with radiographs. A clear gap at the fracture site at 6 months denotes non-union. Not uncommonly, at 6 months a fracture line is still visible, though partially consolidated. Such fractures can be classified as ‘probably united’ and in such cases CT is useful in confirming union (Figure 12.29.10).
Scaphoid non-union: A) PA radiograph demonstrating a clear fracture gap and cavitation; B) sagittal CT scan demonstrating collapse, cyst formation.

Natural history

Osteoarthritis is the inevitable consequence of non-union. Although, radiographically arthritis is rarely seen before 4 years it is present in all patients with symptomatic non-union at an average of 8 years following injury. Even in the absence of symptoms from a non-union the natural history appears to be the same, and osteoarthritis will occur regardless of the patient being asymptomatic.

Treatment

The population that scaphoid non-union affects tends to be the young and active. If left untreated pain and osteoarthritis are the probable consequences. Therefore, non-union surgery is indicated in both symptomatic and non-symptomatic cases. A careful assessment for osteoarthritic change should be made, especially when the presentation is delayed. When significant arthritis is present, dealing with the non-union alone is no longer appropriate and salvage procedures are considered depending on symptoms.

The objectives of non-union surgery are:

- To achieve union of the fracture
- To decrease the incidence of osteoarthritis
- To abolish symptoms
- To improve function.

Surgery for non-union (Box 12.29.11)

Scaphoid non-union is treated by bone grafting with or without internal fixation. The standard exposure to the distal two-thirds of the scaphoid is through a volar approach. Dorsal approaches are utilized for proximal pole exposure and when utilizing certain vascularized bone grafting techniques.

Assessment of the non-union is made on direct inspection and with the aid of intraoperative radiographic examination. The following points are noted:

- The location and orientation of the non-union
- The deformity present. The scaphoid will demonstrate varying degrees of flexion deformity and loss of height
- The condition of the articular surfaces
- The integrity of the scapholunate ligament complex. Coexisting scapholunate laxity can be present, although frank instability is rare
- The vascularity of the proximal scaphoid pole.

Following careful assessment the non-union is prepared to accept the desired graft. The edges of the fracture site are cut back to healthy bone using osteotomes. K-wires inserted as joysticks and laminar spreaders are useful in distracting the fracture to restore scaphoid dimensions so that the defect can be measured and the size and shape of the required graft ascertained.

Types of bone graft (Box 12.29.12)

Interposition grafts

Cancellous or corticocancellous graft can be harvested from the distal radius or the iliac crest. Harvesting from the distal radius can be performed from the volar aspect through a slightly extended volar approach, or through a separate dorsal exposure of Lister’s tubercle. A trapezoid-shaped wedge is inserted with the broader surface volarly to correct the flexion deformity. The wedge shape causes a tendency to extrude, so some form of fixation is employed.

Inlay grafts

This technique involves excavating a cavity crossing the non-union site, from proximal to distal fragments, and inlaying strips of corticocancellous graft snugly across the non-union to immobilize it. Matti in 1937 originally described grafting done through a dorsal approach, Russe (1960) modified Matti’s operation adopting a palmar approach (which he believed would be less likely to cause injury to the vascular supply of the scaphoid). The grafts can be harvested from iliac crest or distal radius and fixation may be reinforced with supplemental implant fixation.
Fixation with cannulated compression device
Postoperative cast for 6–8 weeks.

**Box 12.29.12 Bone grafts**

- **Non-vascularized:**
  - Distal radius or iliac crest
  - Interposition or inlay
- **Vascularized, pedicled:**
  - Volar radius (volar carpal artery or pronator quadratus)
  - Dorsal radius (1,2 ICSR artery)
  - Index metacarpal
  - Distal ulnar
- **Vascularized, free:** medial supracondylar femur.

**Longitudinal pegs**

Grafts are fashioned into a peg and positioned longitudinally in the same axis as a screw.

**Vascularized bone grafts (Figure 12.29.11)**

Vascularized grafts can be pedicled, based on local arterial branches feeding the transplanted bone, or free transfers. Grafts can be harvested from:

- The volar radius. A pedicle can be based on the volar carpal artery or on a strip of the distal margin of pronator quadratus. Graft harvest can be incorporated into an extended standard volar exposure of the scaphoid and flexion deformity secondary to the volar bone loss can be corrected
- The dorsal radius. The arteries supplying the dorsal radius are described by their relationship to the extensor retinaculum compartments. Vessels lie within compartments or in between (intercompartmental). The 1,2 intercompartmental supraretinacular vessel feeds the distal radius on its dorso-radial aspect and graft can be based on this pedicle
- The index metacarpal
- The distal ulnar based on the ulnar artery

**Click to view larger**

Fig. 12.29.11  
Vascularized, pedicled bone grafts from the distal radius: A) volar. Based on the VCA (volar carpal artery) and B) dorsal. Based on a branch of the 1,2 ICSR (1,2 intercompartmental supraretinacular artery).

- Free vascularized bone graft harvested from the medial supracondylar region of the femur and based on branches of the genicular arteries supplying the bone in this region. Anastomosis is performed onto the radial artery and its venae commitantes.

**Prognosis (Box 12.29.13)**

The following are important prognostic factors in bone healing following non-union surgery:

**The site of the non-union**

The convention to divide the scaphoid into proximal, middle (waist) and distal thirds is arbitrary and prone to intra- and interobserver error. A more accurate method is to describe the non-union site as a ratio of the fracture fragments. Following non-vascularized
Bone grafting with internal fixation union rates vary from 27–100% depending on the site of non-union calculated using the fragment ratio method (Figure 12.29.12).

**Fig. 12.29.12**
Union rates following non-vascularized bone grafting and internal fixation for scaphoid non-union. Rates progressively worsen with more proximal site of non-union.

The time between injury and surgery

With delays of more than 5 years, mean union rates fall to around 60% following non-vascularized bone grafting with or without fixation. The effect that time from fracture has on union varies with the site of fracture, being weaker for more distal fractures.

**Avascular necrosis of the proximal pole (Box 12.29.14)**

Increased density of the proximal scaphoid on radiographs has traditionally been interpreted to denote avascularity. However, apparent increased radiographic density may not be due to avascularity and this method is unreliable. MRI and enhanced MRI with gadolinium offer more accurate assessment of blood flow. Intraoperative assessment remains the most reliable technique and absence of punctate bleeding from the bone is a poor prognostic indicator.

Although avascularity does not prevent union it is an important factor contributing to non-union. When the proximal scaphoid fragment is completely avascular it has no intrinsic repair capacity and must rely on repair from the distal fragment.

Smoking

Has a deleterious effect on bone healing, however, the effect it has on prognosis of scaphoid non-union is controversial. A greater than threefold risk of failure of non-vascularized bone grafting with screw fixation has been reported in smokers undergoing non-union surgery, whilst others have shown smoking to have no influence on the rate of union following surgery.

**Box 12.29.13 Outcome of non-union surgery**

- 71% union with non-vascularized grafting and internal fixation
- Worse results with proximal fractures
- Worse results with increasing age of non-union
- Worse results with AVN of proximal pole.

**Vascularized versus non-vascularized bone grafting**

The union rates of non-vascularized bone grafting, with or without fixation, are reliably reported at 70–80%. Russe and subsequently Green contended that in the presence of complete AVN of the proximal fragment inlay grafting is highly likely to fail. Interposition grafts have been used in the presence of AVN with success in 53%.

Improving the vascularity of the proximal pole directly by implanting a vascular pedicle has not been successful, thrombosis of the implanted vessels and lengthy periods for bone revascularization to occur being cited as reasons. Vascularized pedicle bone grafts were introduced to overcome these problems.

There are currently no randomized series comparing vascularized versus non-vascularized grafting in the presence of AVN. Published series on pedicled distal radial vascularized grafting report union rates between 80–100%, but cohorts are
heterogeneous for the presence of AVN. A recent meta-analysis shows that non-vascularized, interpositional grafts used in the presence of AVN have a union rate of only 47% compared to 88% when vascularized grafts are used. Recent publications on free medial femoral grafts used in the treatment of scaphoid waist non-unions, with an avascular proximal pole, report promising success rates.

**Box 12.29.14 Avascular necrosis**

- Density on x-ray unreliable as a sign of AVN
- Assess with MRI
- Intraoperative assessment most reliable
- Consider vascularized graft.

The case for vascularized grafting remains inconclusively. For most waist fracture non-unions without other adverse features (AVN, failed previous surgery, long duration of non-union, proximal pole non-union) non-vascularized bone grafting is probably sufficient.

**Secondary arthritis**

The pattern of arthritis that develops in association with non-union is progressive and occurs in a predictable sequence (Figure 12.29.13). The term scaphoid non-union advanced collapse or 'SNAC' has been coined to describe this pattern, which closely parallels the pattern seen in chronic scapholunate ligament incompetence (scapholunate advanced collapse, SLAC wrist).

**Fig. 12.29.13**

Scaphoid non-union advanced collapse (SNAC). Degenerative changes start between the radial styloid and distal scaphoid fragment. The joint between radius and lunate is seldom affected.

Non-union is usually associated with alteration in the shape of the scaphoid with flexion plus shortening leading to articular incongruity. With additional mobility of the fracture fragments and altered carpal motion, joint surfaces are exposed to excessive and abnormal forces, and the mechanisms for degeneration are established. The site of initial change is between the radius and mobile distal scaphoid fragment, stopping at the site of non-union. Osteophytes form at the tip of the styloid and subsequently the joint space is lost. The articulation between the radius and proximal pole fragment is preserved because both are spherical in nature, allowing congruency in all positions. Rotation of the distal scaphoid fragment and loss of the radius-distal fragment joint space allow the capitale to migrate. The capitale drives off the radial side of the lunate and destruction of the capitale-proximal fragment joint ensues followed by the capitale-lunate joint. The joint between radius and lunate is seldom affected (Figure 12.29.13).

**Treatment (Box 12.29.15)**

**Radial styloideotomy**

In the initial stages, where degeneration is isolated to the articulation between the radial styloid and distal scaphoid fragment, simple excision of the styloid can be performed. Excision is performed removing the degenerate styloid up to the junction of normal articular cartilage. Caution is needed to preserve the important extrinsic volar ligaments (radioscaphocapitate and radiolunate ligaments) as detaching theses may lead to instability.

Although some success for isolated styloideotomy is reported, pain relief is unpredictable as it is difficult to know whether pain is coming from the radioscaphoid arthritis or from the non-union. Combining grafting of the non-union with styloideotomy is a reasonable and logical alternative.
**Excision of the scaphoid**

A very small proximal fragment can be excised but resections of larger fragments of the proximal or distal poles, or the whole scaphoid, results in collapse of the carpus into a DISI deformity. Techniques to stabilize the carpus, following excision of part or all of the scaphoid, include some form of limited arthrodesis or some form of prosthetic replacement.

**Limited carpal fusion**

Watson popularized scaphoid excision with arthrodesis of the lunate, capitate, hamate and triquetrum (‘four-corner fusion’) for reconstruction of SLAC wrist. The procedure has successfully been applied to palliation for SNAC wrist. It can be used when degeneration has extended into the midcarpal articulation. The residual fusion mass articulates at the radiolunate articulation which is not usually affected until late in the arthritis process. In a series of 100 procedures performed by Kirk Watson and associates, the average range of motion was 53% and 59% of normal in flexion/extension and radioulnar deviation respectively. Grip strength reached 80% of normal (Figure 12.29.14).

![Click to view larger](image)

**Fig. 12.29.14**

Scaphoid excision and ‘four-corner’ fusion: A) ‘hub-plate’ and b) K-wires.

**Replacement of part or all of the scaphoid**

Silastic implants have been widely used since their introduction including replacement of the proximal scaphoid pole and total scaphoid replacement. However, the problem of silicon synovitis causing cyst formation and progressive to total destruction of the carpus, has led to the abandonment of such arthroplasties. Alternative materials, including acrylics, metal alloy and cadaveric bones have failed to gain wide popularity. More recently the development of pyrocarbon implants has received some attention.

**Excision of the proximal carpal row**

Is an established treatment for SLAC and SNAC patterns of arthritis involving the articulation between the radius and scaphoid. Following proximal row carpectomy (PRC) the head of the capitate articulates with the lunate fossa of the radius, and these surfaces need to have good articular cartilage if this procedure is being performed. Evidence of degeneration at the lunate-capitate articulation should be sought on preoperative radiographs, but preservation of the articular surfaces can only be confirmed at time of operation. If articular damage exists then an arthrodesis procedure is preferable and patients are preoperatively counselled accordingly.

PRC is simpler to perform than limited fusion and lower rates of complication are reported. Good pain relief can be achieved with this procedure as well as improvements in grip strength. The range of motion in flexion-extension is 60–70% of normal. Progression of arthritis in the radius-capitate articulation has been observed and this may be a concern, especially in younger patients, but the procedure has been shown to be durable at 10 years.

**Denervation of the wrist**

Denervation interrupts the sensory pathways from the pathological wrist. It is more conservative than other salvage procedures, with less potential for complication, and preserves wrist movement. However, the innervation of the different tissues making up the wrist joint is complex, and the exact sources of pain are not completely understood. Total denervation aims to interrupt all sensory nerves supplying the wrist. This is difficult as sensory afferents are numerous and variable. The technique requires the division of ten nerve branches through five separate incisions. Partial denervation selectively interrupts those regions most likely responsible for generating pain. The posterior and anterior interosseous nerves can be sectioned through a single dorsal incision, and high levels of patient satisfaction using this technique are reported. Other clinical reports suggest pain relief is somewhat inconsistent and only transient.

**Complete arthrodesis of the wrist**

In cases where advanced arthritis is causing marked pain, arthrodesis is reliable and predictable. The amount of movement that the patient has in the wrist when arthritis is advanced is usually, already, markedly limited. In such cases the further loss of movement is usually outweighed by the advantage of loss of pain.

**Conclusion**
The scaphoid fracture tends to occur in active, young males. Most fractures will heal with the appropriate treatment, but a few will go onto non-union. If left untreated a non-union, even when initially asymptomatic, will result in arthritis and eventually pain, although this may not be for several decades. The role of the surgeon is to make definitive early diagnosis and institute effective treatment. Unnecessarily long periods of immobilization should be avoided and early fixation may prove to be a more satisfactory strategy in the future. Despite newly developed techniques and implants for fixation non-union continues to occur. Our understanding of the factors involved in non-union has increased but the optimum treatment approach has yet to be defined.

Chapter: Instabilities of the carpus

Author(s): David Lawrie, Chris Little, and Ian McNab

DOI: 10.1093/med/9780199550647.003.012030

Summary points

♦ Most injuries occur in hyperextension
♦ The force vector and size dictates the injury
♦ History and x-rays still prevail in diagnosis
♦ Classification has helped choose management
♦ Instability often associated with poor bone healing.

Introduction

Carpal instabilities can seem unduly complicated and unapproachable. With a better understanding of the anatomy and ligamentous support of the wrist, the instabilities seen become more logical, and the clinical assessments for instabilities makes more sense. Treatments of carpal instabilities, both acutely and established, are emerging with the growing appreciation of the kinematics and carpal kinetics of this complex of articulations.

Wrist anatomy (Figure 12.30.1)

The wrist represents a complex of articulations between the forearm bones, the carpal bones, which are arranged into two rows, and the bases of the metacarpals. The carpal bones are arranged into a proximal and a distal row. This gives rise to a confluent joint between the radius/ulna (covered by the triangular fibrocartilage) and the proximal carpal row, called the radiocarpal joint (RCJ), and a second confluent joint between the proximal and distal carpal rows, called the midcarpal joint (MCJ). The bones of the distal carpal row articulate with the metacarpal bases.

The bones are connected by the intrinsic ligaments, and by ligaments within the capsule that pass from the forearm bones to the carpal bones, collectively called the extrinsic ligaments.

The bones of the distal carpal row are held tightly together by the intrinsic ligaments and so can be considered to act as a monoblock. The intrinsic ligaments of the proximal carpal row allow a greater degree of intercarpal motion. Both the scapholunate (SL) and the lunotriquetral (LTq) ligaments have weak membranous proximal portions (which can be seen arthroscopically from the radiocarpal joint) and stronger palmar and dorsal portions; the SL is stronger dorsally, and the LTq stronger on the palmar side. Fibres of the dorsal and palmar portions of these ligaments connect to form the scaphotriquetral ligaments at the MCJ. As long as the membranous portions of the ligaments are intact, there is no communication between the RCJ and the MCJ; communication through this portion of the ligaments occurs via traumatic or degenerate perforations, which are not necessarily clinically important. The MCJ is supported by intrinsic ligaments on the dorsum by the dorsal intercarpal ligament (DIC) which passes from the triquetrum to the scaphoid, trapezoid and trapezium, blending with the dorsal scaphotriquetral ligament, and on the palmar surface by the triquetrohamatecapitate ligament complex on the ulnar side, and by the scaphocapitate and scaphotrapezial ligaments on the radial side (the latter passing around to the dorsoradial aspect of the MCJ). These ligaments tend to fail by avulsion.

The extrinsic ligaments arise from the palmar and dorsal surfaces of the radius, and on the palmar side, the ligaments broadly form the shape of two inverted Vs running proximal to distal, one with its apex on the lunate (short and long radiolunate and ulnolunate ligaments) and the other with its apex on the capitate (the radioscapohamatecapitate ligament complex, and the ulnocapitate ligament). There is a sulcus between these two Vs on the radial side, connecting into the space of Poirier.

The palmar uncarpal ligaments and the palmar and dorsal radiocarpal ligaments, along with the triangular fibrocartilage between them, form the triangular fibrocartilaginous complex, which is considered in more detail in Chapter 6.4. On the dorsum, the dorsal radiocarpal ligament forms the proximal limb of a radially-based V (the distal limb being the DIC intrinsic ligament) running transversely with its apex on the triquetrum. The extrinsic ligaments tend to fail by midsubstance rupture.

The carpal bones are connected by other ligaments outside the wrist capsule, notably the transverse carpal ligament (TCL) from the hook of the hamate and the pisiform to the distal scaphoid and the trapezium, forming the roof of the carpal tunnel, and the pisohamate ligament (which makes the floor of Guyon’s canal). The TCL helps to maintain the convex-dorsal arch to the carpus in the transverse plane, and its division increases the width and volume of the carpal tunnel.
Fig. 12.30.1
Schematic representation of the most consistently present wrist ligaments. These drawings do not aim to replicate the exact shape and dimensions of the actual ligaments, nor their frequent anatomic variations. A) Palmar superficial ligaments: (1) radioscaphoid, (2) radioscapho-capitate, (3) long radiolunate, (4) ulnocapitate, (5) scaphocapitate, (6) pisohamate, and (7) flexor retinaculum or transverse carpal ligament. B) Palmar deep ligaments: (8) short radiolunate; (9) ulnolunate; (10) ulnotriquetral; (11) palmar scapholunate; (12) palmar lunotriquetral, (13) triquetral-hamate-capitate, also known as the ulnar limb of the arcuate ligament; (14) dorsolateral scaphotrapezial; and (15) palmar transverse interosseous ligaments of the distal row. C) Dorsal ligaments: (16) radiotriquetral; (17) triquetrum-scaphoid-trapezium-trapezoid, also known as the dorsal intercarpal ligament; (18) dorsal scapholunate; (19) dorsal lunotriquetral; and (20) dorsal transverse interosseous ligaments of the distal row.

Carpal kinematics and stability (Box 12.30.1)

As no tendons insert into the proximal row of carpal bones (excepting the sesamoid pisiform bone), the position of the bones is determined by the shape of the joint surfaces, the integrity of ligaments connecting the bones and the forces applied across the carpus by the tendons passing from the forearm to the hand and distal carpal row, making it act as an intercalated segment. There has been an evolution in thinking regarding how the wrist moves, from the ‘row theory’ (proximal and distal carpal rows acting as functional units) through the ‘column theories’ (with combinations of bones from the two rows acting as functional units for load transfer and positioning), to the ‘oval ring theory’ (with the distal carpal row, the scaphoid, the lunate and the triquetrum acting as linked elements in a ring, with failure of any element or the binding ligaments altering wrist motion and load transfer).

In summary, current thinking is that the helicoid shape of the triquetrorhamate articulation and the alignment and ligament attachments of the triquetrum and scaphoid cause them to tend to extend and flex respectively. As long as the SL and LTq ligaments are intact, the lunate remains in a state of dynamic balance within the proximal carpal row; if the linkages within the proximal row fail, the lunate falls under the unopposed influence of the bone to which it remains attached, rotating into dorsiflexion or palmar flexion respectively.

Motion of the wrist starts with movement of the distal carpal row at the MCJ, with palmar flexion coupled to a degree of ulnar deviation and dorsiflexion to a degree of radial deviation. Palmar and dorsiflexion produces motion in the same direction of the proximal row bones, but with the scaphoid showing greater motion than the other proximal row bones, acting as the ‘crank’ in the three-bar linkage mechanism between the proximal and distal rows. When considering radial and ulnar deviation, wrists lie on a spectrum between ‘row’ wrists (where the proximal row slides towards the ulna during radial deviation, with rotation occurring in the coronal plane) and ‘column’ wrists, (where deviation in the proximal row is achieved by scaphoid flexion during radial deviation and by the triquetrum extending in ulnar deviation, the rotation occurring in the sagittal plane).

Normal range of wrist motion is 70 degrees each of palmar and dorsiflexion, 20 degrees radial and 40 degrees ulnar deviation and minimal intracarpal rotation (most occurring at the radioulnar joints); a range of 5 degrees palmar flexion, 30 degrees dorsiflexion, 10 degrees radial deviation, and 15 degrees ulnar deviation is said to be functional.

Carpal kinetics

While load distribution in the wrist is mainly dependent on hand and wrist positioning, most load transfer at the MCJ occurs through the capitoscapholunate articulation. In the main, about half the load will be transferred through the radioscapoid articulation, about a third through the radiolunate articulation, and the remainder through the ulnocarpal joint, although load transfer at the RCJ is affected by ulnar variance (relative shortening of the ulna increasing transfer through the ulnocarpal articulation) and by radioulnar deviation (ulnar deviation increasing load transfer through the lunate).

Box 12.30.1 Carpal kinematics and stability

- No tendons insert into proximal carpal row—the ‘intercalated segment’
- Position of proximal row bones depends on intact intrinsic ligaments
- Scapholunate ligament has stronger dorsal portion
- LTq ligament has stronger volar portion
- Wrist motion begins at mid carpal joint.

Classification of carpal instabilities (Box 12.30.2)

The Mayo classification considers carpal instabilities (CI) to be dissociative (CID), non-dissociative (CIND), combined/complex (CIC) or adaptive (to forearm pathology, CIA); this is outlined in Table 12.30.1.
CID (DISI or VISI pattern)

1. Scapholunate dissociation (early stages)
2. Lunotriquetral dissociation (early stages)
3. Axial dislocations of the carpus (if neither carpometacarpal joints distally nor proximal carpal row joints proximally are involved)
   3A. Axial radial
       Peritrapezoid, peritrapeziun, transtrapezium
   3B. Axial ulnar
       Transhamate/peripisiform, perihamate/peripisiform, perihamate/transtriquetrum

CIND (DISI or VISI pattern or ‘translatory’ patterns)

1. Radiocarpal
   - Dorsal or volar Barton’s fracture/dislocation
   - Distal radius malunion (if extrinsic ligament damage is present or develops)
   - Rupture of radiocarpal extrinsic ligaments (all ruptured equals radiocarpal dislocation; total or partial rupture can result in VISI, DISI, UT, DT, or VT)
   - Radioscaphocapitate
   - Short radiolunate
   - Long radiolunate
   - Ulnocapitate
   - Unnotriquetral
   - Madelung’s deformity (may occur with sufficient ulnar deformity)
   - Ulnar translocation of the carpus
   - Radiocarpal dislocation
   - CLIP (if proximal instability present; the major instability in CLIP is the mid-carpal level instability) Proximal carpal row instability due to radiocarpal level damage only
2. Mid-carpal
   - Proximal carpal row instability due to mid-carpal level damage only (the MCI of the literature)—a VISI deformity
   - CLIP: the characteristic dorsal subluxation of the distal carpal row is due to damage at this level—a DISI deformity

CIC

1. Any of the perilunate to lunate dislocation spectrum
   - Dorsal and volar perilunate to lunate dislocations (ligamentous)
   - Transosseous perilunate variants
   - Trans-scaphoid dorsal perilunate and others
2. Any combination of two or more CID or CIND instabilities
CID which develops extrinsic ligament or additional intrinsic ligament insufficiency, i.e. stage 3 SLD with DISI

CIND which develops intrinsic ligament or additional extrinsic ligament insufficiency, i.e. proximal carpal row instability (either DISI or VISI) with extrinsic ligament damage at both radiocarpal and mid-carpal levels

CIA

Any adaptive or apparent adaptive posture of the carpus not based on carpal injury, but reflecting changes in forearm or hand support structures

Apparent CIND-DISI with a dorsiflexion malunion of a distal radius fracture (Colles type)

Apparent CIND-VISI with a volar flexion malunion of a distal radius fracture (Smith type)

Madelung’s deformity with hypoplasia of the ulnar radius and displacement of the distal ulna

Most examples of CID reflect injuries to the intrinsic ligaments of the proximal carpal row, which can progress to perilunate dislocations with failure of other structures; as this happens, the instability moves into the CIC (complex) group.

The pathoanatomy of perilunate injuries was examined by Mayfield, who described a sequential failure of the structures around the lunate that gives rise to carpal instabilities and perilunate dislocations. In the usual pattern of soft tissue injury (so-called lesser arc injuries), the distal carpal row is subject to extreme extension and carpal supination from an indirect force, which is transmitted to the lunate via the scaphocapitate and scaphotrapezoid ligaments, the scaphoid and SL ligament; the extrinsic ligaments constrain lunate motion, causing tearing of the SL ligament (stage 1). If the force continues to be applied, the distal carpal row dislocates dorsally, tearing the capsule between the palmar extrinsic ligament Vs (stage 2). As the capitate translates dorsally, tension in the triquetrocapitate ligament pulls the triquetrum dorsally and into extension, tearing the LTq ligament (stage 3). At this point, the lunate remains attached to the radius by the short and long radiolunate ligaments and the dorsal capsule, the latter being vulnerable to rupture when the lunate is translated in a palmar direction by the displaced capitae, producing a palmar dislocation of the lunate (stage 4).

This normal Mayfield sequence may be associated with fractures of the radius or the carpal bones, in particular the scaphoid and the triquetrum. These injuries are termed greater arc injuries, and named by the pre-fix 'trans-' (name of fractured bone), perilunate injuries. If force is applied to the ulnar side of the carpus, a so-called reverse Mayfield sequence of structural failure may uncommonly occur.

Damage to the ligaments crossing the MCJ can give rise to CIND instability patterns. This is most commonly seen in constitutionally lax individuals in whom a comparatively minor injury gives rise to on-going symptoms from the resultant manifest midcarpal instability. This often presents with ulnar-sided dorsal wrist pain and an associated sensation of clunking; this occurs as the laxity allows the proximal carpal row to remain flexed for a larger arc as the wrist moves from radial to ulnar deviation, with the flexed proximal row ‘snapping’ into extension with the perception of a clunk (often termed a catch-up clunk). This is the principle underlying the midcarpal pivot shift test.

CIND is also seen at the radiocarpal joint, either due to acute trauma (with extrinsic ligament avulsions), or in rheumatoid arthritis (with ulnar translation of the carpus).

CIA generally reflects carpal malalignments seen after distal radial malunions. Under these circumstances, abnormal inclination of the distal radial articular surface causes the proximal row to adopt an unusual position (e.g. dorsiflexed positioning following a dorsally-tilted malunion after a Colles pattern of fracture), with compensatory instability at the midcarpal joint (palmarflexed in the example given).

Clinical evaluation

Following an acute wrist injury, there should be a high index of suspicion for any underlying carpal bone fracture, ligament injury or
dislocation. These injuries should be actively sought and excluded.

The mechanism of injury determines the magnitude of the forces that have been applied to the wrist and consequently the likely type of injury that must be excluded.

The injury can range from a high-energy road traffic collision (particularly involving a motorcycle) to other high-velocity injuries such as a fall from a height, or during sport, that may cause perilunate dislocations and fracture–dislocations. Lower velocity falls on the outstretched hand/wrist may cause hyperextension and more isolated carpal fractures or ligament injuries. The patient often underestimates the injury severity, assuming that it is a trivial ‘wrist sprain’. Other subtle or apparently trivial injuries that communicate significant extension, flexion or rotational forces to the wrist, such as when a power drill jams while drilling, should also raise suspicions.

Patients with perilunate dislocation injuries present with wrist deformity, limited motion, pain, and swelling. Single carpal bone dislocations may cause a subcutaneous prominence or a hollow over the dislocated bone. More subtle carpal instabilities will present with complaints of pain, swelling, and possibly clicking of the wrist.

Severe pain and swelling may make a careful complete wrist examination difficult in the early stages. However, the wrist should be inspected for haematoma, swelling, and altered shape. Subtle changes are best visualized by comparing the involved and uninvolved wrists.

Wrist palpation is performed following the bony anatomy, the distal wrist flexion crease is proximal to the carpus. There may be global wrist tenderness, but areas of maximum tenderness, and the structures that lie under them, should be identified and prioritized.

The active and passive ranges of motion are assessed, noting any ‘clicks’ or ‘clunks’ indicating possible abnormal kinematics. A detailed neurovascular examination is performed.

Standard posteroanterior (PA) and lateral radiographs are obtained, with a radiographic wrist motion series, if wrist instability is suspected (see later).

**Acute SL dissociation** is generally suspected clinically but confirmed radiographically. However, most patients present with chronic SL dissociation (>6 months after injury). There may be an uncertain mechanism of injury, chronic dorsal or global wrist pain, swelling aggravated by lifting or gripping, and possibly wrist ‘clunking’.

Physical examination may demonstrate, dorsal tenderness over the SL interval, a ballotable proximal scaphoid with pain and crepitus, and occasionally a ‘click’ demonstrable on ulnar to radial deviation, as the scaphoid subluxes or rotates out of the scaphoid fossa in radial deviation and relocates in ulnar deviation.

Watson’s scaphoid shift test (Box 12.30.3) is performed as the examiner (seated opposite the patient) holds the patient’s hand with the examiner’s thumb overlying the distal pole of the scaphoid; the examiner’s finger palpates the proximal pole of the scaphoid on the dorsum, and the patient’s elbow is stabilized on the examination table. Starting with the patient’s hand in ulnar deviation, the wrist is passively moved into radial deviation. Dorsally directed pressure, applied on the scaphoid tuberosity by the examining thumb, will cause the unstable scaphoid to ‘back out’ or sublux dorsally from the radial fossa. It is important to compare tenderness, pain, mobility, crepitus, and ‘clicks’ with the contralateral side. SL instability is likely when the test demonstrates an objective difference in stability of the two sides, or a palpable ‘clunk’ is elicited as the scaphoid proximal pole exits or returns to the scaphoid fossa.

**Box 12.30.3 Investigations**

- Watson’s scaphoid shift test may demonstrated SL dissociation
- AP and lateral radiographs may not demonstrate acute ligament injury
- Clenched fist view may be helpful
- Gilula’s lines is helpful in assessing for carpal dislocation
- Normal scapholunate angle is 30–60 degrees.

**LTq instability** is a subtle clinical diagnosis. With an acute injury, there may be a history of a fall onto the ulnar side of the hand and ulnar sided wrist pain and swelling. LTq instability often presents as a chronic problem with ulnar-sided wrist pain and swelling aggravated by power grip, and popping or ‘clunking’ on radial/ulnar deviation. There is tenderness directly over the LTq interval, and increased pain, crepitus, and excessive motion compared with the other side, when performing a LTq ballottement test. During this test the examiner stabilizes the patient’s triquetrum with their index finger volarly and the thumb dorsally. The patient’s lunate is increased pain, crepitus, and excessive motion compared with the other side, when performing a LTq ballottement test. During this test the examiner stabilizes the patient’s triquetrum with their index finger volarly and the thumb dorsally. The patient’s lunate is

CIND conditions present following repeated stress or trauma with a history of underlying congenital ligamentous laxity in approximately 50% and poorly localized chronic wrist pain and tenderness (aggravated by activities). A ‘catch-up clunk’ of the proximal carpal row may be demonstrated (by either the patient or the examiner moving the wrist from radial to ulnar deviation or vice versa, or through a circumduction arc, possibly under axial compression).

Normally the helicoid articulation between the triquetrum and the hamate, causes a tendency for the triquetrum to dorsiflex (with
Asymptomatic wrists of patients evaluated for wrist pain. In a traumatised or congenitally lax wrist, the laxity of the carpus permits exaggerated or prolonged flexion of the proximal carpal row in radial deviation. With ulnar deviation there is a delay before the proximal carpal row ‘snaps’ back into place and congruent articulation is restored.

Perilunate dislocations often occur in the context of high-energy trauma and a multiply injured patient and can cause characteristic wrist deformities. When the carpus is dislocated dorsally the radius is prominent in the carpal tunnel, on the palmar surface of the wrist as is the lunate in a pure lunate dislocation. Despite this up to 25% of these injuries are diagnosed late.

In dorsal perilunate dislocation the palmar skin and median nerve must be examined carefully. Median nerve damage is the most common associated injury and laceration of the palmar skin may indicate an open dislocation or fracture-dislocation. Palmar skin ischaemia may also be caused by pressure from the radius. Both arterial and compartment problems may occur and must be excluded. Bones or their fragments may be significantly displaced or even extruded.

### Investigations

**Imaging**

Radiographic evaluation of wrist pain should include standard PA and lateral radiographs of the carpus. The PA film is centred over the radiocarpal articulation to assess accurately the SL interval, scaphoid position, LTq articulation, ulnar styloid, distal radius articular surface, and distal radioulnar joint.

The PA film is taken with the shoulder abducted 90 degrees, the elbow flexed at 90 degrees, neutral forearm rotation, an overhead x-ray beam, and the wrist placed flat on the x-ray plate. A good lateral radiograph of the wrist should display: complete superimposition of the lunate, proximal scaphoid pole and triquetrum, the scaphoid tubercle overlies the pisiform, the radial styloid is in the ‘centre’ of the radius, and metacarpal shaft superimposition. If the lateral radiograph is incorrectly taken in ulnar deviation, then proximal carpal row dorsiflexion will produce an apparent DISI pattern.

Scaphoid views are obtained if there is tenderness in the anatomic snuffbox or if the PA and lateral radiographs suggest scaphoid pathology. The coned scaphoid waste view is obtained with the wrist in maximal ulnar deviation and 10-degree distal x-ray beam angulation. This produces an elongated, enlarged, detailed image of the scaphoid waste accentuating the trabecular pattern.

A wrist motion series includes flexion lateral, extension lateral, PA radial deviation, and PA ulnar deviation radiographs of both wrists. In ulnar deviation the scaphoid extends and appears elongated, while in radial deviation it should flex and appear shortened. SL diastasis usually accentuates in ulnar deviation and closes in radial deviation.

A so-called ‘six shot’ wrist series includes: PA, PA radial deviation, PA ulnar deviation, PA clenched fist, lateral, and lateral clenched fist views.

The normal SL interval on a PA radiograph measures 3mm or less. Diastasis beyond this indicates a possible SL dissociation. In SL dissociation, the scaphoid typically rotates out of the radial fossa into increased flexion. When viewed on the PA radiograph, this ‘scaphoid rotatory subluxation’ produces an ‘end on’ image of the scaphoid with overlapping cortical edges, known as the ‘scaphoid cortical ring sign’.

Gilula described three smooth arcs, assessed on PA radiographs which can be traced along the proximal radiocarpal surface of the scaphoid, lunate, and triquetrum; the distal midcarpal surface of these same bones; and the proximal midcarpal surface of the capitate and hamate. An assessment of Gilula’s lines provides a quick screen for fracture, dislocation, or instability of the carpus.

A PA distraction view (20–25-kg finger-trap traction) helps to define carpal fractures and dislocations in complex acute injuries such as perilunate dislocations. It can alert the physician to other injuries, e.g. palmar avulsion fracture of the triquetrum indicating a significant ulnar-sided ligament injury.

The normal lateral SL angle (formed by the intersection of the longitudinal axes of the lunate and the scaphoid) measures 30–60 degrees. An angle greater than 70 degrees is diagnostic for DISI pattern, while an angle less than 30 degrees represents a VISI pattern. A ‘double check’ for this diagnosis is the evaluation of the capitulunate angle (measured as the angle bisecting the longitudinal axis of the lunate and the capitane, normally 0 degrees) measuring greater than 15 degrees in a DISI deformity and less than 0 degrees in a VISI deformity. An apparently increased SL angle will appear with displaced scaphoid fractures and displaced/malunited Colles type distal radius fractures.

### Arthrography

Standard arthrography has traditionally been used as an aid to the diagnosis of carpal ligament injuries. However as discussed in Chapter 12.31 (injuries to DURJ) false positive results can occur, particularly if, for example, there is a small perforation in an otherwise functionally competent SL ligament, which still allows contrast to pass from the radiocarpal to the MCJ. Arthroscopy remains the gold standard in the diagnosis of intraosseous ligament tears. Cadaveric studies have shown a high incidence of asymptomatic communications. Bilateral wrist arthrography has demonstrated similar communications in the contralateral wrist.
asymptomatic wrists of patients evaluated for wrist pain.

Magnetic resonance imaging (MRI) or computed tomography (CT) scanning is now commonly performed as adjunct to plain arthrography, further improving its diagnostic accuracy, and providing extremely useful diagnostic information that helps to inform the patient and physician in the decision-making process prior to embarking on more invasive procedures.

**Computed tomography scan**

CT scanning is now widely available and is extremely useful, particularly in the context of acute injuries, for identifying suspected carpal bones fractures that remain ‘occult’ on plain radiographs, and for assessing preoperatively the true nature and full extent of complex wrist injuries. Unless it is combined with arthrography, it does not demonstrate wrist ligament injuries well.

**Magnetic resonance imaging**

Where high field strength magnets and dedicated wrist coils are employed, high-resolution MRI scans offer increasing accuracy in the diagnosis of carpal ligament injuries, particularly if combined with magnetic resonance arthrography (MRA).

MRI can demonstrate bone oedema, injury, and circulation, and intraosseous ligament damage, and increasingly also evidence of extrinsic or capsular ligament injuries. Gadolinium-enhanced MRI scans provide additional information about the vascularity and viability of carpal bones that is helpful in the context of scaphoid or lunate fractures, presenting with delayed or non-union.

**Arthroscopy (Box 12.30.4)**

Wrist arthroscopy remains the gold standard in the diagnosis of intra-articular wrist disorders and ligament injuries.

If non-invasive investigations have failed to identify a cause for a patient’s wrist pain, particularly if follows a significant injury, then an examination under anaesthetic and diagnostic wrist arthroscopy should be considered.

Despite some limitations, which result from the necessity to place the wrist in traction, wrist arthroscopy provides a dynamic evaluation of the wrist including the status of: cartilage surfaces; synovium; most portions of the ligaments (intrinsic and extrinsic); the relative stability/motion between carpal bones; any anomalous structures, entrapped tissues, cartilage or bone debris, and tethering scar tissue.

Classifications of arthroscopic findings have been devised to facilitate accurate descriptions and to grade their significance as part of the decision-making process for treatment. For example, the classification of SL instability described by Geissler based on arthroscopic findings (Table 12.30.2).

**Table 12.30.2 The Geissler classification of SL ligament tears**

**Treatment**

**Carpal instability dissociative**

CID is when instability arises due to injury between two bones in the same carpal row. Most commonly this occurs between the scaphoid and lunate or the lunate and triquetrum.

**Box 12.30.4 Arthroscopy**

- Arthroscopy most sensitive technique for assessing intrinsic ligament injuries
- Geissler classified arthroscopic findings of SL injuries.

**Scapholunate dissociation**
Acute scapholunate dissociation

Following a ligament injury, the normal forces that act on the carpal bones can lead to the development of a progressive DISI carpal malalignment. This may be prevented if following an acute injury an anatomical reduction is achieved and maintained for long enough to allow the soft tissues to heal correctly.

Acute SL injuries without carpal malalignment may be treated with percutaneous K-wire fixation under image intensifier control. Temporary K-wires are inserted from the dorsum and used to ‘joystick’ the scaphoid and lunate to ensure anatomical reduction. Ideally two K-wires (mechanically more stable than one wire) are then passed from the scaphoid into the lunate to maintain position while the SL ligament heals. The wires are maintained for 8–10 weeks, so must be left buried under the skin to reduce the risk of infection. To reduce the risk of wire breakage, the wrist is immobilized in a below-elbow cast, until the wires are removed. Following which, intensive physiotherapy is commenced.

Some authors have reported good results with arthroscopically assisted K-wire fixation, allowing improved accuracy of reduction and wire placement. Arthroscopy also facilitates the debridement of any prominent ligament remains.

Complete disruption of the SL ligament may result in dynamic SL dissociation, where DISI malalignment of the carpal bones occurs only when forces are applied across the wrist. Following an acute injury of this magnitude, it is desirable to restore the anatomical position of the carpus and to formally repair the ligaments. The SL ligament can rupture through its midsubstance or be avulsed from (usually the scaphoid) with or without bone.

Although volar and dorsal approaches have been described, studies have suggested that a dorsal repair may be adequate. The wrist joint is approached between the third and fourth dorsal compartments. Anatomical reduction of the carpal alignment is achieved and maintained with buried K-wire fixation (as described earlier). A direct suture repair of midsubstance tears may be possible, but augmentation with bone anchors is often required. Small avulsion fractures are also reattached with bone anchors. The repair may also be augmented with a Blatt’s dorsal capsulodesis, tightening the capsule between the radius and the distal scaphoid and preventing excessive scaphoid flexion. Postoperatively the patient is treated as previously described.

Static reducible scapholunate dissociation

If the presentation is delayed and the SL dissociation has not been treated in the acute phase, then the remains of the SL ligament retract and a primary repair is no longer possible. If the secondary restraint of the external ligaments fails progressively a permanent DISI carpal malalignment may develop. In symptomatic patients where carpal subluxation is still reducible and no degenerative changes have developed, a soft tissue reconstruction is possible.

Several ligament reconstruction techniques are described using tendon grafts, to maintain the normal carpal alignment. Perhaps the most popular tendon reconstruction currently is that described by Brunelli, who described using a distally based strip of FCR which is passed through a drill hole in the distal scaphoid. The remaining FCR tendon is then sutured across the SL interval to the remains of the SL ligament and attached to the distal radius. This was later modified to avoid crossing the radio carpal joint and instead the FCR tendon is (attached with a bone anchors to the dorsal lunate) and passed under the dorsal radiotriquetral ligament and then sutured back on its self. The long-term benefits of this procedure are not yet known.

Scapholunate advanced collapse wrist

Long standing SL dissociation may eventually lead to the characteristic progressive secondary degenerative changes described as a Scapholunate advanced collapse (SLAC) wrist. Many patients who reach this stage will respond to non-operative treatment. If this fails to control their symptoms then surgical intervention with one of the following salvage procedures may be considered.

The early stages of SLAC wrist involve the development of painful isolated radioscaphoid degenerative changes, which can be successfully treated with a radial styloidectomy. This pain relieving procedure does not correct the underlying pathological process, and degenerative changes may continue to progress across the midcarpal joint.

Proximal row carpectomy with excision of the scaphoid, lunate and triquetrum, creates a new articulation between the capitate head and the lunate fossa of the radius. This procedure does not rely on successful bone healing at an arthrodesis site and so allows early mobilization. However, it requires healthy articular cartilage on both the capitate head and the lunate fossa, so is contraindicated when degenerative changes have already spread across the MCJ. Patients report good pain relief and a functional range of movement and grip strength. If symptomatic degenerative changes subsequently develop between the capitate head and radius a wrist arthrodesis can be performed.

Box 12.30.5 Acute scapholunate dissociation

- In acute SL injuries reduction, K-wire fixation ± SL repair should be performed
- In delayed presentation with no arthrosis, soft tissue reconstruction may be appropriate (e.g. modified Brunelli procedures)
- In long-standing injuries with secondary arthrosis salvage procedures need to be considered (e.g. proximal row carpectomy or scaphoidectomy + four-corner fusion).

Scaphoid excision and four-corner arthrodesis (capitate, lunate, triquetrum and hamate) is a successful procedure for an intermediate stage SLAC wrist. Various fixation techniques have been used to stabilize the arthrodesis site including K-wires,
staples, screws, and more recently low profile circular plates. A supplementary circular bone graft can also be placed at the junction of the four bones. Healthy cartilage in the radiolunate joint is a prerequisite for this procedure, but it is successful at relieving pain even in the presence of degenerative change in the MCJ, between the capitale head and lunate.

In all the chronic wrist instabilities with associated degenerative change, pan-carpal wrist arthrodesis remains a salvage option. In order to obtain a successful outcome, solid fusion of the radioscaphoid, radiolunate, SL, capitolunate, scaphocapitate and capitale–third metacarpal joints needs to be achieved. Various fixation techniques have been described, including K-wires, interosseous pins, and dynamic compression plates. Dedicated AO wrist arthrodesis plates benefit from built in wrist extension, smaller 2.7-mm screws for the metacarpal shaft, 3.5-mm screws for the radius, and achieve high rates of successful fusion.

Lunotriquetral dissociation

Acute lunotriquetral dissociation

These injuries were previously treated non-operatively in a moulded cast. However this does not prevent the subsequent development of a chronic VSI deformity. The development of wrist arthroscopy has enabled the early diagnosis and treatment of LTq dissociation. It is desirable to reduce and fix these acute injuries with percutaneous K-wires, or to perform a repair by open or arthroscopically assisted means, in a manner similar to that for the treatment of acute SL dissociation.

Chronic dynamic lunotriquetral dissociation

As with the management of a delayed SL dissociation, the remains of the LTq ligament can be debrided arthroscopically. If the deformity is still reducible, tendon reconstruction may be attempted using a strip of ECU between the lunate and triquetrum, as described by Shin and Bishop. LTq arthrodesis has also been attempted, but with a relatively high rate of failure to achieve bony fusion.

Chronic static dissociation

Late ligament reconstruction is not possible, and if LTq arthrodesis does not adequately control the deformity, then a midcarpal or pancarpal arthrodesis should be considered.

Carpal instability non-dissociative

CIND occurs when the instability is due to dysfunction between the proximal and distal rows. The relationship between individual bones within a row however remains unaffected.

Radiocarpal dislocation

Pure dislocation of the radiocarpal joint is rare. It is more usually associated with an avulsion fracture of the radial styloid and urgent reduction is required. Neurovascular injury is commonly associated with these injuries. Following reduction, the radiocarpal joint is often unstable and open ligament reattachment may be required. Any associated radial styloid fracture is reduced and fixed restoring joint congruence and ligament stability.

Midcarpal instability

Acute midcarpal fracture dislocation is rare and should be treated in a similar manner to an acute perilunate dislocation. Chronic instability and malalignment of the MCJ represents a complex spectrum of conditions. When it presents as a dynamic problem, in the context of a congenital increase in ligamentous laxity, the initial treatment should be non-operative with splintage, activity modification and physiotherapy. Several soft tissue reconstructions and fusions have been described for patients with persistent symptoms, but these are all small studies.

Carpal instability complex

CIC covers a group of injuries in which there is disruption between bones of the same row and between separate rows.

Perilunate dislocation

Dislocation of the carpus around the lunate can be treated with an initial closed manipulation. If there are symptoms of median nerve compression then urgent carpal tunnel decompression is performed.

The extreme instability that results from these severe, often high-energy injuries, means that it is unusual for a true anatomical reduction to be achieved by closed manipulation alone. Therefore, early percutaneous K-wire fixation should be considered. Reduction of the lunate and scaphoid can be achieved using ‘joystick’ K-wires. Buried K-wires are then placed, in a similar manner to that described earlier for SL and LTq dissociations, to maintain the carpal alignment.

Severe injuries with gross instability, or those that are not fully reducible by percutaneous means, require open reduction via a dorsal approach which allows precise anatomical carpal alignment. The reduction is restored and maintained with the placement of transfixed K-wires. The dorsal approach facilitates the repair of the dorsal intrinsic and extrinsic ligaments. An additional palmar approach, via an extended carpal tunnel decompression, may also facilitate the reduction (especially of palmar dislocations) and a repair of the palmar wrist capsule.

Trans-scaphoid perilunate dislocation
The treatment of trans-scaphoid perilunate dislocations follows similar principles to pure perilunate dislocations. Urgent reduction and probable carpal tunnel decompression are required. It is important to achieve an anatomical reduction and stable fixation of the scaphoid fracture.

Open reduction and internal compression screw fixation of the scaphoid fracture and repair of the dorsal ligaments is best achieved via a dorsal approach. Arthroscopically assisted percutaneous scaphoid fixation may also be considered. The perilunate dislocation component of the injury is then stabilized with percutaneous K-wires as described earlier.

The wrist is initially immobilized for 8 weeks until the K-wires immobilizing the LT and MCJs are removed. Further immobilization may then be required if there is delayed healing of the scaphoid fracture. Ultimately, if a scaphoid fracture non-union develops it may require reconstruction with a bone graft and repeat fixation.

Patients should always be advised to avoid cigarette smoking to ensure the optimum bone-healing environment is maintained.

Greater-arc injuries

This variation of a perilunate dislocation involves fractures through the carpal bones adjacent to the lunate and is distinguished from the lesser arc injury in which there are purely ligamentous disruptions between the lunate and its neighbouring carpal bones. The classic injury involves fractures of the scaphoid, capitate, hamate, and triquetrum, but other fracture patterns or combinations of fractures and ligamentous injuries can occur. These severe injuries usually require open reduction via a dorsal approach, anatomical fracture reduction and internal compression screw fixation. Postoperative treatment is similar to that which is required following the lesser arc perilunate dislocation.

Scaphocapitate syndrome

This rare injury involves a scaphoid waist fracture and a transverse fracture of the capitate proximal pole, which then rotates through 180 degrees. The injury represents an incomplete greater-arc injury, propagated from the radial side of the carpus. Treatment includes open reduction and internal fixation and good results have been reported.

Results of treatment

Early reconstruction of SL dissociation has been show to have better outcomes compared with delayed treatment. In a study of 21 patients who underwent direct repair of the SL ligament with or with out capsulodesis, 19 patients had and improvement in their pain and grip strength. In addition a normal SL angle was maintained at 3-year follow-up.

There are few reports of the long-term results of delayed tendon reconstruction. Seventy-nine percent of patients undergoing a Brunelli reconstruction have satisfactory results. These results are promising, but the longer-term results are not yet known.

Radiocarpal arthrodesis is often avoied due to the potential for a reduced range of movement. However radiolunate fusion has been used with success in carpal instability. Pain relief was excellent and the preoperative range of motion was maintained. Radiocarpal fusion still allows movement at the MCJ, in particular the functional ‘dart throwing’ movement (radial-extension toward ulnar-flexion).

Advanced degenerative changes (SLAC wrist) are best treated with either an excision of scaphoid and four-corner arthrodesis, or a proximal row carpectomy. A prospective study comparing these two procedures in 30 cases found no difference in pain or functional improvement. However, there were more complications in the four-corner arthrodesis group.

Proximal row carpectomy results in a high degree of patient satisfaction, a functional range of wrist motion and good pain relief but requires healthy articular cartilage on capitate head and lunate fossa.

If the degenerative SLAC wrist changes have extended to involve the capitate head then an excision of scaphoid and four-corner arthrodesis should give the best results. However, as with any midcarpal arthrodesis, it will result in the loss of approximately 50% flexion and extension and some radial deviation at the wrist.

In cases with advanced SLAC degenerative changes that require a pan carpal wrist arthrodesis as a salvage procedure, the AO wrist arthrodesis plate has been demonstrated as a reliable implant and technique.

Perilunate dislocations of the wrist are devastating injuries with poor results if left untreated. Despite treatment more than 50% of patients will go on to develop degenerative changes. However the incidence of carpal instability is reduced with open reduction and SL repair. If these injuries are treated appropriately at the time of injury, reasonable results can be achieved. In 14 patients with trans-scaphoid perilunate fracture dislocations whom underwent open reduction and internal fixation, all the scaphoid fractures healed and more than two thirds reported good functional recovery (Box 12.30.6).

Box 12.30.6 Treatment of perilunate dislocations

- Perilunate dislocations require urgent reduction and stabilization
- Urgent carpal tunnel decompression is often required
- If associated with a scaphoid fracture (trans-scaphoid perilunate dislocation) then scaphoid fixation is also required
- Care should be taken to exclude an associated capitate fracture.
The best reported results of radiocarpal dislocation have been with percutaneous K-wiring with or without open ligamentous repair.

### Fractures of carpal bones other than the scaphoid

#### Evaluation and treatment

**Lunate**

Acute fractures of the lunate are relatively rare. They usually occur following a fall on a hyperextended wrist. Patients complain of pain and tenderness over the dorsum of the wrist. Standard poster anterior and lateral radiographs should be performed. If these appear normal, but a fracture is suspected, a CT scan should be obtained. Most small or undisplaced fractures can be treated non-operatively in a forearm cast. Displaced fractures require open reduction and internal fixation with cannulated screws (or K-wires). Wrist arthroscopy may be used to aid fracture reduction.

Perhaps the most common cause of lunate fractures is fragmentation secondary to the osteonecrosis seen in Kienböck’s disease. The diagnosis of Kienböck’s is usually based on the changes on plain radiographs. In the very early stages of the disease when radiographs remain normal, an MRI may be diagnostic. A more detailed discussion of Kienböck’s disease is given in Chapter 6.3.

As with all carpal bone fractures, there may be a somewhat tenuous blood supply to the fracture site, and a harsh mechanical environment. Biological and mechanical factors should be addressed to ensure an optimal bone-healing environment is maintained and patients should always be advised to avoid cigarette smoke.

**Triquetrum**

Fractures of the triquetrum are the second most common carpal bone fracture. Tenderness over the ulnar side of the wrist raises the possibility of a triquetral fracture. Triquetral fractures may be associated with other carpal bone fractures or perilunate dislocations.

Small dorsal cortical triquetral fractures are common and may be due to impaction against the ulnar styloid or avulsion. These fractures can usually be treated with immobilization in a cast or splint. If they fail to unite and become symptomatic, then the fragment can be excised. Triquetral body fractures are usually identified on routine poster anterior radiographs of the wrist while dorsal chip fractures are generally identified on the lateral radiograph.

Triquetral body fractures can occur with perilunate injuries so these patients should be carefully examined for wrist instability. Open reduction and internal fixation should be considered for displaced triquetral body fractures.

Palmar ligamentous avulsion fractures are often not demonstrated on plain radiographs, but may be identified on CT scanning. These fractures may indicate a ligamentous injury with carpal instability. These injuries are managed as a LTq instability.

**Trapezium**

Fractures of the trapezium should be suspected in patients with pain at the base of the thumb after a direct blow. The fracture may be evident on plain radiographs or on a CT scan with sagittal reconstruction.

Trapezial ridge fractures may be identified on a carpal tunnel view. These usually represent an avulsion injury of the flexor retinaculum. These and nondisplaced trapezial body fractures may be treated by thumb spica cast immobilization for 4 weeks followed by mobilization if the fracture has healed clinically. Displaced trapezial body fractures with intra-articular extension require open reduction to restore the joint surface. Fixation is achieved with screws or K-wires. Subsequent symptomatic degenerative changes may later require arthrodesis or excision arthroplasty.

**Trapezoid**

Fractures of the trapezoid are extremely rare, most are detected on plain PA and lateral radiographs, but CT scanning will demonstrate fracture anatomy more precisely. Non-displaced fractures or small fragments should be treated conservatively in a short arm cast for 4 weeks followed by mobilization. Displaced fractures may require open reduction and pin or screw fixation.

**Capitate**

Capitate fractures can occur in isolation or in association with other carpal bone fractures and wrist ligament disruptions. Isolated non-displaced capitate fractures may be treated with cast and immobilization for 6 weeks followed by mobilization, provided clinical union is present. Isolated displaced capitate fractures require open (or arthroscopic assisted) reduction and internal fixation. Capitate fractures are prone to non-union and secondary post-traumatic osteoarthrosis. Capitate fracture non-unions should be treated with open reduction and internal fixation with bone grafting, possibly incorporating a partial arthrodesis.

**Hamate**

Hamate fractures either involve the body or more commonly the hook. Since hamate body fractures generally occur as a result of high-impact injury, a careful neurological examination is required. Standard PA, lateral, and oblique radiographs are obtained initially although a CT scan may be to determine the orientation of the fracture. Undisplaced, isolated body fractures can usually be treated conservatively with immobilization. If the fracture is displaced and involving the CMC joint, or if there is CMC joint instability, then reduction and fixation is required.
Fractures of the hook of the hamate typically present with hypothenar pain and tenderness. The diagnosis can often be difficult. A carpal tunnel view can be helpful, while CT scanning will usually confirm the diagnosis. Patients complain of pain in the hypothenar region which is worse on gripping. If diagnosed early, hamate hook fractures may be treated with a short arm cast for 4 weeks. However, painful hamate hook non-union is not unusual and can cause secondary flexor tendon attrition ruptures. Excision for hamate hook non-union through a carpal tunnel approach generally produces excellent results.

Pisiform

Pisiform fractures are uncommon, difficult to diagnose on radiographs, and are consequently often missed. As the Pisiform lies close to Guyon’s canal, the ulnar nerve must be carefully examined. Pisiform fractures are treated with 4 weeks of short arm cast immobilization. If the fracture is comminuted, non-union occurs, or post-traumatic osteoarthrosis of the pisotriquetral joint develops, excision of the pisiform may be performed via a short longitudinal incision at the base of the hypothenar eminence (just distal to the distal wrist flexion crease). There is no significant loss of grip strength following pisiform excision.

Summary

Carpal instabilities represent a continuum of injuries, including subluxations, dislocations, unstable fractures, and fracture-dislocations, that are propagated from the radial or ulnar side of the wrist as a force is applied across a wrist (usually in hyperextension but occasionally in flexion). The force applied, site of application, force direction, and wrist position all determine the type of injury.

A detailed history and clinical examination with high-quality radiographs and if indicated a radiographic motion series remain the principle initial diagnostic tools. Additional imaging with standard arthrography, plain CT or MRI scans, or CT or MR arthrography are now providing increasingly accurate additional diagnostic information that can help the patient and physician to make informed decisions about treatment. Although more invasive, arthroscopy remains the gold standard investigation for diagnosing wrist ligament injuries.

The ‘intercalated segment’ concept helps to relate injuries to structure and function, to classify injuries, and to develop a logical approach to their diagnosis and treatment. Carpal instabilities can be classified as CID, CIND, or CIC, along with the simulated instabilities of ‘CIA’. These injuries can then be further modified descriptively as DISI or VISI. Improved understanding of the complex anatomy and kinematics of the wrist is helping to further the development of rational surgical treatments for these problems, with earlier and more anatomic repair/reconstruction, and rehabilitation.

The carpal bones and their associated ligaments form an anatomically compact unit that functions by sharing forces throughout the carpus. Consequently, isolated carpal bone fractures are unusual but do occur. Because they are rare, they are often overlooked or passed off as insignificant.

Fractures of the proximal scaphoid, lunate, and capitate have a precarious interosseous blood supply and an increased risk for osteonecrosis. Symptomatic non-union of hamate hook fractures or pisiform fractures may be successfully treated with excision. Instability is often the ‘common ingredient’ in carpal injuries and its improved understanding and management remains central to the treatment of wrist injuries.

Summary points

♦ Commonly missed injury
♦ Triangular fibro-cartilagenous complex integrity essential for DRUJ stability
♦ Arthroscopy useful in assessing instability and the injury
♦ MRI increasingly accurate in diagnosis
♦ Ulnar shortening can be very useful in impingement.

Introduction

Once the acutely injured patient has been stabilized including a secondary survey, one must be vigilant regarding the potential for hand and wrist injury, which accounts for 17.6% of all missed fractures following blunt trauma. Injuries to the distal radioulnar joint (DRUJ) that are not detected or treated in the acute phase may present later with symptoms of ulna sided wrist pain or instability.

Relevant surgical anatomy and biomechanics (Box 12.31.1)

The ulna head articulates with the sigmoid notch of the distal radius (the DRUJ proper), and also with the ulnar side of the proximal carpal row (through the interposed triangular fibrocartilage—TFC). Injuries to the DRUJ can affect both articulations. The radius of curvature of the sigmoid notch is greater than that of the ulna head, reducing skeletal stability from bony congruence and allowing slide and glide motion in the DRUJ. The soft tissues around the ulna head are important for stability of the DRUJ and the proximal carpal row.

Load transfer from the hand is normally primarily radiocarpal (81.4%) but the proportion is dependent on the relative lengths of the ulna and radius (termed ulnar variance). When the ulna is lengthened by 2.5mm (positive ulnar variance), load transmission through the ulnocarpal articulation and TFC increases to 41.9% and reduces to 4.3% with 2.5mm ulnar shortening (Figure 12.31.1). The thickness of the TFC in a given individual varies depending on their ulnar variance. When assessing variance with post-traumatic ulnar wrist pain, comparison views of the uninjured side can be helpful. The TFC is also thinner in its central portion, where perforations are found with increasing prevalence with age.

Most people have a range of approximately 90 degrees of supination and approximately 80 degrees of pronation. Normal forearm rotation is important for many daily activities. The activities of daily living (ADL) require a 100-degree arc of forearm rotation.

Supination is particularly important for ADLs and pronation very important for tasks such as use of a computer keyboard or mouse. While shoulder abduction can compensate for lost pronation, deltoid fatigues with prolonged abduction. Supination losses cannot be so easily overcome. With forearm rotation, the ulna remains essentially fixed and the radius rotates around the ulnar head. As the radius and ulna are joined proximally and distally, the relative lengths of the two bones (and so the ulnar variance) depends on the rotational position of the forearm; pronation is associated with relative shortening of the radius. This explains the ulnar-sided symptoms seen with forearm rotation in ulnocarpal impingement (see later).

The TFC is part of a complex soft tissue structure referred to as the triangular fibrocartilaginous complex (TFCC), the integrity of which is essential for DRUJ stability. The soft tissue can usefully be thought of as a complex of tissue whose form and function varies. The palmar and dorsal rims of the TFC form the palmar and dorsal radioulnar (RU) ligaments. The TFC and the deep portion of the ligaments insert into a fovea, the pre-styloid recess, which is found at the base of the ulnar styloid; this point marks the axis of rotation of the forearm. The superficial elements of the RU ligaments insert into the base of the ulnar styloid. The insertion may be affected by basal ulnar styloid avulsion injuries, so explaining why DRUJ instability following trauma is much more common with basal styloid fractures than with tip fractures.
The blood supply to the TFC enters through its peripheral dorsal and palmar margins, giving these areas a rich blood supply and the best healing potential. The relatively avascular central portion has poor healing potential. Perforations of the TFC have been classified into acute and chronic lesions, and are described in Chapter 6.4.

During forearm rotation, the radius slides dorsally with supination (ulna head translates palmar) and palmar with pronation (ulna head translates dorsally). The tensions in the RU ligaments vary with forearm rotation, although studies have reached different conclusions regarding which become tense with pronation and which with supination. The apparently contradictory results were reconciled by an anatomical study that found that both the deep dorsal and superficial palmar ligaments tighten with supination (reciprocal changes seen with pronation).

The capsule of the DRUJ attaches to the proximal margin of the RU ligaments and the ulnocarpal ligaments (to the triquetrum and lunate) arise from the RU ligaments distally. On the dorsum, the capsule is thickened to form the floor of the fifth dorsal compartment and the floor of the sixth dorsal compartment explaining the crucial role of the extensor carpi ulnaris (ECU) and its subsheath in ulnar head stability.

Clinical evaluation: acute injury (Box 12.31.2)

Clinical examination of an acute wrist injury begins with examination of the forearm and elbow for fractures of the radius and ulna, elbow dislocation, fracture of the radial head, and dislocation of the proximal RU joint. Associated DRUJ and interosseous membrane injuries in this setting will have implications regarding treatment of the forearm and elbow injuries—the Essex-Lopresti injury (see Chapter 12.33).

Examination of the DRUJ itself begins by inspecting the location of the ulnar head. Dorsal prominence indicates dorsal DRUJ subluxation or dislocation, although swelling may partially obscure this. Palmar subluxation or dislocation may be less obvious clinically. The position, stability, and mobility of the distal ulna must be compared with that of the contralateral uninjured side.

By convention, DRUJ instability causing a dorsal prominence of the ulna head is described as ‘dorsal subluxation/dislocation’ (usually accentuated in pronation). Palmar subluxation or dislocation may be less obvious clinically. The ulna is actually the fixed bone in the forearm, around which the radius rotates. Thus, dorsal prominence of the ulna head actually represents palmar subluxation of the distal radius at the DRUJ and vice versa.

Box 12.31.1 Anatomy and biomechanics

- Ulna head articulates with the sigmoid notch of the distal radius
- Shallow sigmoid notch results in low skeletal stability
- Soft tissues key to stability:
  - TFCC
  - Ulnocarpal ligaments
  - ECU and sub sheath
- Central portion TFC prone to perforations (classified by Palmer).

Systematic palpation for deformity or tenderness in the region of the carpus, ulnar styloid, TFCC, and DRUJ must be performed. In the acute situation, it may not be possible to examine the full range of wrist motion, but it is important to establish that full forearm rotation is possible if a DRUJ injury is suspected.

DRUJ stability is assessed with the so-called ‘piano key’ test. The elbow is flexed and stabilized on the arm of the examining chair or couch. Attempts are made to translate the distal ulna out of the sigmoid notch of the radius in both palmar and dorsal directions, in positions of pronation, supination and neutral forearm rotation. Comparison is made with the contralateral uninjured side.

The neurovascular status of the hand must be evaluated, especially with palmar DRUJ dislocations, where the ulnar nerve and artery are at risk of injury.

Clinical evaluation: subacute or chronic injury

In the subacute setting, a careful history and physical examination are vital to establish whether ulnar-sided wrist pain is due to pathology in the DRUJ, TFCC, ulnar carpus, or other structures. If forearm rotation is reduced, it is important to establish whether it is due to incongruity of the DRUJ, proximal RU pathology, or malunion of a forearm fracture.

The patient should be asked to explain in detail the exact mechanism of injury, the specific movements that now provoke their symptoms, and, if possible, to indicate the precise anatomical origin of their pain, by pointing with a static finger. As with an acute injury, systematic direct palpation helps determine which of the ulnar-sided structures are involved in the injury.

It is important to establish the range of forearm rotation, especially the characteristic loss of supination in dorsal dislocations/subluxations, and pronation in volar dislocations/subluxations, and to compare this with the uninjured side to help determine the best method of treatment.
Ulnar-sided wrist pain may be due to increased contact forces between the ulnar head, the triangular disc, and the triquetrum or lunate. This ulnocarpal impingement is more common in the presence of positive ulnar variance and may be diagnosed clinically by performing the following examination manoeuvre. The wrist is passively ulnar deviated, and a longitudinal axial load is applied to the wrist while it is then placed into supination and pronation. The test is positive if the patient’s pain is reproduced. Logically the pain should be worst in pronation as this is the position where the radius is relatively shortened, but pain may also be provoked in supination.

**Box 12.31.2 Acute injury**

- Consider Essex-Lopresti injury when assessing injury
- Assess neurovascular status (especially ulnar nerve and artery)
